4 Blood Supply, Meninges and Cerebrospinal Fluid Circulation

Introduction

The vascularization and the circulation of the cerebrospinal fluid (liquor cerebrospinalis, CSF) of the brain and the spinal cord are of great clinical importance. The main vascular syndromes are summarized in Table 4.1. In this chapter, the anatomy of blood vessels, meninges and circumventricular organs will be discussed. The central nervous system, which is of ectodermal origin (Chap. 2), is surrounded by mesodermal structures. A system of three connective tissue layers, the meninges, and a fluid compartment containing CSF are located between the bony skull and vertebral column and the nervous tissue of the brain and the spinal cord. Blood vessels, themselves of mesodermal origin, are surrounded by derivatives of the meninges over their full extent, until the interface between the capillary wall and the glial basal membrane makes exchange of substances possible. CSF is produced by the choroid plexus of the ventricles. It circulates from the interstitial spaces of the nervous tissue and the choroid plexus, through the ventricles and their apertures in the roof of the fourth ventricle, to the CSF compartment of the subarachnoid space and its exit through the arachnoid villi to the venous system. The nervous tissue of the central nervous system and the CSF spaces remain segregated from the rest of the body by barrier layers in the meninges (the barrier layer of the arachnoid), the choroid plexus (the blood-CSF barrier) and the capillaries (the blood-brain barrier). The circulation of the CSF plays an important role in maintaining the environment of the nervous tissue; moreover, the subarachnoidal space forms a bed that absorbs external shocks.

Arteries of the Brain

The arteries of the brain originate from two of the greater vessels in the neck: the paired internal carotid and vertebral arteries (Fig. 4.1). The *internal carotid artery* enters the skull through the petrosal bone in the carotid canal. It loops through the sinus cavernosus (carotis syphon), where it emits the *ophthalmic artery*. Immediately beyond the origin of the posterior communicating artery it splits into the middle and anterior cerebral arteries. The vertebral arteries enter the skull through the foramen magnum. After their passage through the dura, the arteries become located within connective tissue derived from the pia mater and the arachnoid.

The middle cerebral artery supplies the convexity of the hemisphere (Figs. 4.3, 4.4, 4.5) and the anterior cerebral artery vascularizes approximately the anterior and upper half of the medial aspect of the hemisphere, up to the precuneus (Fig. 4.2). The vertebral arteries unite into the basilar artery at the ventral aspect of the medulla oblongata. Its terminal

19 + 20 + 21 + 24 Arterial circle (left half)

Fig. 4.6. The cerebral arteries viewed from the basal side (1/1×). Part of the left temporal lobe has been removed to show the sphenoid part of the middle cerebral artery and the arterial supply of the choroid plexus of the lateral ventricle. The lateral occipital artery has been interrupted to gain a clear view of the diencephalic, mesencephalic and retrosplenial branches of the posterior cerebral artery

branches are the left and right posterior cerebral arteries, which supply the posterior, medial and basal aspects of the cerebral hemisphere. The vertebro-basilar arteries also supply the brain stem and the cerebellum. It gives rise to the inferior, middle and superior cerebellar arteries (Fig. 4.11). Frontal and lateral projections of the arterial system are shown in Figs. 4.9 and 4.10.

A system of communicating arteries, known as the *circle of Willis* [18, 36], interconnects the anterior and middle cerebral arteries of both sides with the vertebro-basilar system (Figs. 4.6 and 4.14). It is located at the base of the brain and surrounds the infundibulum and the optic chiasm. It includes the *anterior communicating artery*, which interconnects the anterior cerebral arteries, immediately in front of the optic chiasm, and the two *posterior communicating arteries*, which form an anastomosis between the most distal part of the internal carotic and the posterior cerebral artery near their origin from the basilar artery.

The initial segments of the middle and anterior cerebral arteries give rise to *central arteries* (Figs. 4.6, 4.8, 4.12), which enter the brain in the anterior perforated substance (Fig. 3.4). Together with branches from the posterior communicating artery, they supply the basal ganglia, the internal capsule and the thalamus. The *middle cerebral artery* enters the sulcus lateralis. Just before this point it emits the anterior choroidal artery, which also supplies a branch to the globus pallidus (Fig. 4.8). At the surface of the insula the middle cerebral artery branches into anterior, middle and posterior trunks. The branches of the middle cerebral artery loop over the opercula and ramify over the surface of the cerebral hemisphere to supply the cerebral cortex and the adjacent white matter (Figs. 4.3, 4.4). The *anterior cerebral artery* enters the longitudinal fissure to branch on the medial aspect of the hemisphere. The anterior communicating artery, which connects the two anterior cerebral arteries, is located immediately rostral to the optic chiasm (Fig. 4.2).

The *vertebral arteries* enter the skull through the foramen magnum. They give rise to the *anterior spinal artery*, which descends in the anterior median fissure of the cord, and emit the *posterior inferior cerebellar arteries*. The vertebral arteries unite into the *basilar artery* at the ventral aspect of the brain stem. The basilar artery gives origin to the *anterior inferior* and *superior cerebellar arteries* and splits into the posterior cerebral arteries. The oculomotor nerve emerges between the superior cerebellar and the posterior cerebral arteries and thus marks the bifurcation of the basilar artery (Fig. 4.11). The posterior cerebellar artery makes a characteristic, caudally directed curve before it reaches the cerebellum. Both the posterior inferior and superior cerebellar arteries contribute branches to the dorsolateral brain stem.

The *posterior cerebral artery* supplies the medial aspect of the temporal and occipital lobes. The border region of the vascularization territories of the posterior and middle cerebral arteries include the temporal and occipital poles. The latter contains the posterior portion of the primary visual (striate) cortex with the representation of the fovea. Occlusion of the posterior cerebral artery thus leads to loss of peripheral vision, with maintained central vision ("tunnel vision") (Table 4.1). The borders of the arterial territories of the cerebral hemisphere do not correspond to the borders of the the four major lobes distinguished in the gross anatomy of the cerebral hemipheres (Fig. 4.7). Asymmetries of the brain's arterial system are frequently observed, most often in the calibre of the vertebral, the posterior cerebral and the posterior communicating arteries.

The vertebral, basilar and posterior cerebral arteries also give rise to smaller branches, which enter the brain stem in the median sulcus and more laterally (Fig. 4.11). Branches from the basilar and posterior cerebral arteries (Fig. 4.18) enter the mesencephalon in the posterior perforated substance, located in the floor of the interpeduncular fossa (Fig. 3.12). The vascularization territories of these arteries have been thoroughly studied by Duvernoy [12]. These territories are illustrated in a number of transverse sections in which both arterial supply and venous drainage are visualized (Figs. 4.18–4.20). These figures also document the important contributions of the cerebellar arteries to the vascularization of the brain stem.

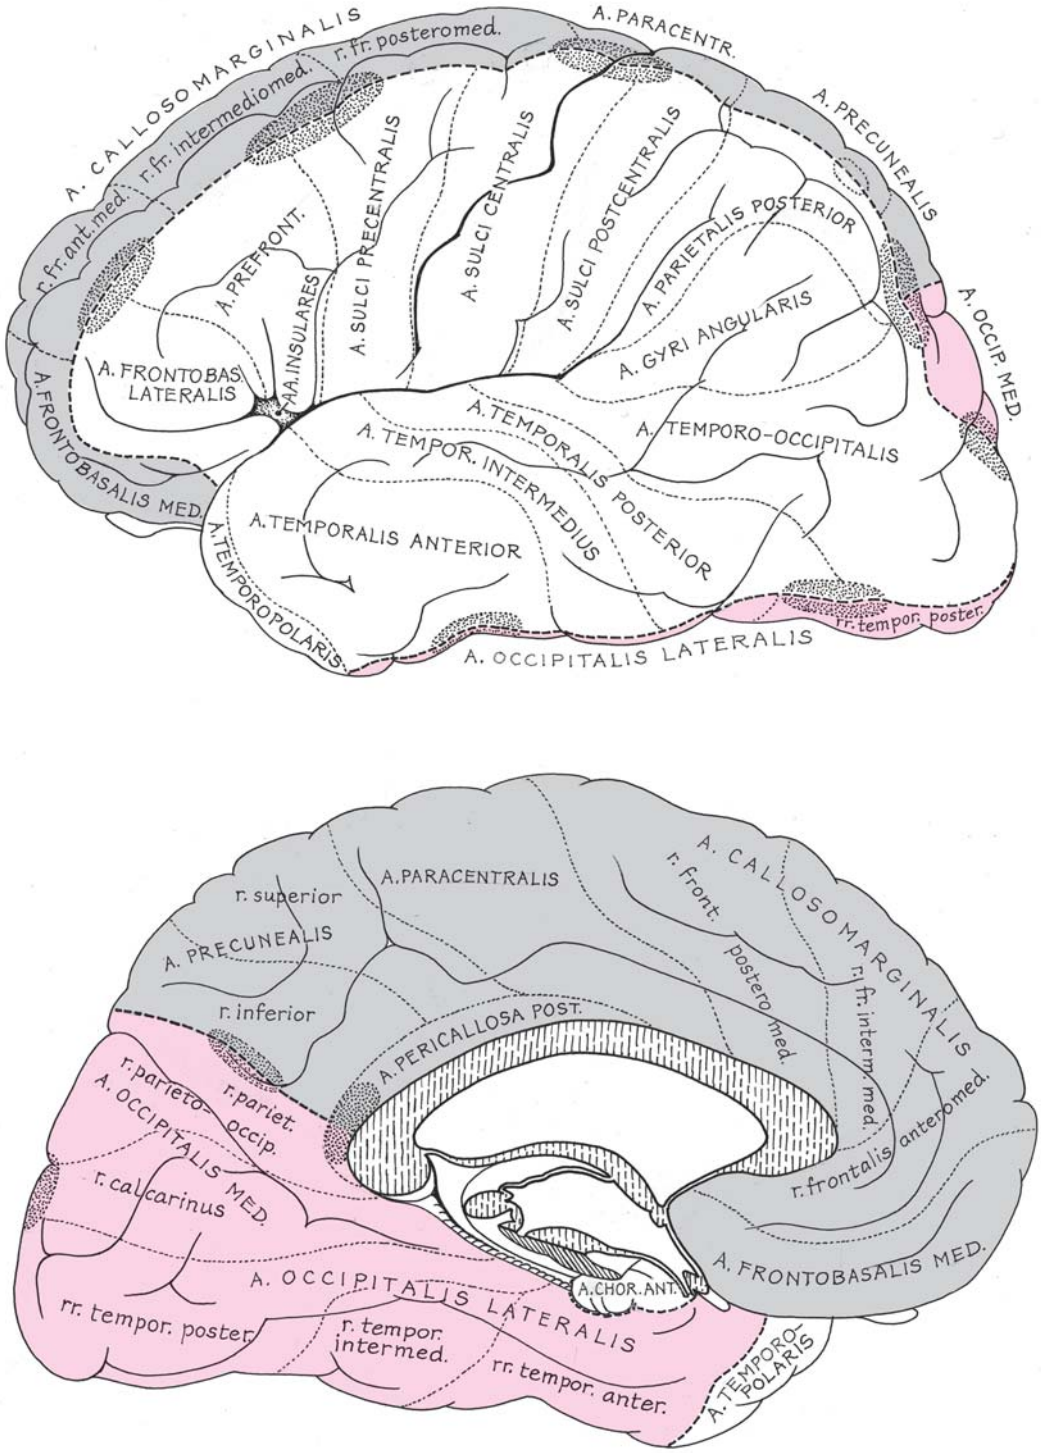

Fig. 4.7. Cortical territories of the three cerebral arteries; semidiagrammatic lateral and medial views of the left cerebral hemisphere (2/3×). The territories correspond to the vascularization pattern illustrated in Figs. 4.2–4.4. *Stippled areas*: sites of possible cerebrocerebral arterial anastomoses, mostly according to Gillilan [13]

48 Occipital vein

Fig. 4.13. Collateral circulation in the venous system of the head; semidiagrammatic lateral view (2/3×). Unpaired sinuses in the median plane are drawn *without outlines;* the extracranial veins draining into the internal and external jugular veins are in *black;* between the intravertebral venous plexuses a fragment of the spinal medulla can be seen. The *arrows* indicate the continuity of the superficial temporal veins

The existence of a collateral circulation is of great significance for the vascularization of the CNS. There are different types and different sites of anastomoses; moreover, the diameter of these anastomoses may differ considerably. Anastomoses between arteries can be found in relation to three arterial systems, i.e. between the two main arterial systems of the carotid and vertebral arteries and between the arterial systems of the brain and the external carotid artery.

Apart from the main arterial anastomosis between the systems of the internal carotid and the vertebral-basilar arterial system in the arterial circle of Willis, cerebro-cerebral anastomoses are present between the branches of the middle cerebral artery (Figs. 4.2, 4.14). Anastomoses between the cerebellar arteries are documented in Figs. 4.9 and 4.11.

Anastomoses with the external carotid artery occur both with meningeal and extracranial branches of this artery. Four types of anastomoses with branches of the external carotid artery are indicated with asterisks in Fig. 4.1. Orbital anastomoses with branches of the ophthalmic artery are enumerated as two special categories.

Meninges, Cisterns and Cerebrospinal Fluid Circulation

The brain is completely enclosed by three connective tissue layers: the meninges. These are, starting from the brain's surface, the *pia mater*, the *arachnoid* and the *dura mater*. The dura is also known as the pachymeninx, due to its strength and thickness, which is imparted by multiple layers of collagen tissue. The thin and loose tissue of the pia mater and the arachnoid is collectively known as the leptomeninx.

The cranial dura is merged with the periosteum of the inner table of the skull. As a consequence, the dura is firmly attached to the skull, especially at the sites of the sutures. Dural septa are located between the main divisions of the brain. In the midline, the *falx cerebri* is located between the cerebral hemispheres and the tentorium cerebelli extends between the occipital and temporal lobes of the hemisphere and the cerebellum. Venous sinuses occupy the inner and outer margins of the falx (superior and inferior sagittal sinus), the junction of the falx and the tentorium (straight sinus, or sinus rectus), and the attachment of the tentorium to the skull transverse sinus and superior petrosal sinus (Figs. 4.14–4.16). The *pia mater* closely covers the surface of the brain and intrudes into its sulci and depressions. The *arachnoid* covers the brain at a variable distance, thus creating a subarachnoidal space between the pia and the arachnoid. This space is bridged by many trabeculae. It contains the CSF. Widenings of the subarachnoid space are known as the cisterns.

For the understanding of the production, circulation and drainage of CSF, the fine structure of the interface of the CSF compartments, the nervous tissue and the mesenchymal tissue of the meninges is important. The central nervous system is isolated from the rest of the body by a series of cellular barriers, which limit the flux of hydrophilic molecules between these cells. These barriers generally consist of extensive tight junctions between the cells, where the outer leaflets of the plasma membranes of two opposing cells are fused. These barriers are found in the epithelium of the choroid plexus (blood-CSF barrier), the outer (barrier) layer of the arachnoid and in the endothelium of capillaries located within arachnoid and the pia mater and nervous tissue (blood-brain barrier).
