hfloat

a C++ library for high precision computations

Jörg Arndt
arndt@jjj.de

this documentation[1] was LaTeX'd at October 14, 2000

[1] This document and hfloat are online at http://www.jjj.de/hfloat/

0.1 What hfloat is (good for)

- hfloat (for 'huge floats') is a library package for doing calculations with floating point numbers of extreme precision. It is optimised for computations with 1000...several million digits. The computations can be done in (almost) arbitrary radix.
- The library contains routines for addition, subtraction, multiplication, division, n-th power, square root, n-th root, logarithm, exponentiation and many more.
- There are implementations of several superlinear converging algorithms for the computation of pi=3.14159265... (in src/pi/). The computation of 1 million decimal digits of pi takes about 2 minutes on an AMD Athlon/800.
- Code examples for the usage of the library are in `examples/`.
- Code for a binary that collects the pi algorithms can be found in `calcpi/`.
- Included is the fxt-library, containing many FFT-implementations, code for convolution, correlation, spectrum and much more.
- High precision computations test your systems reliability (hardware and compiler): every little error results in garbage digits.
- Digits of appropriate constants can be used as high quality 'random' numbers eg. for cryptographic stuff.
- You may (and are encouraged to) use the fast multiplication in your own noncommercial bignum software.
- hfloat (and the accompanying texts) may help you to learn about fast arithmetical algorithms.

0.2 Compiling the library

hfloat is developed under Linux with GNU C It has been compiled under Linux on intel (386, 486, 586 and compatibles and ia64), power pc, alpha and S/390. Compilation under other UNIXes should be possible with few or no changes, especially if GNU C is used. Basically you need a decent make-utility and a C-compiler[1], GNU C and GNU make are strongly recommended. To compile the library

- Type '`make dep`' (for dependency files)
- Type '`make lib`' to make the library

0.3 Functions of the hfloat library

Member functions of the `hfloat` class are declared in `src/include/hfloat.h`

Static member functions, they affect some property of the whole `hfloat` class:

- `hfloat::default_prec()` returns the default precision that can be used (unit is `LIMBs`)[2];
  `hfloat::default_prec(unsigned long m)` sets the default precision `m`;
  call it once at the beginning of your code

[1] expect problems with crippled Microsoft compiler-oids

[2] for the notion of a `LIMB` see page 4

- `hfloat::radix()` returns the radix, which is the same for all `hfloats`;
  use `hfloat::radix(unsigned long r)` to set the radix.
  Note that after a radix change all `hfloats` contain garbage data in their mantissa so they must be reassigned new values before they are read.
  normally you will use `hfloat::radix(unsigned long r)` once at the beginning of your code

Nonstatic member functions, they affect one particular instance of an `hfloat`:

- the constructor `hfloat()` creates an `hfloat` with `default_precision()`
- the constructor `hfloat(unsigned long n)` creates an `hfloat` with `n` `LIMBs`
  Create `hfloats` like `hfloat a;` (for default precision) or `hfloat a(1024);` (for a precision of 1024 `LIMBs`). Direct initialization like `hfloat a = 1234;` is not possible because the constructor `hfloat(unsigned long)` has the explicit modifier. Instead say: `hfloat a; a = 1234;` .
- the copy constructor `hfloat(const hfloat &h)` creates a copy of the `hfloat h`
- the(assignment) operator `=`
  for arguments (i.e. right hand side quantities) `int`, `long`, `unsigned long`, `double`, strings (i.e. `char *`) and `hfloat`,
- `size()` returns the size of the mantissa (in `LIMBs`)
  `size(unsigned long s)` resizes the mantissa to `s` `LIMBs`
- `prec()` returns the current working precision (in `LIMBs`)
  `prec(unsigned long p)` sets the working precision to `p` `LIMBs`, resizes if necessary.
- `exp()` returns the exponent (with respect to `LIMBs`);
  `exp(long)` sets the exponent
- `sign()` returns $+1, 0, -1$ as usual;
  `sign(int s)` sets the sign

Operators for `hfloats` are declared in `src/include/hfloatop.h`:

- the shortcut operators `+=`, `-=`, `*=`, `/=`
  for right arguments `long` and `hfloat`,
- comparison operators `==`, `!=`, `>=`, `<=`, `<`, `>`
  for comparisons of `hfloats` with `hfloats` or `longs`
- comparison operators `<`, `>`
  for comparisons of `hfloats` with `doubles`

Functions for `hfloats` are declared in `src/include/hfloatfu.h`:

- functions of the type func(src,result)
  where `func` $\in$ `inv, sqr, sqrt, isqrt, cbrt, log`[3], `exp, ...`
- functions of the type f(src1,src2,result)
  where `func` $\in$ `add, sub, mul, div, pow, root, iroot, log, ...`

The function names should be self-explanatory.
Print `hfloat.h`, `hfloatfu.h` and `hfloatop.h` now!

[3] logarithm to base 2.71828...

There are also the binary operators `+, -, *, /` and functions that return a `hfloat`, like `func(src)` where `func` ∈ `inv, sqrt, ...` but do not use them if you are after performance: they create temporary `hfloats` and are there only to allow lazy coding.

E.g. instead of
`x = a + b;`
use
`x = a; x += b;`
or
`add(a, b, x);`

Instead of
`x = exp(a);`
use
`exp(a,x);`

Note that the result is always the rightmost argument.

0.4 Using hfloats in your own code

In order to write your own code that uses hfloats

- you must `#include src/include/hfloat.h` to get the functions of the hfloat lib.
- use `hfloat::default_prec(n)` where `n` is the precision in `LIMBs` (use a power of two)
- use `hfloat::radix(rx)` where `rx` is the radix (use 10000 for decimal numbers or 65536 for hex numbers)
- use `hfverbosity::tell_all()` if you like to have many operations echoed, `hfverbosity::hush_all()` for silent operations
- when compiling `yoursrc.cc` that uses `hfloats` link it against the library `libhflt.a`
- for extreme precisions increase the maximal workspace size, as described on page 3.

Cf. `examples/ex*.cc` for some simple examples of how to use hfloats. Look into `examples/index.txt` for what's there.

0.5 Computations with extreme precision

In order to do computations with the maximal possible precision on your computer you have to manually set the maximal workspace size: Set the environment variable `NOSWAP_BYTES` according to the size of physical RAM where no swapping will occur, e.g. with bash say:
`export NOSWAP_BYTES=32M`
See `src/fxt/auxil/workspace.cc` for the default.

Do *not* give the total amount installed RAM, your machine will swap to death if you try really use it for hfloat. Currently if you don't give a power of 2 then the size is increased to the next bigger power of 2. You may append 'k' for kilobyte or 'M' for megabyte.

0.6 Precision and radix

For the quick readers I begin with the resumee:

- for decimal digits and precisions up to 2^{23} `LIMB`s[4] use radix 10,000 (for even greater precisions choose radix 1,000)
- for hexadecimal digits and precisions up to 2^{18} `LIMB`s[5] use radix 65,536 (for even greater precisions choose radix 4,096)

The mantissa of a `double` consists of (typically) 53 bits[6], its radix (base of representation) is 2. The analogous quantity in the mantissa of a hfloat is a `LIMB` (typedef'd to a 16 bit unsigned int). So the radix of a hfloat can be in the range 2...65536($= 2^{16}$).

If one wants to get decimal numbers one would *not* use radix 10 but the greatest power of 10 that is $\leq 2^{16}$, which is 10000. Due to the implementation of the convolution there is a second restriction to the radix: The cumulative sums c_k have to be represented exactly enough to distinguish every (integer) quantity from the next bigger (or smaller) value. The highest possible value for a c_k, c_m, must not jump to $c_m \pm 1$ due to numerical errors. For radix R and a precision of N `LIMB`s

$$c_m \quad = \quad N\,(R-1)^2 \tag{1}$$

This is N times the product of two 'nines' $(R-1)$, which can appear in the middle term of the convolution. c_m needs

$$\log_2(N\,(R-1)^2) \quad = \quad \log_2 N + 2\,\log_2(R-1) \tag{2}$$

bits to be represented exactly.

Due to numerical noise there must be a few more bits for safety. The c_k are computed using `double`s. We need to have

$$M \quad \geq \quad \log_2 N + 2\,\log_2(R-1) + S \tag{3}$$

where S :=safetybits and M :=mantissabits. With $\log_2(R-1) < \log_2(R)$ we have equivalently

$$N_{max}(R) \quad = \quad 2^{M-S-2\,\log_2(R)} \tag{4}$$

Thus if we want base 2 numbers we would first choose radix $R = 2^{16}$ but this can (if we have $M = 53$ mantissabits and require $S = 3$ safetybits) only be used for precisions up to

$$N_{max}(\text{radix} = 65,536) \quad = \quad 2^{53-3-2\cdot 16} = 2^{18} = 256 kilo\texttt{LIMB}\text{s} \tag{5}$$

(corresponding to $4096 kilo$ bits $= 1024 kilo$ hex digits).

$$N_{max}(\text{radix} = 32,768) \quad = \quad 2^{20} = 1 Mega\texttt{LIMB}\text{s} \tag{6}$$

(corresponding to $15360 kilo$ bits $= 3840 kilo$ hex digits).

$$N_{max}(\text{radix} = 16,384) \quad = \quad 2^{22} = 4 Mega\texttt{LIMB}\text{s} \tag{7}$$

(corresponding to $57344 kilo$ bits $= 14336 kilo$ hex digits).

For decimal numbers

$$N_{max}(\text{radix} = 10,000) \quad = \quad 2^{53-3-2\cdot 13.29} = 2^{23.42} > 8 Mega\texttt{LIMB}\text{s} \tag{8}$$

($N = 23$ corresponding to $32 Mega$ decimal digits).

$$N_{max}(\text{radix} = 1,000) \quad = \quad 2^{30.07} > 1 Giga\texttt{LIMB}\text{s} \tag{9}$$

[4] corresponding to more than 32 million decimal digits
[5] corresponding to more than 1 million hexadecimal digits
[6] Of which only the 52 least significant bits are physically present, the most signicant bit is implied to be always set.

($N = 30$ corresponding to $3Giga$ decimal digits).

If the LIMBs weren't restricted to 16 bits:

$$N_{max}(\text{radix} = 100,000) \quad = \quad 2^{16.78} > 16kilo\texttt{LIMBs} \tag{10}$$

($N = 16$ corresponding to $80kilo$ decimal digits).

$$N_{max}(\text{radix} = 1,000,000) \quad = \quad 2^{10.13} > 1kilo\texttt{LIMBs} \tag{11}$$

($N = 10$ corresponding to $6kilo$ decimal digits).

0.7 Compiling & running the π-example code

To compile the code in the directory `calcpi/`

- Type '`make pi`'.
- cd to the `bin` directory, find the example binary `pi` there.
- Type '`pi --help`' for usage information (the help text can also be found in the file `doc/pihelp.txt`).
- Type '`pi 10`' to run the program. It will compute 4096 decimal digits of π (in about 1 second on a not very ancient computer).
- See the file `result.txt` for the digits of π. All but the last few digits (10 or so) of the output should be correct. Check correctness like this:
- Type '`pi 10 314`' to run the program selftest which uses several algorithms and outputs how many LIMBs differ in the results.
- Type '`pi 8 0 65536`' to get 1024 hexadecimal digits of π.
- Type '`pi 18 16`' to get $>$ 1 million decimal digits of π.

0.8 Limitations of hfloat

Let me emphasize: hfloat is *experimental* code, it is **not** thoroughly tested !

It is not very good for 'real' work, it was and is intended mainly for learning about high precision computations.

Other limitations are:

- lousy performance for small precisions like <200 decimal digits
- no trigonometric functions
- no type complex
- general code uglyness, if you'd like to learn programming: please look elsewhere.

0.9 Structure of hfloat

The hfloat code is divided into two layers:

The class hfloat (top, user interface) layer. A hfloat consists of a unique id number (for internal use only), sign and exponent plus and a pointer to class hfdata. Currently there is a one-to-one correspondence between hfloats and hfdata (it possibly will remain like this). The arithmetical operators and functions like `mul(src1,src2,dest)` are here. The iterations (for root extraction, inversion, ...) are also in this layer.
Declarations are in `src/include/hfloat.h` (class), `src/include/hfloatop.h` (operators) and `src/include/hfloatfu.h` (functions). Source files are in `src/hf/`.

The class hfdata (mantissa operations, number crunching) layer. A hfdata consists of a pointer to the digit field, the size and precision of the mantissa data. Typical function names are `dt_something(...)`, Declarations are in `src/include/hfdata.h` (class) and `src/include/hfdatafu.h` (functions). Source files are in `src/dt/`.

0.10 Organisation of the files

directory	which files are there
`bin/`	binaries and libs
`doc/`	the main documentation
`examples/`	simple example code, look there!
`calcpi/`	π example
`src/`	(source directory)
`src/fxt/`	source for the fxt-librarry
`src/fxt/mult/`	source for the fft-multiplication
`src/include/`	header files for the hfloat-librarry
`src/tz/`	source for the transcendental functions
`src/hf/`	source for the hfloat-layer
`src/dt/`	source for the hfdata-layer
`src/pi/`	source for the π-library
`testing/`	cryptic test routines, better ignore
`*/bucket/`	garbage & trash

Selected files in some directories:

- `src/include/`: (declarations)
  - `hfloat.h`: the hfloat class
  - `hfloatfu.h`: hfloat functions
  - `hfloatop.h`: hfloat operators
  - `hfverbosity.h`: adjust how talkative the hfloat operations are
  - `hfdata.h`: the hfdata class
  - `hfdatafu.h`: hfdata functions
- `src/pi/`: implementations of the π-algorithms
- `src/hf/`:
  - `hfloat.cc`: hfloat class member functions
  - `hfloatop.cc`: hfloat class operators

  - `init.cc`: magic initialiser for the hfloat class
  - `it*.cc`: code for iterations (inverse, sqrt, inverse n-th root)

- `src/dt/`:
  - `hfdata.cc`: hfdata class member functions
  - `dt*.cc`: hfdata functions
