Foreword

Statistical computing provides the link between the statistical theory and applied statistics. As at previous COMPSTATs, the scientific programme covered all aspects of this link, from the development and implementation of new statistical ideas through to user experiences and software evaluation. Following extensive discussions, a number of changes have been introduced by giving more focus to the individual sessions, involve more people in the planning of sessions, and make links with other societies as Interface or International Federation of Classification Societies (IFCS) involved in statistical computing. The proceedings should appeal to anyone working in statistics and using computers, whether in universities, industrial companies, government agencies, research institutes or as software developers.

This proceedings would not exist without the help of many people. Among them I would like to thank especially to the SPC members D. Banks (USA), H. Ekblom (S), P. Filzmoser (A), W. Härdle (D), J. Hinde (IRE), F. Murtagh (UK), J. Nakano (JAP), A. Prat (E), A. Rizzi (I), G. Sawitzki (D) and E. Wegman (USA); the session organizers D. Cook (USA), D. Banks (IFCS, USA) C. Croux (B), L. Edler (D), V. Esposito Vinzi (I), F. Ferraty (F), V. Kůrková (CZ), M. Müller (D), J. Nakano (ARS IASC, JAP), H. Nyquist (S), D. Peña (E), M. Schimek (A), G. Tunnicliffe-Wilson (GB) and E. Wegman (Interface, USA); as well as to all who contributed and/or refereed the papers.

Last but not least, I must sincerely thank my colleagues from Department of Statistics of the Charles University, Institute of Computer Science of the Czech Academy of Sciences, Czech Technical University, Technical University of Liberec and to Mme Anna Kotěšovcová from Conforg Ltd. Without their substantial help neither this book nor the COMPSTAT 2004 would exist.

My final thanks go to Mme Bilkova and Mme Pickova, who retyped most of the contributions and prepared the final volume, and Mme G. Keidel from the Springer Verlag, Heidelberg, who extremely carefully checked the final printing.

THE HISTORY OF COMPSTAT AND KEY-STEPS OF STATISTICAL COMPUTING DURING THE LAST 30 YEARS

Wilfried Grossmann, Michael G. Schimek and Peter Paul Sint

Key words: COMPSTAT symposium, computational statistics, history of statistics, statistical computing, statistical languages, statistical software.

COMPSTAT 2004 section: Historical keynote.

1 Introduction

First of all we try to trace the situation and the ideas that culminated in the first COMPSTAT symposium in the year 1974 held at the University of Vienna, Austria. Special emphasis is given to the memories of our founding member P. P. Sint who had been the driving force behind early COMPSTAT and had served it for twenty years.

At the time COMPSTAT was established computing technology was in its infancy. Yet it was well understood that computing would play a vital role in the future progress of statistics. The impact of the first digital computer in the Department of Statistics at the University of Vienna on the local statistics community is described. After the first computational statistics event in 1974 it was anything but clear that the COMPSTAT symposia would go on for decades as an international undertaking to be incorporated as early as 1978 into the International Association for Statistical Computing (IASC, `http://www.iasc-isi.org/`), a Section of the International Statistical Institute (ISI).

After the description of the background against which the COMPSTAT idea emerged, the subject area of computational statistics is critically discussed from a historical perspective. Key steps of development are pointed out. Special consideration is given to the impact of statistical theory, computing (algorithms), computer science, and applications. Further we provide an overview of the symposia and trace the topics across 30 years, the period of historic interest. Finally we draw conclusions, also with respect to recent developments.

2 The early history of electronic computing

To start off we describe the situation of computing technology in post-war Vienna and the prominent role of the Department of Statistics (later on Statistics and Informatics) at the University of Vienna. Also the Mathematics Department of this university is of historic interest. There, a well-attended seminar was held in summer 1962 by the Viennese mathematician N. Hofreiter “Zur Programmiernug von elektronischen Rechenmaschinen” (“On the programming of electronic calculators"). Topics were one and two address machines, connectors, and programming of simple loops. The treatment was purely theoretical and no specific machine was envisioned. Highlight was an excursion to the first-ever electronic computer at the university, a Burroughs Datatron 205, installed 1960 at the Department of Statistics. The same professor held classes in computing which started from slide rulers and did not go beyond mechanical calculators (Brunsviga type) because of lacking electro-mechanical machines for teaching.

While finishing his studies in physics Sint became a scholar of the Institute of Advanced Studies (Institut für Höhere Studien, IHS) in Vienna and ended up rather by chance in the Sociology Department. (A planned formal science department had not been realized.) There he learned, besides the basics of sociology, to handle card counting machines, especially the IBM Electronic Statistical Machine Type 101. With such machines one could not only count but also perform simple calculations. Only much later he learned from a historical article [72] that and how it could have been used even to invert matrices.

The punching machines did not produce printouts on the cards. Hence users had to learn the encoding. This was simple for numeric codes but more demanding for alphabetic characters. Sorting of the cards by alphabet or numerically was done sequentially starting from the last digit or character in the field. Sorted output card stacks were stapled and resorted for the next digit respectively character. This procedure made it also possible to perform multiplications of punched multi-digit numbers by "progressive digiting". Statistical machines had been popular in Vienna since the late 19th century. Programming was carried out on plugboard tablets – an invention of the Austrian O. Schäffler [75] – based on telephone switchboard technology [54]. This technology was adopted in the census of the Austro-Hungarian Monarchy in 1890 (at the same time also in the USA). Schäffler later sold his patents [88] to Hollerith's Tabulating Machine Company (which ended up in International Business Machines, IBM). By some tricky programming of the boards sorting was possible by two columns (i.e. characters) of the card in one run. Not knowing this, the famous economist F. Machlup destroyed one of Sint's nearly finished sortings while explaining to him the "proper" way of doing the job (with appropriate excuses afterwards).

3 The institutional environment in which COMPSTAT was born

During these early years so-called statistical machines were also used in sociology. A front runner of the use of formal mathematical methods in social sciences was the Institute for Advanced Studies. It was founded with essential financial help from the US Ford Foundation (hence locally known as "Ford Institute"). The famous sociologist P. Lazarsfeld, founder of the Institute for Applied Social Psychology at the University of Vienna in 1929, and its director until his emigration to the USA in 1933, later professor at Columbia University and O. Morgenstern (together with J. von Neumann), the father of game theory and a former director of the Austrian Institute of Trade Cycle Research, were the driving forces behind the foundation of the Ford Institute [39]. At that time formal-mathematical as well as empirical methods were practically absent from the syllabus of economics and sociology in most academic institutions in Austria.

S. Sagoroff was a key person during the foundation of the Ford Institute and also its first director. He had already an interesting personal history: After receiving his doctor degree from the University of Leipzig (Germany) and studying in the USA under the supervision of J. A. Schumpeter 1933/34 on a Rockefeller grant, he became professor of statistics, president of the statistical office, and director of the Rockefeller Institute for Economic Research in Bulgaria before World War II. Later he was Bulgarian Royal Ambassador to Germany in Berlin until 1942 (when Bulgaria joined the Allies). In that function he was involved in the delay of the delivery of Bulgarian Jews. While in Berlin and with a broad interest in science he had befriended with some of Germany's intellectual elite, including a number of Nobel laureates who cherished his dinner parties. After liberation from his internment in Bavaria he had worked for the US Ambassador R. D. Murphy and had spent some time at Stanford University, before becoming professor of statistics at the University of Vienna.

Sagoroff was certainly an able organizer for the start-up of IHS but might not have been the best choice for running the institution in a way ensuring high scientific standards. Still, the Ford Institute was a tremendous place to learn and to get acquainted with current thoughts in social and economic sciences, offering contacts to researchers of high reputation. In the following decade IHS played an important role in the reversal of the former situation at Viennese academic institutions, advocating mathematical and statistical approaches.

Sagoroff's USA experience had also been crucial to the fact that he was successful in receiving a Rockefeller grant for the University of Vienna to buy a digital computer. The foundation paid for half of the price (83.500 US$) and the computer company gave an educational grant covering the other half. The university had to pay just for transportation and installation. That Sagoroff was interested in computers and on the lookout for one was most likely fueled by the fact that at the very time H. Zemanek was constructing the first transistorized computer in Europe at the Technische Hochschule (now University of Technology) in Vienna. At that same time Sagoroff's assistant at the Statistics Department, A. Adam, also tried to build a simple electronic statistical calculator and obtained also a patent on this device. But he definitely had not the technical expertise of Zemanek and his machine was never used in practice. Nevertheless his historical findings on the early history of computing remain a landmark in the historiography of the area ([18] widely distributed during the 1973 ISI Session in Vienna).

The arrival of the first "electronic brain" in Vienna in 1960 was not only of interest for the scientific community but meant also a major event for the Austrian media. The electronic tube-based machine needed a special powerful electricity generator to convert the 50 Hz alternating current in Austria to the 60 Hz used in the USA. It was installed in the cellar of the new university annex building. The windows of the computer room had to be equipped with specially coated glass to ensure constant temperature.

This Datatron 205 was a one address machine with one command (or address) and two calculating registers. The machine owned a drum storage with 4000 cells. Each cell held 10 binary-decimal digits (each digit was represented by 4 bits and the uppermost values beyond 0-9 were not used). The 11th digit was used for signs and as a modifier in some commands. The 4000 cells were divided in 40 cylinders on the drum each containing 100 words with an average access time (half turn of the drum) in the millisecond domain. It possessed a feature later reinvented by IBM and marketed in a more elaborate form under the name virtual memory: two cylinders could accept repeated identical runs of 20 words (commands) which reduced access time to one fifth. The critical parts of the program code were shifted to this 'fast storage' with one block command and the program execution shifted (often simultaneously) to the first command in this storage which meant it was transferred into command register A.

The implementation was in digital code: Each command was a two digit number acting on one address, for instance the command "64" imported a number into register A:

0000641234 Import the content of cell 1234 (on the drum)
into calculating register A
While 74
0000741235 Add the content of cell 1235
to the content of the register A

60 stood for multiplication, 61 for division. Other arithmetic operations, floating point operations, shift operations, logical operations, conditional jumps, printing of registers were performed similarly. An additional register could be used independently or to enlarge the number of digits in register A. 02 stored results back to the drum. 08 stopped the run.

In principle there existed an assembler with mnemonic alphabetic codes, however, there was no tape punching device to enter alphabetic characters. Because one had to know the digit codes for operating the machine (entering and changing commands bit by bit only guided by a display of the registers on the console) the direct way was definitely faster. As one could actually see each bit stored in the registers during programming and debugging one could also spot a malfunctioning hardware unit if one of the bits did not show up properly. In this case one had to open the machine and take out the concerned unit (a flip flop with four tubes). Usually it was easy to spot the culprit by visual inspection or alternatively exchanging the tubes one by one. Only the (preliminary) finished program was printed or punched out on a paper tape. As space was scarce and each letter had to be encoded by two decimal digits, comments accompanying the results were kept to a minimum.

The arrival of this computer was essential to the fact that the Statistics Department became the hub of computing inside the University of Vienna.

Sint's first experiences with real computing in the early nineteen sixties are connected to a programming course for digital computers held by the mathematician J. Roppert, assistant in the Department of Statistics. As one of the few who took an exam in computer programming and as a scholar of IHS, Sint was offered an assistantship at this department. His statistical qualifications were elementary probability theory (not based on measure theory) and some statistics for sociologists. (The type of statistics used in quantum physics were not of much help in a statistics department.) At the IHS he also obtained a first training in game theory from O. Morgenstern. Later, while spending a year in Oxford, he learned more statistics and got interested in cluster analysis. This contact with English statistics helped him doing "real" statistics in the following.

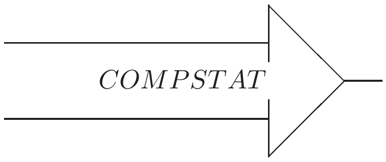
Before Sint could use the new generation of computers (an IBM /360-44 was installed at the University of Vienna in 1968) he had to learn his first programming language, Fortran. For W. Winkler, a professor emeritus of statistics, he wrote his first Fortran program for the calculation of a Lexis-type population distribution on an off-site computer. When he had finished Winkler remarked that it would have been much faster to do the job on a mechanical calculator. At that time correcting card decks and working on a remote machine was extremely time consuming.

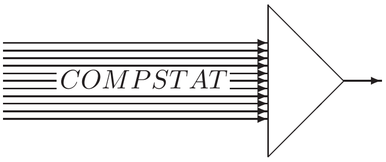
About that time IBM had started developing and distributing statistical software. Most developments were open source Fortran code. Naturally Fortran was a large step forward going along with third generation digital computers. Programme codes for algorithms were published by the US Association of Computing Machinery (ACM). About that time also the first commercial packages arrived. In statistics one could choose between OSIRIS, BMD, P-STAT, and SPSS. The Department of Statistics at the University of Vienna decided for SPSS in December 1973. SPSS, like BMD and P-STAT was implemented in Fortran, offering high portability. All the implementations of statistical methods at the department were programmed in Fortran, not a user-friendly environment from a today's perspective. This included the first administrative program for the enrollment of students and production of corresponding statistics.

4 The first symposium and the Compstat Society

Access to elaborate algorithms on computers increased the awareness of more recent methodological developments in statistics, primarily in the Anglo-American world. In the Statistics Department at the University of Vienna, with its tradition in conventional economic and demographic statistics, the younger members tried hard to establish contacts with the international statistical community. Not having had access to sufficient travel funds, Sint and his colleague J. Gordesch, a trained mathematician, encouraged by A. Liebing, the publisher of the journal Metrika, envisioned a conference on an up-to-date statistical topic in Vienna. Sint was interested in cluster analysis and Gordesch rather in computational probability and model building. These and other topics were ventilated until one settled on a conference on computers and statistics. As for the name in English they took the Journal of the Royal Statistical Society as a model: it comprised series A for *Theoretical Statistics* and series B for *Applied Statistics*. Thus they assumed *Symposium on Computational Statistics* would be a proper name. Sint came up with the acronym *COMPSTAT* arguing that one needs a short name which would still be near to an understandable expression to be easily remembered (this is what is called a logo now).

For the first call for papers the word *COMPSTAT* was embedded in an arrow like graph derived from the symbols used in analog computing: several input lines ending in a triangle (the statistical engines or algorithms). The condensed final result we are still using is displayed in the left figure. Sint and his colleagues were thinking about statistical methods (they were the hub of our ideas about the conference) as means of compressing a large number of inputs in a few meaningful results and *COMPSTAT* as an input to improve the algorithms (being quite aware of the recursivity of these processes).





The original design idea was rather something like the right figure. A sketched drawing similar to this one (without the small arrows and with a smaller number of input lines) had been dropped by the graphics designer of the publisher.

As we know now this was the first freely accessible international conference with an open call for papers in this area. The first COMPSTAT meeting was announced in the American Statistician (attracting some participants from the USA) which helped later to defend the right of name in that country. The only preceding international conference of that kind was organized and financed by IBM. Preceding were also the at first rather local North American Interface symposia starting in Southern California in 1967, sponsored by the local chapters of both the American Statistical Association and the ACM, obtaining an international flavor as late as 1979 (twelfth Interface symposium held at the University of Waterloo, Ontario, Canada). For the Interface Foundation of North America, Inc., and its history see `http://www.galaxy.gmu.edu/stats/IFNA.html`.

Any organizer of a new kind of conference is uncertain about its success and the number of participants he/she might attract. According to the preface of the proceedings [1], Sint and Gordesch were not sure whether "mathematicians specialized in probability theory or statistics, or experts in electronic data processing would look at computational statistics as a serious subject". As the deadline of the call for papers came nearer the organizers became increasingly anxious and started to muster locals for participation. Fortunately, in the first few days after the deadline had expired, a reasonable number of additional abstracts appeared, all together enough to give them peace of mind.

In 1972 Sint had attended a conference where the proceedings papers had to be retyped by clerical staff which turned out to be a disaster. This experience in mind it was decided to ask for camera-ready copies. For the COMPSTAT proceedings it worked out smoothly and the copies could be distributed during the symposium, a practice that has survived till now. The formal invitation to the conference was signed by G. Bruckmann and L. Schmetterer, both professors of statistics at the department, because the young colleagues hoped that the appearance of internationally known personalities would be more acceptable to participants and to the potential buyers of the proceedings (Sint and Gordesch just signed the preface; F. Ferschl was added as an editor by the publisher).

Gordesch had at the time of the conference already left Vienna, and Sint had moved to the Austrian Academy of Sciences. Thus, although the latter was still around (his new boss was Schmetterer, the successor of Sagoroff as professor of statistics), a lot of the preparatory work had to be done by the young colleagues W. Grossmann, G. Pflug, and W. Schimanovich. M.G. Schimek, a first-year student of statistics and informatics in 1974, learning Fortran and SPSS at that time, was a keen observer of all these activities going on in the Department of Statistics and Informatics at the University of Vienna.

The interest of Gordesch in COMPSTAT had remained awake and so the next conference was naturally held in Berlin. From that time onwards it has never been a problem to find places to go. Someone has always been willing to organize the symposium.

To have a permanent platform a *Compstat Society* was created in 1976. Membership was by invitation only. Mainly organizers and chair persons of the first conferences were approached. Sint recalls that only selected members were asked (no formal board decision) when COMPSTAT was transferred to the International Association for Statistical Computing (IASC) in 1978. It was an initiative of N. Victor (1991–1993 IASC President). Readers interested in the history of the IASC are referred to the *Statistical Software Newsletter*, edited for almost three decades by A. Hörmann, and since 1990 integrated as special section into the official journal of the IASC *Computational Statistics and Data Analysis*. Furthermore we want to mention P. Dirschedl and R. Ostermann, (1994 [32]) as a valuable reference for developments in computational statistics (including IASC activities in Germany, the history of the legendary *Reisensburg Meetings* and of the Statistical Software Newsletter).

Formally the Compstat Society was dissolved by the Austrian Registration Office due to inactivity. Numerous members reappeared in the newly founded European Regional Chapter (now European Section) of the IASC. The main stumbling block in the transfer was Physica-Verlag and its owner A. Liebing. He had contributed a lot to the planning of the first symposium to make it a success and was then afraid that, if the conference is taken over by a large organization, other publishers would get interested and grab the proceedings and the then started COMPSTAT Lectures (a series of books apart from the proceedings). The result of the heated discussions during COMPSTAT 1978 in Leiden was a most favourable treatment clause which gave Liebing an advantage over competitors. This worked out satisfactorily until he sold Physica-Verlag to the Springer company because of his retirement as a publisher.

Sint's continued active involvement ceased after 20 years at the second COMPSTAT symposium that took place in Vienna, organized by R. Dutter (University of Technology, Vienna) and W. Grossmann. The 1994 anniversary was also marked by a *COMPSTAT Satellite Meeting on Smoothing* – smoothing having been a hot topic at that time – held in the famous alpine spa Semmering (on the border between Lower Austria and Styria), bringing additional audiences mainly from outside Europe to COMPSTAT. It was organized by M. G. Schimek (Karl-Franzens-University, Graz; currently IASC Vice President). The COMPSTAT baby had become off age and a new generation was following the tradition of P. P. Sint.

5 Some remarks on the development of computational statistics

The idea of COMPSTAT was borne at the University of Vienna in an environment typical for statistics departments in continental Europe at that time against the background of new computer technology, rather specific with respect to statistical methodology. In order to obtain a more detailed picture of the role of COMPSTAT we need to sketch some important issues in the development of computational statistics in connection with other topics. Starting point for our considerations is the following working definition of the term *Computational Statistics*, which is according to a statement of N. Victor in 1986 (cf. Antoni et al., 1986 [7], p. vi) ".....not an independent science but rather an important area of statistics and indispensable tool for the statistician". This statement is made more precise in a definition proposed by A. Westlake (cf. Lauro, 1996 [61]): "Computational statistics is related to the advance of statistical theory and methods through the use of computational methods. This includes both the use of computation to explore the impact of theories and methods, and development of algorithms to make these ideas available to users". This definition gives on the one hand a clarification of the term “area of statistics” in Victor’s statement, on the other hand it emphasizes also the instrumental aspect of statistical methods with repect to their application.

Starting from this definition it is quite clear that we have to consider the progress of computational statistics in connection with developments in statistical theory, developments in computation and algorithms, developments in computer science, and last but not least developments in the application of statistics. In many ways there has always been an exchange of ideas, important for the understanding of computational statistics, stemming from these four areas. In the following we sketch some of these ideas and discuss their interplay.

5.1 Computational statistics and statistical theory

According to B. Efron in 2002 [36] the development of statistics in general can be divided into a *theory area* and a *methodology area*. Efron illustrates the theory area as a journey from applications towards the mathematical formulation of statistical ideas. According to him it all starts around 1900 with the work of K. Pearson and goes on to the contributions of J. Neyman and Sir R. Fisher, finally approaching the decision-theoretic framework for statistical procedures due to A. Wald. A key feature in this development is the foundation of statistical theory on optimality principles. This decision-theoretic framework is capable of bolstering statistical methods by a sound mathematical theory, provided that the problems are stated in precise mathematical form by a number of assumptions. In that sense the theoretical background is a prerequisite for the application of statistics and for the computations in connection with the statistical models. Obviously computation meant in early times paper and pencil calculations or using rather simple (mechanical) computing devices.

To some extent the early investigations were oriented more towards the analysis of mathematical properties of procedures and less towards the analysis of data. A milestone in the shift from the theory area towards the methodology area was the paper of J. W. Tukey in 1962 [83] about the future of data analysis. It emphasizes a number of important aspects, in particular the distinction between confirmatory and explanatory analysis, the iterative and dynamic nature of data analysis, the importance of robustness, and the use of graphical techniques for data analysis. In this paper Tukey is not so enthusiastic about the computer with respect to data analysis. He states that the computer is in many instances “important but not vital”, in others “vital”. However due to the technological development the computer has definitely become more important for the methodology area than one could foresee 40 years ago.

In fact, the methodology area is in many aspects characterized by a strong interplay between statistics and computing, ranging from the implementation of procedures over the definition of new types of models up to the discovery of new aspects of statistical theory. A typical example is Bayesian data analysis, the progress of which has been driven to a considerable extent by new computational techniques (cf. Gelman et al., 1996 [44]). High computing power is needed for these methods, hence they are often summarized under the heading *computer intensive methods*. Another interesting feature of many of these developments is the fact that optimality principles are not necessarily applied in a closed form by defining one objective function in advance, but rather by outlining a number of optimization problems in an iterative and more dynamic way than in traditional statistics. This iterative process is rather statistical in nature compared to the iterative numerical solutions of nonlinear equations. Hence, from a statistical (data analytic) point of view one is sometimes not solely interested in the final solution but also in the behaviour of the algorithm.

In many instances theoretical insight into methods and the development of models go hand in hand with the implementation of these methods respectively models. In the following we list (in alphabetical order) a number of key developments that have resulted in standard approaches of applied statistics (together with early references): Bootstrap Methods (Efron 1979 [35]), EM-Algorithm (Dempster, Laird and Rubin, 1977 [30]), Exploratory Data Analysis (EDA; Tukey, 1970 [84]), Generalized Additive Models (GAM; Buja, Hastie and Tibshirani, 1989 [22], Hastie and Tibshirani, 1990 [50]), Generalized Linear Models (GLM; Nelder and Wedderburn, 1972 [70]), Graphical Models (Lauritzen and Wermuth, 1989 [60]), Markov Chain Monte Carlo (MCMC) – in particular Gibbs Sampling – (Hastings, 1970 [52], Geman, 1984 [45]), Nonparametric Regression (Stone, 1977 [77]), Projection Pursuit (Fisherkeller et al., 1974 [38], Friedman and Tukey, 1974 [43]), Proportional Hazard Models (Cox, 1972 [28]), Robust Statistics (Huber, 1964 [56]), and Tree Based Methods (Breiman et al., 1982 [21]). Besides these developments inside statistics we wish to point out that new aspects of statistical data analysis have in addition occurred in connection with Data Mining (Frawley et al., 1992 [41]), recently explored from a statistical learning perspective by T. Hastie, R. Tibshirani and J. Friedman (2001 [51]).

Apart from these examples that are all characterized by a strong interplay between statistical theory and computational statistics in the sense of Westlake's definition, it should be noted that there are also methods which had been formulated long before they were feasible to compute. An interesting example with respect to the interplay between theory and computation are rank procedures. According to R. A. Thisted (1988 [80]) the motivation of F. Wilcoxon for defining his rank test was the fact that for moderate sample sizes calculation of the rank sum by hand is easier than calculation of the sum and the variance. However, the situation is completely changed in case of large sample sizes and machine calculation. Other examples of theoretical models introduced long before it was feasible to numerically evaluate them are conditional inference for logistic regression as formulated by Sir D. J. Cox

(Mehta and Patel, 1992 [62]) or the empirical Bayes approach of H. Robbins (1956 [74]) that nowadays sees interesting applications in microarray analysis (Efron, 2003 [37]).

Besides these new developments in statistical theory, the advance of computers has also influenced other areas of statistical theory in the sense of providing tools for experimental checking of statistical models under various scenarios. Such types of computer experiments are of interest even in cases where the methods are well underpinned from a theoretical point of view. A well known early example is the Princeton study on robust statistics (Andrews et al., 1972 [20]). Today in theoretical investigations it is rather common to support the results by simulation and graphical displays. In this context one should know that according to H. H. Goldstine (1972 [48]) such computer experiments were already envisioned by J. von Neuman and S. Ulam in 1945 at the very beginning of digital computing. This led to the development of simulation languages, rather independently of conventional statistics, but with an important impact on computer science (see also [65]). Note that Simula was the first object-oriented language ever (Dahl and Nygaard, 1966 [29]). A good overview of simulation from a statistical perspective can be found in B. Ripley's book of 1987 [73].

5.2 Computational statistics and algorithms

Computation in statistics is based on algorithms which have their origin either in numerical mathematics or in computer science. Such methods are summarized under the topic *statistical computing*. Usually textbooks emphasize the numerical aspects (for instance Monahan, 2001 [67]). However in the following we want to review briefly some important developments in numerical mathematics as well as in computer science.

For mainstream statistics the most important area is numerical analysis. The core topics are numerical linear algebra and optimization techniques but practically all areas of modern numerical analysis may be useful. Approximation techniques applying specific classes of functions, for examples splines or wavelets, play an important role in smoothing. Numerical integration is essential for the calculation of probability distributions, and for time series analysis Fourier transforms are of utmost importance (note that the fast Fourier transform, which is one of the most important algorithms of numerical analysis, was invented by J. Tukey in connection with statistical problems (Tukey and Cooley, 1965 [85])). Recursive algorithms and filtering are traditionally linked to time series but recently these methods are also of interest in connection with data streams [86]. However it seems that statisticians apply these methods often more like a tool from the shelf. New innovative aspects occur on the one hand in the theoretical analysis of algorithms in the context of statistical models, on the other hand as adaptation of methods according to statistical needs, which is in fact one of the key issues in computational statistics. The organization of the recent textbook by J. E. Gentle (2002 [46]) is a good example.

Another core topic is generation of random numbers which is conceptually close to computational statistics and computational probability theory and is the basic technique for discrete event simulation. Most early applications concerned the generation of random variates of different distributions for sampling as well as for numerical integration. Nowadays this technique is fundamental to many new developments in statistics like bootstrap methods, Bayesian computation, or multiple imputation techniques. However, also in this field it seems that statisticians are mainly interested in using these technique for their own purposes, in particular the theory of uniform random number generation is traditionally rather linked to number theory and computer science. An important contribution inside statistics is the quite exhaustive monograph on the generation of non-uniform random variates by L. Devroye (1986 [31]).

Apart from numerical analysis, there are algorithms of statistical interest for sorting, searching and combinatorial problems sometimes summarized under the heading *semi-numerical algorithms*. They are of utmost importance for exact nonparametric test procedures and for exact logistic regression as implemented in StatXact and LogXact (see for example [63] and [64]). Combinatorial algorithms are also used in the context of experimental design.

There is another group of algorithms highly relevant for computational statistics. Their origin is mainly in computer science, in particular we are thinking of machine learning, artificial intelligence (AI), and knowledge discovery in data bases. Neural Networks, Genetic Algorithms, Decision Trees, Belief Networks or Boosting are important and actual examples. These developments have given rise to a new research area on the borderline between statistics and computer science. New challenges arise from the need to interpret these non-statistical approaches in a statistical framework. In addition to [51], papers by D. Hand (1996 [49]), and R. Coppi (2002 [27]) discuss some of these issues.

All the above mentioned computational topics cover methods that are also adopted in other areas of mathematical modelling. If one looks into a book of mathematical modelling one might find similar algorithms and techniques as in a textbook about computational statistics. For example the book of N. Gershenfeld (1999 [47]) distinguishes between Analytical Models, Numerical Models and Observational Models. Analytical Models (mainly difference and differential equations) occur also in statistical applications, in particular in finance and epidemiology, but, as Sir D. J. Cox had stated in the preface to COMPSTAT 1992 [10], these topics are not core topics in computational statistics. It seems that the situation has not changed since. Obviously, in the area of Observational Models there is large overlap with methods used in statistical modelling but the focus is a different one. This had already been noticed in the early days of computational statistics by Sir J. A. Nelder (1978 [69]) who identified the following peculiarities of computing in statistics compared to other areas: (i) *Complex data structures*:

Problems analyzed by statisticians have often a rather complex data structure and adaptation of this structure towards the requirements of an algorithmic procedure is many times a genuine statistical task; (ii) *Exploratory nature of statistical analysis*: Usually in a statistical analysis we have not only a pure algorithmic cycle (defined by: get data, do algorithm, put results, stop) but rather a cycle of different computations, which are to some extent defined according to the interpretation of the previous results; (iii) *Competence of users*: Users of statistical methods are not necessarily experts in the area of statistics or in the area of numerical mathematics, but experts in a domain and want to interpret their methods according to their domain knowledge.

With these specific points in mind it is not surprising that graphical computation plays a more prominent role in statistics than in other areas of modelling. J. Tukey is one of the statistical pioneers, in particular with respect to dynamic graphics (Friedman and Stuetzle, 2002 [42]). Statistics has contributed to the development of graphical computation complementary to computer science. L. Wilkinson et al. (2000 [87]) stress the following three key ideas in the progression of statistical graphics, which may be seen as main driving factors behind most genuine statistical innovations: (i) Graphics are not only a tool for displaying results but rather a tool for perceiving statistical relationships directly; (ii) Dynamic interactive graphics are an important tool for data analysis, and (iii) Graphics are a means of model formalization reflecting quantitative and qualitative traits of its variables.

5.3 Computational statistics and computer science

Due to the specific needs of statistical data analysis mentioned in the previous section it was quite natural that even in the early days of computers statisticians were interested in developing specific software tools tailored more towards their needs than mathematical subroutine libraries like NAGLIB or IMSL. As early as 1965 Sir J. A. Nelder started with the development of GENSTAT in Adelaide (South Australia) on a CDC 3000 computer (Nelder, 1974 [68]). The data structure was at that time the data matrix, but in the further developments at Rothamsted Experimental Station (UK) the design was changed towards increasingly statistics-oriented data structures like variates, vectors, matrices or tables with main emphasis on the variate as well as the development of a statistical language. Around the same time also other projects had been started that resulted in major packages: BMD (later BMDP) was developed by W. J. Dixon and M.B. Brown from 1964 onwards at the University of California at Los Angeles as a coherent combination of different analysis subroutines with a common control language (first manual in 1972 [33]). SAS was designed by J. Goodnight and A. J. Barr starting in 1966 (the commercial SAS Institute was founded in 1976 by J. Goodnight, J. Sall, A. Barr and J. Helwigand;

`http://www.sas.com/presscenter/bgndr_history.html`,
`http://www.theexaminer.biz/Software/Goodnight.htm`).

Finally in 1967 N. H. Nie, C. H. Hull and D. H. Bent commenced at the University of Stanford the SPSS project

(`http://www.spss.com/corpinfo/history.htm`).

The latter two packages still flourish as products of service companies.

Many other statistical packages were designed in the subsequent years with the aim of supporting data manipulation and statistical computing. The major developers tried to keep track of the progress made in computing infrastructure in order to improve their products with respect to data storage and data management and to offer numerically more reliable statistical analysis methods. The book of I. Francis (1981 [40]) provides an overview over this early period of statistical software. It describes more than 100 packages available at the beginning of the nineteen eighties. The scope of these programs ranged from data management systems and survey programs to general purpose statistical programs and programs for specific analysis tasks. With respect to programming Fortran was the dominant source language and most of the products were offered for different hardware configurations and operating systems. Today for a number of reasons most of these products are only of historical interest. For specific purpose packages at the forefront of statistical methodology it was difficult to keep their competitive advantage after its methods had become widespread. For other products it was nothing but easy to keep path in their program design with the fast progress of computer technology. Only the major producers were able to follow the developments which also meant a switch from Fortran to other languages like C or C++, an adaptation to new computer architectures, and integration of modern user interfaces as well as of graphic facilities into their packages. Their new orientation towards customized analysis procedures made these products increasingly attractive for statisticians as well as non-statisticians.

More important for computational statistics were other developments aiming at the design of statistical languages as basis for statistical programming environments. Based on the conceptual formulation of the Generalized Linear Model, GLIM seems to have been the first system that was oriented towards the definition of an interactive analytical language for a large class of statistical problems in a unified manner, taking advantage of the previous GENSTAT experiences. The most important step in this direction was the S language, a project starting in 1976. The goal was the definition of a programming language for the support of data analysis processes
(`http://cm.bell-labs.com/cm/ms/departments/sia/S/history.html`).

The computer science oriented concepts of the S language are best described in the so called “green” S book by J. Chambers (1998 [23]). For the statistical aspects we refer to the “white” S book of J. Chambers and T. Hastie (1992 [24]). The general approach, a clever combination of functional programming and object oriented programming, supports perfectly the iterative nature of the statistical data analysis process and forms a new paradigm for computing, which is independent of the statistical application. The ACM honored this contribution to computer science: In 1998 Chambers received the ACM Software System Award for his seminal work which “has forever altered the way people analyze, visualize and manipulate data” [17].

In 1992 based on the S language, R. Ihaka and R. Gentlemen started the R-project at the University of Auckland (New Zealand; cf. Gentleman and Ihaka, 1996, [59] for the early history of R). Due to free availability the R-community grew rather fast and in 1996 the Comprehensive R Archive Network (CRAN) was established at the University of Technology in Vienna (cf. Hornik and Leisch, 2002, [55] for recent developments). A further important step in the development of statistical environments, closely related to R, was the formation of the Omegahat-project (`http://www.omegahat.org/`) for statistical computing in 1998. It serves as an umbrella for a number of other recent open source projects. Its goal, as described in detail by D. Temple Lang [79], is to meet the challenges for statistical computing resulting from new developments in computer science like distributed computing or Web-based services. Examples are extensions of existing systems such as StatDataML (Meyer et al., 2002 [66]) offering a XML interface for data exchange or embedding R into a spreadsheet environment (Neuwirth and Baier, 2000 [71]).

Besides S and R there were a number of other important projects in the area of statistical software development. For instance we want to mention W. Härdle’s XploRe [53], an interactive statistical computing environment, realizing new concepts of nonparametric curve and density estimation as well as statistical graphics in the mid nineteen eighties. In connection with XploRe recent efforts to extend its scope to statistical teaching and to Web applications are worth mentioning. Another project of interest due to L. Tierney in the late nineteen eighties was XLISP-STAT ([81], [82]), a statistical environment based on the public X-LISP language freely available from the *statlib archive*.

A further line of development are efforts to use parallel architectures in statistical computing. Such computer architectures are typically used for the implementation of demanding numerical algorithms. In recent years computer science has widened the scope of parallel computing towards distributed computing. We expect this research area to grow quite rapidly in the future, with an impact on statistical computing.

Another statistically relevant area of computer science is data management. While data structures in statistical computing are usually closely related to formal specifications of data types (e.g. lists, vectors, or matrices), the interpretation of an analysis process makes often use of conceptual and relational structures. Traditionally this topic is treated in the theory of data bases. A major breakthrough in this area was the introduction of the relational data model by E. F. Codd (1970 [26]). It offeres the opportunity to describe complex real world problems from a conceptual point of view in a unified manner. The description of data by data models is nowadays captured under the heading metadata. In this context it is worth mentioning that the term metadata occurred for the first time in connection with official statistics in a book by B. Sundgren (1975 [78]). Modern data base systems offer not only tools for storage and retrieval, but also statistical functionalities, in particular for tabulation (core instruments for official statistics). Despite the fact that they are rather simple with respect to statistical methodology, there are numerous pitfalls from a conceptual point of view. The latter raise interesting operational questions which are treated in the context of data warehouses. An interesting reference which helps to understand the connections as well as the differences between the statistical approach and the computer science approach to multi-dimensional tables is [76].

5.4 Computational statistics and applications

With respect to the interplay between applications and computational statistics we want to discuss now the challenges that arise from application problems. Besides the difficulties resulting from new problems in various research areas, for example analysis of microarrays in biology, one can identify – rather independently from the field of research – the following three interwoven challenges for computational statistics: handling of problems stemming from new data capture techniques, from the complexity of data structures, and from the size of data.

Since the early times of computational statistics a major effort has been the development of tools for automatic data capture and of interfaces to data management systems. This has led to the development of computer-aided survey information collection (CASIC) tools, an area which seems to be nowadays more a topic in official statistics and management of statistical data base systems. Inside computational statistics we observe an increasing interest in the handling of efficient data generation systems. Many times such systems occur in connection with automated monitoring of networks, in particular the Internet. Such data streams are of interest from a computer science as well as a statistical point of view. The statistical perspective is treated in a number of papers in a recent issue of the *Journal of Computational and Graphical Statistics* (e.g. Wegman and Marchette, 2003 [86].

With respect to the data structures the traditional model was characterized by the relation between sample and universe or by a properly designed measurement process. Such data structures can be represented quite well in a relational scheme and appropriate statistical models can be formulated for the analysis, for instance hierarchical models. In connection with data mining applications statisticians are confronted with new data structures which do not fit into the standard model. One has to analyze data combined from different sources which are often rather inhomogeneous with respect to quality (e.g. problem of missing values) and have no immediate interpretation in a traditional statistical framework. Combination of such data sources is a statistical problem in its own right.

The last difficulty is the size of the data. P. J. Huber (1994 [57]) classified data sets from tiny (about 100 bytes) up to huge (about 10^{10} bytes). One can definitely argue that size is always an issue relative to computing power and storage capacity, and problems practically intractable 30 years ago are nowadays routine applications. Nevertheless, today's statisticians and computer scientists have to solve problems for huge datasets. Specific problems concerning the data structure, the data base management, and the computational complexity are discussed in Huber (1999 [58]).

A second important topic for computational statistics with respect to applications is the statistical analysis process itself. The ubiquitous availability of the computer and of statistical software packages has changed the context in many ways. On the one hand statistical software packages support statisticians in the phase of exploratory data analysis and allow them the evaluation of numerous tentative models for the data without careful planning in advance. On the other hand they enable non-statisticians to perform rather complex analyses for their data, in former times solely carried out by professional statisticians. This evolution has weakened in some sense the role of statisticians as custodians of the data and has caused many discussions inside the statistical profession. Here we only want to mention Y. Dodge and J. Whittaker (1992 [34]) who raised the point that this development might bring about a de-skilling of certain parts of the profession. However they also argued that the democratization of facilities does not automatically mean a threat to the profession in the long run. We claim that statistical analysis is definitely more than the application of certain algorithms because an analysis strategy is required too. For instance in the current scientific development of the bio-sciences we see an explosion of highly complex data problems that can only be managed in part with the resources at hand.

In the nineteen eighties the question of automated analysis strategies was intensively discussed in connection with the issue of statistical expert systems. This undertaking ended without substantial success making it clear that it is rather implausible to assume statisticians can be easily substituted by machines in the near future. To put it in a nutshell, not even standard data-analytic problems can be handled easily via routine applications and simple rule systems. Another area of interest in this context is certainly the role of computers in statistical education, in particular for non-professionals, taking advantage of the various opportunities offered in the field of computational statistics.

6 The COMPSTAT symposia

In this section we review the COMPSTAT symposia, giving a tabulated summary of the occurrence of topics and a verbal description of the meetings and proceedings.

As for the summary of topics covered in the COMPSTAT symposia we have produced two self-explaining tables, Table 1 for the period 1974–1988, and Table 2 for the period 1990–2002. The notation in these tables is the following: "p" denotes that a topic was present in the proceedings, "f" denotes that a topic was frequently present in the proceedings (i.e. more than 3 times), "K" represents a keynote paper, "I" represents one or two invited papers, and finally "T" signifies a tutorial. We suggest to read the respective table in parallel with the verbal description of the chronologically ordered COMPSTAT symposia.

The very first COMPSTAT symposium was held at the University of Vienna in 1974, initiated by P. P. Sint and J. Gordesch. Both were also in fact the editors of the proceedings [1]. There were about 50 presentations organized according to five subject areas, reflecting to some extent the interests of the organizers: Computational Probability, Automatic Classification, Numerical and Algorithmic Aspects of Statistical Computing, Simulation and Stochastic Processes, and last but not least Software Packages. In 1974 there were neither formal keynotes nor invited lectures. However, during the opening session a special lecture was delivered by the well-know mathematical statistician L. Schmetterer on stochastic approximation (not in the proceedings).

Naturally the topics within the subject areas were rather scattered, but some of them remained popular across the whole period of 30 years such as Robustness (note that P. J. Huber was present at the first symposium), Time Series Analysis, and Modelling (the latter in its beginning primarily meaning factor analysis and dimension reduction techniques). It is remarkable that a number of statistical packages popular at the time were already covered: R. Buhler's P-STAT and Sir J. A. Nelder's GENSTAT. The presentation of a SAS system, not to be confounded with the later much more successful namesake [25], should also be mentioned. Further, as in succeeding conferences, APL (for details see e.g. [19]) appeared as a popular statistical environment.

With all this in mind Gordesch and Sint speculated in the preface of [1] about a spectacular growth of the field, in writing "which as we hope will now result in techniques of model building being very different today from what it was in pre-computer days".

The second COMPSTAT symposium took place in Berlin 1976, organized by J. Gordesch and P. Naeve (also the editors of the volume [2]). Altogether 58 papers were presented. The subject areas were more or less the same as at the first meeting but the names had changed somewhat: Computational Probability, Automatic Classification and Multidimensional Scaling, Numerical and Algorithmic Aspects of Statistical Models (with subtopics Linear Models, Multivariate Analysis and Sampling), Simulation and Stochastic Processes, and finally Software. A new section "Applications" was introduced (mainly in economics and biology). This selection reflects the understanding of computational topics in the mid nineteen seventies: Multivariate Analysis comprised mainly ANOVA as well as Factor Analysis and Computational

Probability meant random number generators and the calculation of distributions in statistics. Apart from statistical computing Software also comprised recent developments in data bases. In addition there was a dedicated interest in the comparison of software packages with respect to certain technical as well as practical criteria.

The third COMPSTAT symposium in Leiden 1978 was organized by the Department of Medical Statistics in cooperation with the Computer Centre (both Leiden University) and headed by L. C. A. Corsten and J. Hermans. 68 papers were presented and published in the proceedings [3]. For the first time two keynotes were included, delivered by Sir J. A. Nelder and J. Tinbergen. The main topics consisted of Linear and Nonlinear Regression, Time Series, Discriminant Analysis, Contingency Tables, Cluster Analysis, Exploratory Techniques, Simulation and Optimization, Teaching Statistics, and Statistical Software. It is interesting to note that Exploratory Techniques was mainly an umbrella for problems in connection with multidimensional scaling. The topics Simulation and Optimization as well as Computational Probability also comprised contributions which would nowadays hardly find their way into a statistical meeting.

The fourth COMPSTAT symposium was organized by and held at the University of Edinburgh in 1980 with a record number of about 750 participants. Four invited and 82 (out of 250 submissions) contributed papers were presented and published in the proceedings volume [4], edited by M.M. Barrit and D. Wishart. This meeting clearly marks the beginning of the transition from batch to interactive computer processing, reflected in a special session. Invited lectures were given by J. Tukey on styles of data analysis, by E.M.L. Beale on branch and bound methods for optimization, by R. Tomassone on survey management of large data sets, and by I. Francis on a taxonomy of statistical software. Other topics were Sampling Methods, Data Base Management, Education, Analysis of Variance/Covariance, Interactive Computing, Linear and Nonlinear Regression, Multivariate Analysis, Optimization and Simulation, Cluster Analysis, Statistical Software, and Time Series Analysis.

The diffusion of interactive personal computing (marking the shift from mainframe to personal computers in the early nineteen eighties) can be clearly identified in COMPSTAT 1982 held in Toulouse (the fifth symposium) with about 500 participants. H. Caussinus, who also published the proceedings [5] together with P. Ettinger and R. Tomassone, chaired the program committee. One finds several new features at this COMPSTAT: the number of invited speakers was increased to 15 in order to cover new developments in computational statistics like Experimental Design, Computing Environments, Numerical Methods, EDA, Parallel Processing in Statistics, and Artificial Intelligence. In contrast to previous proceedings volumes comprising also papers at the border of statistics to other areas, the focus was now less theoretical and more computing oriented (60 papers out of 250 submissions).

Table 2: Topics in the proceedings of the COMPSTAT symposia 1990–2002. p–present, f–frequent (p>3), K–Keynote, I–Invited, T–Tutorial.

Many of them reflect the trends of the time, especially the penetration of personal computers and improved graphical displays into the world of statistics. The wish of statisticians to apply these new technologies, not yet covered by commercial software packages, can be clearly seen. Another novelty was the production of a complementary volume with short communications and posters.

The sixth symposium took place in Prague in 1984, extending the scope of COMPSTAT to the Eastern European countries. As a matter of fact IASC had planned for a meeting in Bratislava (a Slovakian town only 65 kilometers from Vienna) but the (communist) Czechoslovakian Academy of Sciences decided for the central location of Prague. Luckily there were several dedicated statisticians, among them T. Havranek, Z. Sidak and M. Novak, the organizers of the meeting. Many colleagues, who at that time did not have the chance to participate in Western meetings, could attend. Out of a record number of about 300 submissions 65 papers were selected. T. Havranek, Z. Sidak and M. Novak also edited the proceedings [6] and a companion volume of short communications and posters, following the example of 1982. Commemorating the tenth anniversary of the COMPSTAT symposia P.P. Sint was invited to deliver a lecture entitled “Roots in Computational Statistics”. The main topics covered in invited talks were Computational Statistics in Random Processes, Computational Aspects of Robustness, Discriminant Analysis, Statistical Expert Systems, Optimization Techniques, Linear Models, and Formal Computation in Statistics. Besides these topics also the traditional COMPSTAT themes like Cluster Analysis, Multivariate Analysis, Statistical Modelling and Software were present. It is worth mentioning that also a number of more computer science-oriented papers on data management and data preprocessing had found their way into the proceedings, reflecting some of the local interests.

COMPSTAT 1986 (the seventh symposium) was held in Rome and attracted an ever record of about 900 participants. From around 300 submissions for contributions about 60 contributed papers as well as 13 invited papers were published in the proceedings [7], edited by F. De Antoni, N. Lauro and A. Rizzi. A keynote lecture was given by E. B. Andersen about information, science and statistics, discussing the challenges for statistics resulting from the development of statistical software, graphics, interactive computing, and new methods and styles of data analysis. Apart from the invited program the proceedings volume presents itself well-balanced between statistically oriented themes, computer science oriented topics and novel applications. The main statistical themes comprised the traditional COMPSTAT topics like Probabilistic Models in Exploratory Data Analysis, Computational Approaches of Inference, Numerical Aspects of Statistical Computation, Cluster Analysis and Robustness, but also a rather specialized topic entitled Three Mode Data Matrices. The more computer science oriented topics reflect the trend towards Expert Systems and Artificial Intelligence, typical for the mid nineteen eighties. Altogether 9 papers on statistical expert systems were presented. Not so much in the mainstream of the time we identify sections on Computer Graphics, Data Representation, Statistical Software and Statistical Data Base Management. Main application areas were Clinical Trials and Econometric Computing. Additionally there was a section about Teaching Statistics.

Also for COMPSTAT 1988 (the eighth symposium), taking place in Copenhagen, the number of participants remained high with more than 800. It was organized by D. Edwards who also published the proceedings (coeditor N. E. Raun, [8]) and the additional volume of short communications and posters. There were two keynotes delivered by G. W. Stewart on parallel linear algebra in statistical computations and by B. Efron on computer-intensive statistical inference, and 7 invited papers. They were related to Non-Parametric Estimation, Projection Pursuit, Expert Systems, Algorithms, Statistical Methods, Statistical Data Bases, and Survey Processing. Out of approximately 300 submissions 51 contributed papers were selected. At that time computational statistics had become an integrated part of statistics research with new emerging areas, especially graphical techniques and models, Bayes methods, and smoothing techniques. Nonparametric curve estimation and dimension reduction techniques are discussed at COMPSTAT for the first time. At the same time the COMPSTAT evergreen Expert Systems is still quite present. A real innovation were tutorials in the programme. They covered the fields Dynamic Graphics (R. Becker), Artificial Intelligence (W. Gale), and Graphical Models (N. Wermuth). The new availability of modern computing also makes itself visible in the appearance of the proceedings volume with a relatively larger number of electronically produced papers.

The ninth meeting in Dubrovnik 1990 marks a dramatic change in the positive development of the COMPSTAT symposia seen so far. Submissions were down to 115 (43 contributed papers selected). After six years COMPSTAT was back in a communist country, however when this decision was taken, nobody could foresee the disintegration of Yugoslavia. During the conference around Dubrovnik first road barricades were erected and soon after the civil war broke out (the conference hotel on the sea shore was destroyed in the following years). Anticipating the unrest many participants and speakers did not show up (an audience of around 180 was present). Thus the proceedings volume [9], edited by the organizer K. Momirović does not really represent the conference (many more papers than presentations). The programme was dominated by the subject areas Expert Systems, Multivariate Data Analysis and Model Building, and Computing for Robust Statistics. Special topics were Optimization and Analysis of Spatial Data. All these comprised invited talks (6 invited papers in the proceedings). In addition some of the traditional COMPSTAT topics such as Algorithms, Time Series (with an invited paper) and Computational Inference were present. Despite all external problems it is noteworthy that aspects of modelling and appropriate software played an important part in this meeting, establishing a new COMPSTAT focus. T. Hastie (replacing J. Chambers) presented statistical models in S for the first time and new strategies for GLIM4 were outlined by B. Francis. As a matter of fact it was for the first time that the statistical and graphical environment S (the S-Plus package) was discussed in the COMPSTAT community.

In 1992 the tenth symposium was held in Neuchâtel. It was the general hope that COMPSTAT would recover from the Dubrovnik adventure, however the problems went on. Submissions remained low with about 115. Despite the fact that participation was only around 200, some participants had to stay in remote accommodations, forced to use the cable car to get from Chaumont (great views!) down to the conference site and back, reducing the audience even further.

Y. Dodge, the organizer and proceedings editor (co-editor J. Whittaker), decided to reshape the symposium and the volume. In response to the unexpected low number of submissions and the fact that Physica-Verlag had been sold to the Springer company, he changed the format of the proceedings, giving up the established layout and format as well as the tradition of a complementary volume for short communications and posters, in accepting almost all submitted papers as full contributions (Computational Statistics Volume 1 and 2 [10] of a new Springer-Verlag series).

There is an interesting foreword by Sir D. J. Cox with the title "The Role of Computers in Statistics". In a prologue Y. Dodge and J. Whittaker feared that a de-skilling of the profession due to the dissemination of commercial software packages could take place. When studying the two volumes of COPMPSTAT 1992, one dedicated to statistics and modelling and the other to computation, we were astonished by the broad range of topics. The main subject areas in Volume 1 are Statistical Modelling, Multivariate Analysis, Classification and Discrimination, Symbolic and Relational Data, Graphical Models, Time Series, Nonlinear Regression, Robustness and Smoothing Techniques, Industrial Applications and Bayesian Statistics. Volume 2 comprises Programming Environments, Computational Inference, Package Developments, Experimental Design, Image Processing and Neural Networks, Meta Data, Survey Design and Data Bases. Almost all these topics included an invited lecture. There were neither official keynotes nor tutorials.

The new proceedings format had not been approved by the European Regional Section of the IASC and was changed back to the previous COMPSTAT appearance for the year 1994, remaining in this style up to the present.

The twentieth anniversary of COMPSTAT was celebrated at the eleventh symposium held in Vienna 1994. The program committee, chaired by R. Dutter, tried to find a compromise between the traditional COMPSTAT topics and actual topics when selecting the keynote speaker and the invited speakers. The keynote was given by P. Huber and concerned the treatment of huge data sets. The themes of the invited papers were Multivariate Analysis, Classification and Discrimination, Dynamic Graphics, Numerical Analysis, Nonparametric Regression, MCMC, Selection Procedures, Neural Networks, Change Point Problems, Wavelet Analysis, and Time Series Forecasting. Besides these invited lectures two tutorials were organized: W. Schachermayer introduced statistical problems in finance and insurance and B. Sundgren gave an overview on metadata. Furthermore a discussion about the nature of computational statistics was organized. All together about 280 participants attended this meeting. The organizers returned to the traditional format of publishing the proceedings and an additional volume of short communications and posters. The proceedings [11] were edited by R. Dutter and W. Grossmann and contained the invited and 60 contributed papers, selected from approximately 200 submissions. With respect to statistical software the increasing dominance of S for the development of computational statistics was evident. Other more commercially oriented products were presented during the conference and documented in a separate booklet.

After the symposium in Vienna there was a COMPSTAT Satellite Meeting on Smoothing held at Semmering, attracting almost 50 participants. Because of the COMPSTAT anniversary a historic train was bringing COMPSTAT participants and accompanying persons on the oldest mountain railroad in the world (now a World Cultural Heritage) from Vienna to the spa of Semmering in the Austrian Alps.

The meeting was organized by M. G. Schimek and comprised 7 invited lectures (presenters were B. Cleveland, M. Delecroix, R. Eubank, Th. Gasser, R. Kohn, A. van der Linde, and W. Stuetzle) and two software presentations (S-Plus and for the first time XploRe). W. Härdle and the organizer edited a proceedings volume [12] consisting of 10 papers (not published elsewhere) out of 26 given at the meeting. It also includes an expository discussed paper by J. S. Marron ("A Personal View of Smoothing and Statistics") and two other discussed contributions by W. S. Cleveland and C. Loader ("Smoothing by Local Regression: Principles and Methods") and by B. Seifert and Th. Gasser ("Variance Properties of Local Polynomials and Ensuing Modifications"). It is worth mentioning that local regression smoothing is now a principal tool for normalization of microarray data in genetic research. Since the symposium in Copenhagen 1988 nonparametric smoothing techniques and relevant software had played a steadily increasing role in COMPSTAT.

The twelfth COMPSTAT symposium was organized under the auspices of A. Prat in Barcelona 1996, attracting an estimated number of 300 participants. An opening keynote was delivered by G. Box entitled "Statistics, Teaching, Learning and the Computer" and a closing keynote "Information Markets" was presented by A. G. Jordan. Eleven invited papers covered topics like Time Series, Functional Imaging Analysis, Applications of Statistics in Economics, Classification and Computers, Image Processing, Optimal Design, Wavelet Analysis, Profile Methods, Web-based Computing, and Multidimensional Nonparametric Regression. Apart from the invited lectures the proceedings [13] edited by A. Prat present also 56 contributed papers selected from about 250 submissions, arranged in alphabetical order and grouped according to subjects at the end of the proceedings. From the subject areas one gets the overall impression that the main emphasis was on statistical modelling, in particular Bayesian Methods, Classification, Experimental Design and Time Series from the classical areas, and Neural Networks, Genetic Algorithms, Wavelets and Classification Trees as more recent methodologies. Also of interest is a rather broad spectrum of applications presented at the conference. A novelty was the introduction of awards for the best papers of young researchers.

The thirteenth symposium held at the University of Bristol in 1998 had seen less participants than the previous COMPSTAT. Organizers were R. Payne and P. Green. There was a methodological keynote on wavelets delivered by B. W. Silverman and in addition an applied keynote on the analysis of clustered multivariate data in toxicity studies presented by G. Molenberghs. Three of the 10 invited lectures dealt with various statistical techniques in connection with applications like Mortality Pattern Prediction, Covariance Structures in Plant Improvement Data, and Markov Models in Modeling Bacterial Genoms. The other invited lectures consider rather methodological issues like Design Algorithms, Scaling for Graphical Display, MCMC for Latent Variable Models, Decision Trees, Semi- and Nonparametric Techniques in Time Series, and Time Series Forecasting. In addition there was an invited lecture on teaching in network environments. The 58 contributed papers contained in the proceedings volume (edited by R. Payne and P. Green, [14]) were selected from about 180 submissions. Taking R. Payne's affiliation (IACR Rothamsted) into account, it is not surprising that the proceedings show a strong orientation towards statistical modelling and applications. However, there are also papers dealing with more computer science oriented aspects of computational statistics, in particular computing environments and software packages for special problems. The proceedings were accompanied by a volume comprising the short communications and posters, edited by IACR Long Ashton.

The fourteenth COMPSTAT symposium was held in Utrecht 2000. It was organized by P. van der Heijden (Utrecht University) and J. G. Bethlehem (Statistics Netherlands). The number of participants was around 220. It had a substantial applied focus on the social sciences and official statistics. There were two keynotes (one on multiple imputation by D. B. Rubin and the other on official statistics in the IT-era by P. Kooiman) and 13 invited papers. The invited lectures concerned Algorithms, Bayesian Model Selection, GLMs, HGLMs (a further generalization of GLMs), Imputation, Data Mining, Spatio-Temporal Modelling, Survival Techniques, Time Series, and Teaching. Further there were 60 contributed papers (out of around 250 submissions) following mostly the conventional subject areas of COMP-

STAT. A proceedings volume [15] and a supplement comprising the short communications and posters were published (editors P. van der Heijden and J.G. Bethlehem).

The last (fifteenth) COMPSTAT symposium we can report on took place at Humboldt-Universität zu Berlin in 2002. It was organized by W. Härdle and attracted approximately 220 submissions. This time the primary focus was on business applications, especially in connection with the Internet (such as E-Commerce and Web-Mining) and on the handling of massive and complex data sets (e.g. in genetic research). The idea was to expand the traditional scope of COMPSTAT and to make it attractive for new audiences. However the number of about 260 participants made it clear that this endeavour was not sufficient to substantially enlarge the audience for such a meeting. However it is only fair mentioning that many young researchers showed up for the first time, also joining IASC because of a special promotion scheme.

There was a keynote delivered by T. Hastie entitled “Supervised Learning from Microarray Data”. The other 8 invited talks concerned the topics Bayes Methods, Graphical Methods, Internet Traffic, Smoothing, Teaching, and Time Series. Further there were 90 contributed papers connected to the above topics as well as to Algorithms, Classification, Computational Inference, Computing Environments, Data Mining, Meta Data, and Multivariate Methods. Two additional areas of interest have emerged because of submissions received, the statistical language R and functional data analysis. Innovations were that the printed proceedings volume (edited by W. Härdle and B. Rönz [16]) also appeared as a Springer-Verlag e-book and that the companion volume of short communications and posters was published on a CD. Moreover several prices were granted (among them a new one for software innovation).

7 Conclusions

The evolution of computational statistics has always been strongly influenced by developments in statistical theory, in algorithms, in computer science, and by the problems statisticians are confronted with. In statistical theory many actual topics are connected to concepts and methods of computational statistics requiring definitely more than the proper implementation of well-defined algorithms. With respect to computation we can observe a shift from pure numerical analysis to more graphically oriented techniques and algorithms developed in computer science. This brings about a new quality of cooperation between statistics and computer science with a high potential for future development. The traditional knowledge transfer from computer science to computational statistics was primarily in the areas of statistical packages, statistical languages, statistical graphics and statistical data management systems. Yet these conventional areas are still open to new developments, in particular with regard to statistical Web services and the seamless integration of various tools. Concerning applications the main challenges for computational statistics are complex data structures and very large or huge data, as well as the demand for new analysis strategies. Due to the penetration of all areas of our life by computers one can expect an ever increasing number of challenging tasks.

Although we can identify many inter-connections between computational statistics and computer science, symbolic computation has not received the attention it deserves. Mathematica has been used to implement a number of statistical approaches applying general mathematical notation, this way making it feasible to calculate the results with (at least in principle arbitrarily) high precision. One might envisage a development where similar approaches are introduced in environments like S and R or complement these environments. The ability to use abstractions, symbolic representations and/or general objects/classes in everyday work while having access to low level constructs to improve statistical methods based on experiments or to solve non-anticipated practical problems, could be a promising way for the future.

The review of the COMPSTAT symposia has shown that the meetings and proceedings reflect clearly the international developments of computational statistics of the last 30 years, although with some delay in certain subject areas (e.g. Bayesian Methods, Resampling, Statistical Environments, Smoothing Techniques, Statistical Learning, Tree Based Methods, Wavelets). On the other hand the anticipation of new ideas in connection with Dimension Reduction Methods, Expert Systems, and Robust Techniques was very fast. More recently, with respect to content, there seems to be a shift of focus towards topics related to statistical modelling and at the same time less interest in computer science contributions useful in statistics.

There was a continuous uptrend in conference participation during the first 16 years with symposia covering a rather broad spectrum of computational statistics topics. The nineteen eighties have certainly seen the high time of COMPSTAT with many innovations in statistical computing, a boost in algorithms and professional software (emphasizing personal computing in the second half of the decade), and the early adoption of expert systems. This is also reflected in the size of the meetings, going beyond 300 submissions and ranging between 800 and 900 participants in Rome 1986 and in Copenhagen 1988. After the problems with COMPSTAT 1990 in Dubrovnik and COMPSTAT 1992 in Neuchâtel, the symposia have stabilized since at a lower level of participation. In recent years we have typically seen around 200 submissions and about 250 participants (i.e. very little non-contributing participants). This has already led to new formats of presentation to keep the number of parallel sessions as low as possible.

In general, COMPSTAT was probably not the main forum for the presentation of state-of-the-art research results in computational statistics. It was rather an important forum for the exchange of relevant information in the

European statistical community about current developments from all over the world as well as on practical aspects such as new algorithms and statistical software. This was largely achieved by a dedicated invitation policy. One can say that the organizers of the symposia always have given their best to identify distinguished personalities for keynotes and invited lectures. This way the European research community has received a great deal of valuable impulses that often have proven influential for subsequent projects in Europe. Occasional tutorials were another means of this successful policy, not only attracting young researchers.

COMPSTAT has always been an international undertaking. However, most recently there have been discussions at IASC business meetings focusing on strategies for opening up the European COMPSTAT symposia even further to make them world-wide events in the future, integrating other regional sections such as the Asian Section and the planned African Section (an initiative of S. Azen as President). As far as the Interface Foundation of North America, Inc., is concerned, there was a formal proposal in 1987 to transform it into the North American Section of IASC, however it was voted down by the Interface Board. E. J. Wegman (1997–1999 IASC President) from George Mason University (USA) initiated an informal connection between IASC and Interface which has finally led to the establishment of an IASC–Interface Liaison Committee, chaired by M. G. Schimek as IASC Vice President, to foster mutual interests and to organize invited sessions at each others symposia.

We are all looking forward to this year's COMPSTAT symposium in Prague, celebrating the thirtieth anniversary, chaired by J. Antoch (Charles University of Prague). Maybe the first step towards the next generation of COMPSTAT meetings has already been taken as it is organized in compliance with new guidelines. According to its scientific programme on the Web we can already say that the Prague symposium is going to be truly international with contributions from all IASC regional sections, from Interface, and beyond.

HYBRID ALGORITHMS FOR CONSTRUCTION OF D-EFFICIENT DESIGNS

Abdul Aziz Ali and Magnus Jansson

Key words: Exact D-optimal designs, genetic algorithms, local search.

COMPSTAT 2004 section: Design of experiments.

Abstract: We construct exact D-efficient designs for linear regression models using a hybrid algorithm that consists of genetic and local search components. The genetic component is a genetic algorithm (GA) with a 100% mutation rate and ranking selection. The local search methods we use are based on the G-bit improvement and a combination of the Powel multidimensional and Brent line optimization techniques. Computational results show that the hybrid algorithm generates designs that are comparable in efficiency to those found using the modified Fedorov algorithm (MFA), but without being limited to using a given set of candidate points.

1 Introduction

An experimental design is said to be optimal if it meets predefined criteria that determine the precision with which the model parameters or response is estimated. The D-optimality criterion Keifer and Wolfowitz [12] puts emphasis on the precision with which the model parameters are estimated by maximizing the determinant of the model's information matrix. This criterion has the intuitively appealing interpretation of minimizing the volume of the joint confidence ellipsoid of the least squares regression parameter estimates.

Exact D-optimal designs are calculated using optimization algorithms such as those given by Cook and Nachtsheim [6] and Johnson and Nachtsheim [11] among others. These algorithms iteratively maximize the determinant of the information matrix by sequentially, or simultaneously, adding and deleting points to the design. Many of the most used algorithms require an explicit set of candidate points to work with, thus putting heavy demands on prior domain-specific knowledge of the optimization problem. Although not as common, evolutionary algorithms have also been used to calculate D-optimal designs. Govaerts and Sanchez [8] were the first to use genetic algorithms (GAs) to find exact D-optimal designs. However, their algorithm incorporated the use of a candidate set of design points, much like the more traditional algorithms. Poland et al. [17] used a GA to improve on the standard Monte Carlo algorithms by applying DETMAX and k-exchange as the mutation operator. Compared to the exchange algorithms, their algorithm was slower but yielded better results. Broudiscou et al. [5] successfully applied a purely genetic algorithm to the exact D-optimal design problem in a chemometrics setting. GAs have since then been used by Montepiedra et al. [15] who omitted the mutation operator in favor of faster convergence and Heredia-Langner et al. [10] who used real value encoding in place of the more traditional binary encoding. The latter named also give an excellent introduction to the use of GAs in calculating optimal designs.

This paper presents the use of hybrid algorithms in calculating D-efficient or near D-optimal designs. The hybrid algorithms considered here consist of a genetic component with 100% mutation rate and local search methods. The mutation operator is extensively used in order to escape from local optima. The hybrid algorithm is therefore implemented in two stages: The genetic component finds a neighborhood point of a local optimum and the local search finds the local optimum. The genetic component is then updated with the coordinates of the local optimum and the process is repeated until some termination condition is met.

1.1 Model and the exact D-optimal design problem

In many experimental situations, the experimenters usually approximate the relationship between the response variable and the input factors with the linear model

$$\boldsymbol{y} = \boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$$

where $\boldsymbol{X}$ is the $(n \times p)$ matrix of factor levels (design matrix), $\boldsymbol{\beta}$ is the $p \times 1)$ vector of unknown regression parameters, $\boldsymbol{y}$ is the $(n \times 1)$ vector of observations and $\boldsymbol{\epsilon}$ is the $(n \times 1)$ vector of error terms that are assumed to be *iid* (possibly normally distributed) with $E(\boldsymbol{\epsilon}) = 0$ and $E(\boldsymbol{\epsilon}\boldsymbol{\epsilon}^{\mathrm{T}}) = \boldsymbol{\sigma}^2\boldsymbol{I}$.

When the goal is to construct exact designs, the problem becomes one of how to determine $\boldsymbol{x}_i^{\mathrm{T}}$ $i = 1, 2, 3, \ldots, n$ from the region defined by all the level combinations of the factors called the design region χ, so that the resulting design will estimate some function of $\boldsymbol{\beta}$ with a precision that is at least as good as that provided by any other design in χ. The exact n-point design is denoted by

$$\xi_n = \left\{ \begin{matrix} \boldsymbol{x}_1 & \boldsymbol{x}_2 & \cdots & \boldsymbol{x}_k \\ r_1/n & r_2/n & \cdots & r_k/n \end{matrix} \right\},$$

where $\sum_{i=1}^{k} r_i = n$ and r_i is the number of trials at $\boldsymbol{x}_i$. The standardized predictor variance is given by,

$$d(\boldsymbol{x}, \xi) = n\boldsymbol{x}^{\mathrm{T}}(\boldsymbol{X}^{\mathrm{T}}\boldsymbol{X})^{-1}\boldsymbol{x} = \boldsymbol{x}^{\mathrm{T}}\boldsymbol{M}^{-1}(\xi_n)\boldsymbol{x},$$

a function of the design ξ_n and the point at which the prediction is made.

The design ξ^* is an exact D-optimal design if $\boldsymbol{M}$ is a non-singular matrix and the following is satisfied:

$$\min_{\xi} \left|\boldsymbol{M}^{-1}(\xi)\right| = \left|\boldsymbol{M}^{-1}(\xi^*)\right|.$$

A measure of efficiency is the D-efficiency which is defined as follows: A design ξ_1 has a D-efficiency relative to ξ_2 given by

$$D - eff = 100 \cdot \left[\frac{|\boldsymbol{M}(\xi_1)|}{|\boldsymbol{M}(\xi_2)|} \right]^{\frac{1}{p}} .$$

This comparison is valid even when the designs being compared are of different sizes because the comparison is based on the information per point for each design. For the interested reader an excellent review of optimum design theory is given by Ash and Hedayat [3] and books by Atkinson & Donev [2] and Silvey [18].

1.2 Commonly used algorithms and genetic search

Exact D-optimal designs are calculated using optimization algorithms such as those given by Dykstra [7], Cook and Nachtsheim [6], Mitchell [14], Wynn [20] and Johnson and Nachtsheim [11] among others. These algorithms are search heuristics that iteratively maximize the determinant of the information matrix by sequentially adding and deleting points to the design or exchanging points between the existing design and a candidate set of points. The algorithms update the design matrix with rank-one matrices derived from the candidate points as shown by the following formula which is often used for computational efficiency. Upon the addition of a point to a n point design ξ_n, the change in the information matrix is,

$$\left| \boldsymbol{X}^{\mathrm{T}} \boldsymbol{X} \right| \rightarrow \left| \left(\boldsymbol{X}^{\mathrm{T}} \boldsymbol{x} \right) \begin{pmatrix} \boldsymbol{X} \\ \boldsymbol{x}^{\mathrm{T}} \end{pmatrix} \right| = \left| \boldsymbol{X}^{\mathrm{T}} \boldsymbol{X} \right| \cdot \left(1 + \frac{d(\boldsymbol{x}, \xi_n)}{n} \right) .$$

As a consequence the point $\mathbf{x}$ whose addition to the design maximizes the determinant of the information matrix is the point whose standardized predicted response variance calculated from the current design is largest.

A major drawback of these algorithms is that for each iteration the sequential algorithms have to calculate the variance functions of the current designs. Exchange algorithms calculate the variance functions of all possible pairs of candidate and the current design's points, a process that puts heavy demands on memory and speed even for moderately large designs.

Although not as commonly used as the exchange algorithms, evolutionary algorithms have also been used to calculate D-optimal designs. Genetic algorithms (GAs) have been successfully used to search for optimal or near optimal solutions in large-scale optimization because of their versatility. GAs do not require convexity or even continuity of a function and have their strong points as a powerful computational tool for function optimization because they are less susceptible to being trapped in local optima as compared to many other numerical optimization techniques.

GAs usually, but not always, encode the possible solutions to an optimization problem using binary strings. For example, if the range of possible solutions lies in the interval $[-\alpha, \alpha]$ then the 8-bit binary string 00000000 will represent $-\alpha$ and 11111111 will represent $+\alpha$. A randomly generated set of strings forms the initial population from which the GA starts its search. Initial candidate solutions (strings) are usually uniformly sampled from the search space in order to introduce variability in the set of candidate solutions. This initialization process is a random search whereby a number of possible solutions are randomly generated and the best solutions (the fittest strings) are remembered.

2 GA implementation for finding D-efficient designs

2.1 Encoding the designs

The GA is implemented by encoding each complete design, including the number of experimental runs, as a one bit-string. Binary encoding is the most widely used form of representation because of its flexibility and also because its theoretical framework is well developed Goldberg [9]. Binary encoding also allows for a simple way to apply the mutation and recombination operators. Consider the m-bit representation of a single factor design at the high and low levels. The base 10 (decimal) representation of the coordinate points will be 0 and $2^m - 1$ respectively. This design region is transformed to the familiar $[-1, 1]$ by the function $f : x \mapsto \frac{2x}{2^m-1} - 1$, where x is the decimal representation.

The length of the bit-string is determined by the number of bits required to code the coordinates of the levels taken by each factor, the number of factors, and the number of trials. For example, an n-trial experimental design with k factors each requiring p bits to code its coordinates would require npk bits.

2.2 Initialization and selection

The initial population of strings (at iteration 0) consists of N strings. Because the D-optimality criterion pushes the design points to the edges or vertices of the design region, initial designs are generated by drawing random variates from a U-shaped distribution which puts more mass on the edges. The *Beta* distribution with $\alpha = 0.35$, $\beta = 0.35$, transformed from $[0, 1]$ to cover the design region for each factor is used. This is done in order to sample fitter strings than would have otherwise been found using the commonly used uniform distribution. The designs are then evaluated, ranked according to their fitness, and encoded as bit-strings. The first iteration produces the N fittest strings.

In the second and subsequent iterations, the N fittest strings from the earlier iteration are selected, N mutated copies of these are made, and M strings which result from their recombination are generated. These $2N + M$ strings are evaluated and ranked according to their fitness and the N fittest strings are kept. This type of selection leads to what is known as an elitist algorithm. It ensures that the fittest strings are preserved from one iteration to the next and removes the possibility that all strings found in iteration $i+1$ are poorer than the fittest string found in iteration i. Other methods of selection such as selection with probability proportional to fitness may result in the loss of the fittest strings as there is a positive probability that any one string could be lost.

2.3 Recombination

Recombination when applied to strings with binary coding is usually performed by single or multi-point crossover. Single point cross-over is used in this application because of its simplicity and ease of execution. This is done by sampling without replacement of a pair of strings with probability proportional to their fitness. A point is randomly chosen and each string is divided into two segments. The strings then swap their segments and a new pair of strings is created. In this way, strings with high fitness are paired with each other and exchange sub-strings. Those that inherit segments which result in high fitness (also called building blocks) are kept for the next iteration.

2.4 Mutation

Mutation relocates the candidate solutions to some other points in the search space. Although it is common to use mutation with low probability so as not to destroy highly fit strings and prolong the computation times, we always apply mutation with probability $p_m = 1$. The reason for mutating in this way is that copies of the strings are made prior to mutating them so that strings are not lost because of mutation. Also a ranking selection which results in the elitist algorithm is used. This algorithm implements mutation by switching one randomly selected bit per string. The inversion operator is a generalization of the mutation operator. Whereas the mutation operator switches one bit per string, the inversion operator flips a whole string segment. The start and end positions for the inversion are randomly decided. Inversion is used when there is no improvement in fitness in at least one iteration.

The GA search process is thus iterative: evaluation, selection and recombination using the basic operators: selection, cross-over and mutation, until some termination condition is met. The basic algorithm is given by the pseudo code below.

If $s(i)$ is the set of strings processed by the GA at iteration i and f is the objective function then,

```
$i = 0$; initialize $s(i)$;
 evaluate $f(i)$;
  do while (termination condition is not met);
   select $s(i+1)$ from $s(i)$;
```

```
        recombine $s(i+1)$;
        mutate $s(i+1)$;
        evaluate $s(i+1)$;
    $i = i + 1$;
    End;
```

3 Local search methods

Local search is a strategy of searching a neighborhood until a gradient is found, moving along the gradient, then updating the starting point and generating a new neighborhood. We will examine two local search methods. The first method is local improvement on the genetic algorithm using a modified version of the G-bit improvement, Goldberg [9]. The G-bit improvement is implemented in the following manner.

1. Select the fittest string which the genetic algorithm generates.
2. Sweep the string bit by bit, evaluating the fitness of every string that results from one-bit switches. If a bit change results in a violation of any of the constraints then discard the string.
3. When a string is found that has a better fitness than the first (starting) string then replace the starting string with the fitter string.
4. Repeat the process until no further improvement is made after sweeping through the fittest string.

An objective function is evaluated for every switch which makes the method somewhat slow. The method is therefore most useful when the genetic algorithm converges to a point on the search grid that is very close to the optimum and there is a steep gradient between the two points. This method is only used on the fittest string found after the termination condition has been met by the GA.

Because of the difficulty of computing the directional derivatives of poorly characterized functions, we use methods that do not require differentiability. Local search is traditionally done using greedy algorithms such as those of Lawler [13] and Syslo et al. [19]. We implement local search by a combination of Powell's method and Brent line optimization as given in Press et al. [16]. Powell's method is given below. Readers interested in the technical details are referred to *Numerical recipes in C* available on-line at `www.library.cornell.edu/nr`. The algorithm establishes the direction along which the optimization takes place and then the Brent line optimization is used iteratively. Because minimization and maximization are trivially related, we consider the optimization problem as the minimization of a function f without loss of generality.

The algorithm begins by initializing the direction set to the basis vectors of the n dimensional space i.e.

$\mathbf{u}_i = \mathbf{e}_i \; i = 1, \ldots, n$.

1. Save the starting position as $\mathbf{p}_0$.
2. For $i = 1, \ldots, n$, move $\mathbf{p}_{i-1}$ to a minimum of f along the direction $\boldsymbol{u}_i$ and call this point $\boldsymbol{p}_i$.
3. Set $\boldsymbol{u}_{n+1} \leftarrow \boldsymbol{p}_n - \boldsymbol{p}_0$.
4. Move $\boldsymbol{p}_n$ to a minimum along the direction $\boldsymbol{u}_{n+1}$ and call this point $\boldsymbol{p}_0$.
5. Set $\boldsymbol{u}_k \leftarrow \boldsymbol{u}_{n+1}$, $(1 \leq k \leq n)$ where k is the index where the objective function made its greatest decrease.

In addition to the design region itself which is a constrained space in $\mathbb{R}^n$, it is not unusual to encounter constraints in design problems. The main difficulty when using these methods in constrained spaces is that the direction set degenerates to vectors of null norm at the edges of the search space. Bracketing minima may be impossible because one of the points needed to bracket the minimum may not be within the limits of the constraints. To overcome these limitations we have modified the algorithm to re-initialize the direction set along the edges of the design region. When local search leads to a point that violates any constraint, a new search is initiated closer to the starting point.

4 Examples

4.1 Response surface design in two factors

Box and Draper [4] analytically determined D-optimum designs for a second order response surface model in two factors using 6 to 9 design points. Exact D-efficient designs for their model are found using the hybrid algorithm and the genetic component of the hybrid algorithm used alone for comparison as well as for validation and for testing the performance of the algorithms.

The second order response surface model in two factors is given by:

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{12} x_1 x_2 + \beta_{11} x_1^2 + \beta_{22} x_2^2 + \epsilon \,.$$

The design region is given as: $\chi = [-1, 1]^2$.

8 bits were used to encode each coordinate point and 6 strings were used to initialize the algorithm.

The hybrid and genetic algorithms were run $10,000$ times and the average efficiencies of the resulting designs computed. Details of the performance and the average D-efficiencies of the designs found using the algorithms are summarized in Table 1.

The hybrid algorithm required an initial population of only 6 strings and 12 iterations to calculate exact D-efficient designs for the response surface

		Analytical	*Hybrid Algorithm*		*Genetic Algorithm*	
N	i	$\|(\mathbf{X}^T\mathbf{X})^{-1}\|$	$\|(\mathbf{X}^T\mathbf{X})^{-1}\|$	*D-eff**	$\|(\mathbf{X}^T\mathbf{X})^{-1}\|$	*D-eff**
6	12	3.7350E-3	3.7698E-3	99.84	3.6233E-2	68.47

model with 6 to 9 points. This indicates that the local search component of the hybrid algorithm was used to a large extent to find the designs that minimize $|(\mathbf{X}^T\mathbf{X})^{-1}|$.

Exact D-efficient designs are rarely found using analytical function optimization as shown above. When the design region is poorly characterized and/or constrained, it is usual practice to generate efficient designs using computerized algorithms. The next two examples are mixture designs with both linear and non-linear as well as single and multi-component constraints imposed on their design regions.

4.2 Mixture experiment with quadratic constraints

This example is found in Atkinson & Donev [2, pp. 186–187]. Using a three component mixture experiment, models have been first fitted to two responses after which measurements are made on a third response, but only in the region where the other two responses have satisfactory values. The requirements that $\widehat{Y}_1 \geq c_1$ and $\widehat{Y}_2 \geq c_2$ for specified c_1 and c_2 lead to the following quadratic constraints:

$$-4.062x_1^2 + 2.962x_1 + x_2 \geq 0.6075$$

$$-1.174x_1^2 + 1.057x_1 + x_2 \geq 0.5019$$

The D-optimum continuous design for the second order canonical polynomial uses 6 support points with equal weight and is given in Atkinson & Donev [2]. We applied the hybrid and genetic algorithms to finding exact D-efficient designs for this problem using 12 design points and compared them to the designs found using 200 iterations of the MFA with a randomly generated set of 72 points that satisfy all the constraints. The candidate points were generated by one execution of the GA. The MFA used the value ϵ=1.0E-7 as the smallest value that is considered to be non-zero when the search no longer yields an improved design.

The hybrid and GA were initialized using 6 strings (designs) assembled from the same set of candidate points that were used by the MFA. Each coordinate point was encoded using 16 bits which gives a search grid step

Algorithm	i	$\lvert(\mathbf{X}^T\mathbf{X})^{-1}\rvert$	*D-eff**	*Time**(s)
Modified Fedorov	200	7.5698E5	100	0.5

Genetic Algorithm	200	1.6356E6	87.97	20.88

i=number of iterations *D-eff**=Average D-efficiency *Time**=Average time

Table 2: Results for the example in section 4.2.

of size $1/2^{16}$=1.52587E-5. This search grid is finer than that used for the previous example because the design region for this example is not as regular and symmetric. The termination condition was when 200 iterations had been completed regardless of when the last improvement was made. The genetic and hybrid algorithms were run $10,000$ times and the average efficiencies and times are shown in Table 2.

The results show that the combination of the GA and local search finds efficient designs in a relatively short time using few iterations as seen from the optimized objective function value. This, in the presence of non-linear constraints on the design region.

4.3 Resin vehicle characterization

Altekar and Scarlatti [1] designed an experiment to characterize gel vehicles for use in lithographic inks. A combination of a factorial and a mixture design was used to study the effects of varying the ratio of two resins and other formulation variables on the viscosity of the inks. Each formulation consisted of two resin solids, gelling agent, ink oil and alkyd varnish. The amount of alkyld varnish was fixed at 7% in each formulation and the ink oil was an inert variable used as a filler. The ratio of the two resins was varied as follows: Resin A/Resin B ratio 60/40, 50/50 and 40/60, and were coded as $[-1, 0, 1]$ for the low, mid and high levels respectively.

In order to test the hybrid and genetic algorithms, the same mixture proportions were used to find D-efficient designs. To make the problem more challenging, the ratio of the solids was allowed to vary continuously between 6/10 and 10/6. Table 3 shows the constraints on the design region for the mixture experiment.

Because the resin solids, gelling agent and ink oil had to add up to 93%, the amount of ink oil was automatically restricted to 37–47.67%. In addition to the constraint that all the mixture proportions sum to unity, the following multi-component constraints are also imposed:

$$\text{Resin solids: } 0.45 \leq x_1 + x_2 \leq 0.55.$$

$$\text{Ratio of solids: } \frac{6}{10} \leq \frac{x_1}{x_2} \leq \frac{10}{6}.$$

Component	*Minimum*	*Maximum*
x_1- Resin A	0.0000	0.5500
x_2- Resin B	> 0.0000	0.5500
x_3- Gelling agent	0.0033	0.0100
x_4- Ink oil	0.3700	0.4767
x_5- Alkyd varnish	0.0700	0.0700

Table 3: Restrictions on the design region.

Algorithm	i	$\lvert(\boldsymbol{X}^T\boldsymbol{X})^{-1}\rvert$	*D-eff**	*Time**(s)
Modified Fedorov	200	5.3805E26	79.02	1.32
Hybrid Algorithm	200	8.1824E25	100	31.84
Genetic Algorithm	200	1.0412E27	72.76	29.32

i=number of iterations *D-eff**=Average D-efficiency *Time**=Average time

Table 4: Results for the example in section 4.3.

Let the solids be given by $x_2^* = x_1 + x_2$. The following model was considered for the purposes of evaluating the algorithm:

$$y = \beta_1 x_1 + \beta_2 x_2^* + \beta_3 x_3 + \beta_4 x_4 + \beta_{23} x_2^* x_3 + \beta_{13} x_1 x_3 + \beta_{14} x_1 x_4 + \beta_{24} x_2^* x_4 + \epsilon\,.$$

A 24 point design was generated using the hybrid algorithm. For comparison purposes 200 iterations of the MFA with a candidate set of 144 points which satisfy all the constraints was used. The candidate set was again generated using the GA. The hybrid algorithm and the GA were later re-initialized using the same set of points assembled into 6 designs. Each coordinate point was coded using 16 bits and the termination condition was when 200 iterations had been completed. The GA and hybrid algorithm were run $10,000$ times. Details of the average efficiencies and times are shown in table 4.

Table 4 shows that the hybrid algorithm finds on average designs with higher relative efficiency than those found using the MFA for this problem. Whereas the MFA can only be as good as the quality of its candidate points, the hybrid algorithm generates new design points through local search, selection, and recombination. As a result, the hybrid algorithm arrives at efficient designs without the benefit of using a specific set of candidate points.

5 Conclusions

A hybrid algorithm used to find D-efficient designs for linear regression models is presented in this paper. The genetic component of the hybrid algorithm allows for a high mutation probability without necessarily prolonging the time to convergence. This is possible because mutated copies of the strings are re-injected into the population of strings during every iteration and only the fittest strings are selected for the succeeding iterations. This greatly increases the chances of escaping local optima when applied to poorly characterized functions with many local extrema. Genetic algorithms are very efficient and are designed to search large spaces. However, they require a large initial population of strings to work with and the resulting variation inevitably leads to long computing times if the search domain is to be thoroughly explored. Searching the neighborhood of each point and updating the population of strings at every iteration of the GA with fitter strings that result from local search leads to much faster convergence than using the GA alone. The hybrid algorithm presented here therefore uses a small population of strings to search for efficient designs. It also requires a relatively few number of iterations and as a consequence less computing time is required to find efficient designs. The computing times for the examples used in this paper are real times (not CPU times) when using a 2.0 GHz Pentium PC. It should be noted that although the hybrid algorithm provides designs that are as efficient as those obtained using the MFA, it usually is slower depending on the the number of the candidate points supplied to the MFA, but has a distinct advantage when the candidate set of points is not of high quality or even not available. This relieves the experimenter from having to start with some previous knowledge of the search domain.

The algorithm presented in this paper is coded in *Pascal* using *Borland Delphi version* 4 and is available as a *.exe* file upon contacting the authors. The application that runs the algorithm allows for customizing of all the GA and local search parameters and generates the design points, the design matrix, the information matrix and its eigenvalues, the variance function plots as well as the records and graphical history of the optimization process, among other things.

GEOMETRY OF LEARNING IN MULTILAYER PERCEPTRONS

Shun-ichi Amari, Hyeyoung Park and Tomoko Ozeki

Key words: Learning, information geometry, singular statistical model, neural networks.

COMPSTAT 2004 section: Neural networks and machine learning.

Abstract: Neural networks provide a good model of learning from statistical data. Multilayer perceptron is regarded as a statistical model in which a nonlinear input-output relation is realized. The set of multilayer perceptrons forms a statistical manifold in which learning and estimation takes place. This is a Riemannian manifold with Fisher information metric. However, such a hierarchical model includes algebraic singularities at which the Fisher information matrix degenerates. This causes various difficulties in learning and statistical estimation. The present paper elucidates the structure of singularities, and how they influence the behavior of learning. The paper describes a new learning algorithm, named the natural gradient method, to overcome such difficulties. Various statistical problems in singular models are discussed, and the models selection criteria (AIC and MDL) are studied in this framework.

1 Introduction

The multilayer perceptron is a simple feedforward model of neural networks, which transforms input signals to output signals nonlinearly. It is a universal approximator in the sense that any nonlinear transformation is approximated sufficiently well by an adequate perceptron, if the number of hidden units is large.

In order to realize a good approximator, examples of input-output pairs are used. On-line learning receives a series of training examples one by one, and modifies the parameters of a perceptron each time when one example is given. Usually old examples are then discarded. Batch learning keeps all the examples and modifies the parameters in a batch mode.

A multilayer perceptron is an old model of learning machines, and the error-correcting learning algorithm was established for simple perceptrons in the sixties. Amari proposed a gradient descent learning method for multilayer perceptrons [2], which was rediscovered later independently and became popular under the name of backpropagation [23].

We study the set of multilayer perceptrons of a fixed architecture, which include a number of modifiable parameters called connection weights and biases. The set forms a multi-dimensional manifold, where all these parameters play a role of admissible coordinate systems. Learning takes place in the manifold, drawing a trajectory.

It is important to study the geometrical structure of the manifold which we call a neuromanifold. We will show by statistical considerations that the neuromanifold is Riemannian whose metric is specified by the Fisher information matrix [3]. Moreover, it has a pair of affine connections [4], but we do not state them in the present paper. The neuromanifold has singularities where the Fisher information (or the Riemannian metric) degenerates [5]. This is an interesting statistical model, because the conventional Cramér-Rao paradigm excludes such a model, assuming the existence and non-degeneracy of the Fisher information matrix as regularity conditions.

It is known that the convergence speed of a multilayer perceptron is usually very slow. This is caused by the Riemannian character in particular by its degeneracy, because the conventional backprop learning method does not take the Riemannian nature into account. The state of a network is often attracted by singularities by the conventional algorithm and takes long time before getting rid of them. The natural gradient learning algorithm was proposed to overcome the flaw, which takes the Riemannian gradient instead of the conventional gradient [3]. We show in the present paper the reasons why it works so well. We also explain an adaptive method of implementing the natural gradient [8]. In the case of the squared error criterion under Gaussian noises, the natural gradient algorithm coincides with the adaptive version of the Gauss-Newton method, but they differ in more general models (see [17]).

We finally study the dynamics of learning and the nature of singularities and explain the reason why learning trajectories are attracted to and stay longer in a neighborhood of singularities. The statistical analysis of behaviors of estimators in a neighborhood of singularities is another important problem to be studied. We show the conventional criteria of model selection such as AIC and MDL fail in this case.

2 Neuromanifold of multilayer perceptrons

Let us consider a multilayer perceptron of h hidden units and one output unit, which receives n-dimensional input signals $\boldsymbol{x} = (x_1, \cdots, x_n)$. A hidden unit, say the i-th unit receives $\boldsymbol{x}$, and takes its weighted sum, resulting in the potential

$$u_i = \boldsymbol{w}_i \cdot \boldsymbol{x}. \tag{1}$$

Here $\boldsymbol{w}_i = (w_{i1}, \cdots, w_{in})$ is the weight vector of the i-th unit, and we neglect the bias term for the sake of simplifying the notation. The unit calculates the nonlinear transform of the potential, $\varphi(u)$, where the nonlinear function is

$$\varphi(u) = \tanh u. \tag{2}$$

The final units collects all the outputs of the hidden units, and its final output is their weighted sum, if no noise intervenes. We put

$$f(\boldsymbol{x}, \boldsymbol{\theta}) = \sum v_i \varphi\left(u_i\right) = \sum v_i \varphi\left(\boldsymbol{w}_i \cdot \boldsymbol{x}\right), \tag{3}$$

where we summarized all the modifiable parameters in a large vector $\boldsymbol{\theta} = (v_1, \cdots, v_m \,;\, \boldsymbol{w}_1, \cdots, \boldsymbol{w}_m)$. The final output of the perceptron is disturbed by noise, so that

$$y = f(\boldsymbol{x}, \boldsymbol{\theta}) + \varepsilon, \tag{4}$$

where we assume that ε is a Gaussian noise with mean 0 and variance 1. Therefore, its behavior is represented by the conditional probability of y given $\boldsymbol{x}$,

$$p\left(y|\boldsymbol{x}, \boldsymbol{\theta}\right) = c \exp\left\{-\frac{1}{2}\left(y - f(\boldsymbol{x}, \boldsymbol{\theta})\right)^2\right\} \tag{5}$$

or the joint probability distribution of $(\boldsymbol{x}, y)$,

$$p(y, \boldsymbol{x}; \boldsymbol{\theta}) = q(\boldsymbol{x}) p\left(y|\boldsymbol{x}, \boldsymbol{\theta}\right) \tag{6}$$

where $q(\boldsymbol{x})$ is the probability distribution of inputs $\boldsymbol{x}$. The set of all the perceptrons is a manifold called a neuromanifold M where $\boldsymbol{\theta}$ plays the role of the coordinate system. Each point of the neuromanifold corresponds to the probability distribution (5) or (6).

3 Fisher information matrix and the Riemannian metric

The Fisher information matrix G is given by

$$G(\boldsymbol{\theta}) = E\left[\nabla \log p(y, \boldsymbol{x}; \boldsymbol{\theta}) \nabla \log p(y, \boldsymbol{x}; \boldsymbol{\theta})^T\right] \tag{7}$$

which is further calculated as

$$G(\boldsymbol{\theta}) = E\left[\nabla f(\boldsymbol{x}, \boldsymbol{\theta}) \nabla f(\boldsymbol{x}, \boldsymbol{\theta})^T\right], \tag{8}$$

where E denotes expectation, $\nabla = (\partial/\partial\theta_i)$ is the gradient and T denotes transpose of a vector. Let us define the square of the distance between two nearby perceptrons whose parameters are $\boldsymbol{\theta}$ and $\boldsymbol{\theta}+d\boldsymbol{\theta}$. Information geometry gives the squared distance by the quadratic form

$$ds^2 = d\boldsymbol{\theta}^T G(\boldsymbol{\theta}) d\boldsymbol{\theta}. \tag{9}$$

This is the Riemannian metric, where the Fisher information metric is used as the Riemannian metric tensor [19]. This is the only invariant metric to be introduced in the manifold of probability distributions.

Given a (large) number N of independently generated input-output pairs $(\boldsymbol{x}_1, y_1), \cdots, (\boldsymbol{x}_N, y_N)$, the maximum likelihood estimator (or any other first order efficient estimator) satisfies the Cramér-Rao bound. Hence, the distance is large when two perceptrons are well separated in the sense that their estimation can be done precisely. However, different from the ordinary statistical model, the neuromanifold includes points at which the Fisher information degenerates and its inverse diverges. This is related to the unidentifiability of network parameters.

4 Identifiability of perceptrons and singularity

The behavior of a perceptron is invariant under the following two operations [10]:

1. Change of signs of v_i and $\boldsymbol{w}_i$ at the same time.

2. Permutation of the hidden units, which causes permutation of the weight vectors $\{\boldsymbol{w}_i\}$ and the output weight $\{v_i\}$ at the same time.

This causes the following unidentifiability:

1. When $v_i = 0$ or $\boldsymbol{w}_i = 0$, the behavior is the same whatever value $\boldsymbol{w}_i$ or v_i takes.

2. When $\boldsymbol{w}_i = \boldsymbol{w}_j$ (or $\boldsymbol{w}_i = -\boldsymbol{w}_j$), the behavior is the same when

$$v_i + v_j = v_i' + v_j' \qquad \left(v_i - v_j = v_i' - v_j'\right) \tag{10}$$

holds for two perceptrons $\{\boldsymbol{w}_i, v_i\}$ and $\{\boldsymbol{w}_i, v_i'\}$.

We call the set

$$C = \{\boldsymbol{\theta}|\ v_i \left|\boldsymbol{w}_i\right| = 0 \quad \text{or} \quad \boldsymbol{w}_i = \pm \boldsymbol{w}_j\} \tag{11}$$

the critical set on which unidentifiability takes place. The Fisher information degenerates on the critical set, because the unidentifiability implies that the estimation error does not converge to 0 even when N goes to infinity. Hence the statistical model is non-regular, and the Riemannian metric is singular. See also [7], [8], [9], [15]; [24], [27].

Let us introduce the equivalence relation $\approx$, by which two perceptrons with different parameters are equivalent when their input-output behaviors are the same. Then the set

$$\tilde{M} = M/\approx \tag{12}$$

includes algebraic singularities and dimensions are reduced on the critical set. The conventional theory of statistical estimation does not hold in a neighborhood of singularities.

5 Natural gradient learning algorithm

Let

$$D = \{(\boldsymbol{x}_1, y_1), (\boldsymbol{x}_2, y_2), \cdots, (\boldsymbol{x}_N, y_N)\} \tag{13}$$

be the set of input-output examples, which we call the training set. Here we assume that the examples are generated independently by using the true perceptron whose parameters are given by $\boldsymbol{\theta}_0$.

Given the training set, we want to obtain the estimated parameters $\hat{\boldsymbol{\theta}}$ which is closest to the true one. The performance of the estimator $\hat{\boldsymbol{\theta}}$ is measured by the generalization error, which is the expectation of the squared error for a new example $(\boldsymbol{x}, y)$,

$$L\left(\hat{\boldsymbol{\theta}}\right) = \frac{1}{2} E\left[\left\{y - f\left(\boldsymbol{x}, \hat{\boldsymbol{\theta}}\right)\right\}^2\right]. \tag{14}$$

The conventional on-line learning algorithm uses the gradient of the instantaneous error at time t,

$$\nabla e\left(\boldsymbol{x}_t, y_t, \hat{\boldsymbol{\theta}}_t\right) = \frac{1}{2}\nabla\left\{y_t - f\left(\boldsymbol{x}_t, \hat{\boldsymbol{\theta}}_t\right)\right\}^2 \tag{15}$$

to update the current parameters $\hat{\boldsymbol{\theta}}_t$ to the new one,

$$\hat{\boldsymbol{\theta}}_{t+1} = \hat{\boldsymbol{\theta}}_t - c\nabla e. \tag{16}$$

The gradient of a function is believed to be the steepest direction of change. This is true only when the coordinate system $\boldsymbol{\theta}$ is orthonormal in a Euclidean space. The steepest direction of e is given by

$$\tilde{\nabla} e = G^{-1}\nabla e \tag{17}$$

in a Riemannian space, where G^{-1} is the inverse of the Riemannian metric matrix.

Amari [3] proposed to use the Riemannian gradient for learning,

$$\hat{\boldsymbol{\theta}}_{t+1} = \hat{\boldsymbol{\theta}}_t - c\,G^{-1}\nabla e, \tag{18}$$

which is called the natural gradient method. The natural gradient method is proved to give an Fisher efficient estimator, even though examples are used only once when they are observed, and then discarded.

The performance of the natural gradient method is largely different from the conventional method, when the Riemannian structure is very different from the Euclidean one. It will be seen that this is indeed the case with multilayer perceptrons, because they include singularities where the Riemannian metric degenerates.

It is known that the learning trajectory is often trapped in the so called plateaus, at which the parameters change so slowly, and it takes long time to get rid of. The statistical physical approach made it clear that the parameters are once attracted to the critical set of the neuromanifold, so that the set becomes plateaus of learning [25], [21], [18]. Rattray, Saad and Amari [20] analyzed the dynamics of the natural gradient learning method, and showed that it has an idealistic characteristic for avoiding plateaus. See also [14].

6 Implementation of natural gradient—Adaptive natural gradient method

In order to implement the natural gradient method, one needs to use the inverse G^{-1} of the Fisher information matrix. However, it is in general difficult to calculate the Fisher information matrix, because it uses the expectation with respect to the unknown distribution $q(\boldsymbol{x})$ of inputs. Moreover, it is computationally heavy to invert the matrix G when the number of parameters is large.

Amari, Park and Fukumizu [8] proposed an adaptive method to obtain an estimate of the inverse of the Fisher matrix. It is an iterative method, and the estimate $\hat{G}^{-1}\left(\hat{\boldsymbol{\theta}}_t\right)$ is calculated by

$$\hat{G}^{-1}\left(\hat{\boldsymbol{\theta}}_t\right) = (1+c')\,\hat{G}^{-1}\left(\hat{\boldsymbol{\theta}}_{t-1}\right) - c'\tilde{\nabla} f_t \left(\tilde{\nabla} f_t\right)^T, \tag{19}$$

where $f_t = f(\boldsymbol{x}_t, \boldsymbol{\theta}_t)$ and c' is another learning constant which may depend on t. One should choose c and c' carefully. By using this estimate $\hat{G}^{-1}\left(\hat{\boldsymbol{\theta}}_t\right)$, we can obtain the update rule of the adaptive natural gradient method of the form,

$$\hat{\boldsymbol{\theta}}_{t+1} = \hat{\boldsymbol{\theta}}_t - c\,\hat{G}^{-1}\left(\hat{\boldsymbol{\theta}}_t\right)\nabla e, \tag{20}$$

Park, Amari and Fukumizu [17] generalized the idea to be applicable to more general cost functions.

7 Dynamics of learning in the neighborhood of the critical set

In order to see the dynamics of learning, let us consider the special case of perceptrons consisting of two hidden units. Let us consider the set $Q(\boldsymbol{w}, v)$

$$Q(\boldsymbol{w}, v) = \{\boldsymbol{w}_1 = \boldsymbol{w}_2 = \boldsymbol{w}, v_1 + v_2 = v\} \tag{21}$$

which is a part of the critical set. This corresponds to the set of all the perceptrons which have only one hidden unit, where the weight vector is $\boldsymbol{w}$ and the output weight is v. Let the true parameters be $\boldsymbol{\theta}_0 = \{\boldsymbol{w}_1, \boldsymbol{w}_2, v_1, v_2\}$, where $\boldsymbol{w}_1 \neq \boldsymbol{w}_2$ so that it needs two hidden units.

Let $\bar{\boldsymbol{\theta}} = (\bar{\boldsymbol{w}}, \bar{v})$ be the best perceptron with one hidden unit that approximates the input-output function $f(\boldsymbol{x}, \boldsymbol{\theta}_0)$ of the true perceptron. Then, all the perceptrons of two hidden units on the line:

$$\boldsymbol{w}_1 = \boldsymbol{w}_2 = \bar{\boldsymbol{w}}, \quad v_1 + v_2 = \bar{v} \tag{22}$$

corresponds to the best approximation by one hidden unit perceptron. Let us transform the two weights as

$$\boldsymbol{w} = \frac{1}{2}(\boldsymbol{w}_1 + \boldsymbol{w}_2), \quad \boldsymbol{u} = \frac{1}{2}(\boldsymbol{w}_1 - \boldsymbol{w}_2). \tag{23}$$

Then, the derivative of $L(\boldsymbol{\theta})$ along the line is 0, because all the perceptrons are equivalent along the line. The derivative in the direction of changing $\bar{\boldsymbol{w}}$

and $\bar{v}$ are zero, because they are the best approximator. The derivative in the direction of $\boldsymbol{u}$ is again 0, because the perceptrons having $\boldsymbol{u}$ is equivalent to that having $-\boldsymbol{u}$ that is derived by changing the two hidden units. Hence the line forms critical points of the cost function. This implies that it is very difficult to get rid of it once the parameters are attracted to $Q(\bar{\boldsymbol{w}}, \bar{v})$.

Fukumizu and Amari [12] calculated the Hessian of L. When it is positive definite, the line is really attracting. When it includes the negative eigenvalues, the state is escaping in these directions eventually. They showed that, in some cases, a part of the line is really attracting in some region, while it is really a saddle having directions of escape (although the derivative is 0). In such a case, the perceptron is once truly attracted to the line, and stays inside the line fluctuating around it because of random noise until it finds the place from which it can escape from the line. This is clearly a plateau.

This explains the plateau phenomenon. In order to show why the natural gradient works well, we need to evaluate the natural gradient in the neighborhood of the critical points. We can then prove that the natural gradient has a large magnitude in the neighborhood of the critical set, so that the plateau phenomena will disappear. Computer simulations confirm this observation.

8 Estimation and testing in the neighborhood of the critical set

The Fisher information matrix degenerates on the critical set. Therefore, the Cramér-Rao paradigm cannot be valid in the neighborhood of the critical set. Let us consider the statistical test

$$H_0 \; : \; \boldsymbol{\theta} = \boldsymbol{\theta}_0 \tag{24}$$

against

$$H_1 \; : \; \boldsymbol{\theta} \neq \boldsymbol{\theta}_0 \tag{25}$$

The likelihood ratio statistics is given by

$$\lambda = \frac{1}{2} \log \frac{\sum p\left(y_i, \boldsymbol{x}_i, \hat{\boldsymbol{\theta}}\right)}{\sum p\left(y_i, \boldsymbol{x}_i, \boldsymbol{\theta}_0\right)}, \tag{26}$$

where $\hat{\boldsymbol{\theta}}$ is the maximum likelihood estimator. When the true point $\boldsymbol{\theta}_0$ is a regular point, that is, it is not in the critical region, the mle (maximum likelihood estimator) is asymptotically subject to the Gaussian distribution with mean 0 and the variance-covariance matrix $G^{-1}(\boldsymbol{\theta}_0)/N$, where N is the number of observations. In such a case, the log likelihood-ratio statistics is expanded in the Taylor series, giving

$$\lambda = \left(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0\right)^T G^{-1}(\boldsymbol{\theta}_0) \left(\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0\right). \tag{27}$$

Hence this is due to the χ^2-distribution of the degrees of freedom equal to the number k of parameters. Its expectation is

$$E[\lambda] = \frac{k}{N}. \tag{28}$$

However, when the true distribution $\boldsymbol{\theta}_0$ lies on the critical set, the situation changes. The Fisher information matrix degenerates, and G^{-1} diverges, so that the expansion is no more valid. The expectation of the log likelihood estimator is asymptotically written as

$$E[\lambda] = \frac{c(N)}{N} k \tag{29}$$

where the term $c(N)$ takes various forms depending on the nature of singularities. Fukumizu [11] showed that

$$c(N) = \log N \tag{30}$$

in the case of multilayer perceptrons under a certain condition. In the case of the Gaussian mixture,

$$c(N) = \log \log N \tag{31}$$

holds [13], [16].

Since the parameters are not identifiable, we cannot estimate the parameters when the true one is on the critical set. However, we can estimate its equivalence class, and the consistency holds with the order of $\sqrt{N}$. When the true one is close to the singular point, the estimation of the parameters suffers from similar difficulty. For fixed N, the variance of the estimators diverges in inversely proportional to the square of the distance from the critical set. We need a new framework to analyze such singular cases.

9 Bayesian estimator

The Bayesian estimator is used in many cases where an adequate prior distribution is assumed for the purpose of penalizing complex models based on data. It is empirically known that the Bayesian posterior distribution or its maximizer behaves well in the case of large scale neural networks. In such a case, one uses a non-zero smooth prior on the neuromanifold.

However, a smooth prior is not regular in the equivalence class $\tilde{M}$ of the neuromanifold, because a point in the equivalence class includes infinitely many equivalent parameters when it is in the critical point. This implies that the Bayesian smooth prior is in favor of singular points (perceptrons with a smaller number of hidden units) with an infinitely large factor. Hence the Bayesian method works well in such a case to avoid overfitting. One may use a very large perceptrons with a smooth Bayesian prior, and an adequate smaller model is selected.

The Bayesian estimator of singular models was studied by Watanabe [28], [29] by using the method of algebraic geometry, in particular Hironaka's theory of resolution of singularity and Sato's formula in the theory of algebraic analysis.

10 Model selection

In order to obtain an adequate model, one should select a good class of models based on data, that is, one should determine the number of hidden units. This is the problem of model selection. AIC, BIC and MDL have been widely used as criteria of model selection.

AIC [1] is the criterion to minimize the generalization error. The model that minimizes

$$\mathrm{AIC} = \text{training error} + \frac{k}{N} \tag{32}$$

is selected by this criterion. This is derived from the asymptotic statistical analysis, where the mle estimator $\hat{\boldsymbol{\theta}}$ is subject to the Gaussian distribution asymptotically.

MDL [22] is the criterion to minimize the length of encoding the observed data by using a family of parametric models. It is given asymptotically by the minimizer of

$$\mathrm{MDL} = \text{training error} + \frac{\log N}{2N} k \tag{33}$$

The Bayesian criterion BIC [26] gives the same criterion as MDL.

However, in the case of multilayer perceptrons, the neuromanifold of perceptrons with a smaller number of hidden units are included in that with a larger number, but the former is the critical set of the larger neuromanifold. Therefore, the maximum likelihood estimator (or any other efficient estimators) is no more subject to the Gaussian distribution even asymptotically. Model selection is required when the estimator is close to the critical set, and hence the validity of AIC and MDL fails to hold. One should evaluate the log likelihood-ratio statistics more carefully in such a case [6].

There have been reported many computer simulations of applications of AIC and MDL. Sometimes AIC works better, while MDL does better in other cases. Such confusing reports seem to be given rise to by the difference of regular and singular models and also the different nature of singularities.

11 Conclusions

Multilayer perceptrons are popular nonlinear models for nonlinear regression analysis of observed data. A class of perceptrons is specified by the number of hidden units, and a smaller class is included in a larger class. A class of multilayer perceptrons forms a manifold named the neuromanifold, where modifiable parameters play the role of the coordinate system.

The neuromanifold is a Riemannian space, where the Fisher information matrix plays the role of the Riemannian metric. A remarkable point is that it is singular in the sense that the Riemannian metric degenerates on a subset of the manifold, in which the neuromanifold of a smaller hidden units are embedded.

We proposed the natural gradient learning method, which takes the Riemannian nature into account. It works well because it avoids the plateaus existing in to the critical set corresponding to the neuromanifold of a smaller number of hidden units.

Conventional statistical analysis assumes the existence and non-degeneracy of the Fisher information matrix. However in the case of multilayer perceptrons, as well as other similar hierarchical models, the singularity is unavoidable in its nature. The criteria of model selection such as AIC and MDL fail their validity under such circumstances.

The present paper reviews such aspects of learning in neural networks, which require a new statistical analysis of singular models. Geometry will be useful for this purpose.

VISUAL DATA MINING FOR QUANTIZED SPATIAL DATA

Amy Braverman and Brian Kahn

Key words: Massive data sets, cluster analysis, multivariate visualization.

COMPSTAT 2004 section: Applications.

Abstract: In previous papers we've shown how a well known data compression algorithm called Entropy-constrained Vector Quantization (ECVQ; [3]) can be modified to reduce the size and complexity of very large, satellite data sets. In this paper, we discuss how to visualize and understand the content of such reduced data sets. We developed a Java tool to facilitate this using simple multivariate visualization, and interactively performing further data reduction on user selected spatial subsets. This enables analysts to compare reduced representations of the data for different regions and varying spatial resolutions. The ultimate aim is to explain physically observed differences, trends, patterns and anomolies in the data.

1 Introduction

This work came about because of challenges posed by NASA's Earth Observing System (EOS). EOS is a long-term data collection program for studying climate change, its consequences for life on Earth, and effects of human activities on it. The centerpieces of EOS are three satellites, Terra, Aqua and Aura. Terra and Aqua are already in orbit, and Aura is due for launch in 2004. Each carries a suite of instruments that collect massive amounts of observational data; so massive that it is difficult to take full advantage of them. Different instruments have different sampling strategies, resolutions, file naming conventions, and collect data about different physical processes. The information is provided to users in files corresponding to individual spacecraft orbits or parts of orbits, each of which can be very large, and must be stitched together properly to provide a global or even a regional picture. To make these data more accessible, NASA produces global summary data sets called Level 3 data products.

Traditionally, Level 3 products are simple maps of mean quantities and standard deviations at coarse spatial resolution, by month. In [2], we proposed methods for constructing nonparametric, multivariate distribution estimates to replace traditional maps. For instance, the Multi-angle Imaging SpectroRadiometer (MISR) aboard Terra collects data about clouds. A key goal is to better understand the spatial distribution of clouds since they have great influence on Earth's energy budget. The information MISR collects includes three variables seen at high resolution: scene albedo, height, and cloud presence indicator. Albedo is a measure of scene reflectivity measured roughly on a scale of zero to one. Scene height is measured in meters above the Earth's surface ellipsoid. The cloud indicator is a binary variable taking value one if the scene is cloudy, and zero otherwise. To summarize this information traditional Level 3 products are created by partitioning one month's data into spatial subsets corresponding to one degree latitude–longitude grid cells. Six maps are then produced: mean and standard deviation of albedo, mean and standard deviation of height, and mean and standard deviation of cloud indicator.

The Level 3 product we proposed regards each triplet of albedo, height and cloud indicator as a three-element vector, and uses ECVQ to cluster data each grid cell. We report a set of cluster representatives, the number of original data points belonging to each cluster, and within–cluster mean squared error, also called distortion. We call this a summary, or a compressed or quantized version of the grid cell's data. Figure 1 illustrates. For one grid cell it shows a three dimensional scatterplot of the original data in light gray. Positions of cluster representatives are shown by the embedded balls, and ball shading shows cluster population according to the color bar on the right. Two key features of the summary are that i) cluster representatives be centroids of cluster members, and ii) data vectors must be assigned to clusters with the nearest (euclidian distance) representatives. This ensures that mean squared error between grid cell data points and their representatives are at least locally minimized, and that representatives and mean squared errors resulting from aggregation to coarser resolutions will be properly preserved. Details of the algorithm like the one used to produce these summaries can be found in [1].

Starting with a monthly summary of MISR cloud data at one degree resolution, our challenge is to discover and understand how relationships among grid cell distributions change spatially, and over different resolutions. In other words, instead of examining spatial patterns of average behavior and variability only, we want to examine spatial patterns of other distributional characteristics such as the number of modes, presence of outliers, and nonlinear regressions. This requires interactively comparing summaries of different grid cells, and of aggregated spatial areas. Thus, we want to quickly visualize summaries, and construct summaries of summaries in hierarchical fashion. The main subject of this paper is the Java tool L3View, written to facilitate this.

2 L3View

The basic data structure underlying L3View is a 180 × 360 array of objects called L3Cell's. An L3Cell contains a variable–length vector of Cluster objects, with the number of objects depending on grid cell data complexity. A Cluster records a three-dimensional cluster representative, a cluster count, and a within–cluster mean squared error. L3View presents a map of the world, and when the user clicks on it the with the mouse, L3View translates the mouse position into geographic coordinates. L3View opens a separate

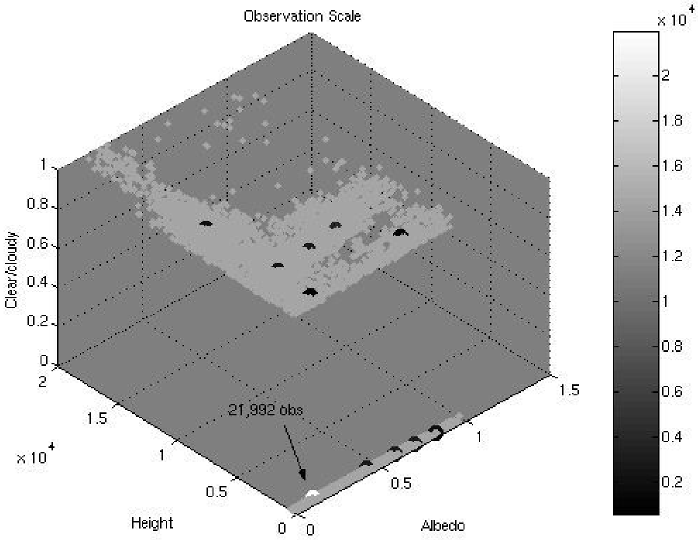

Figure 1: Three-dimensional scatterplot of MISR albedo, height and cloudiness data, in light gray, for a one degree grid cell in northern Oklahoma (southwest corner 38°N, 98°W) in March 2000. The embedded balls show the locations of cluster representatives. The ball colors show cluster populations using the gray-scale color bar on the right.

window, and displays a simple, multivariate visualization of the summary for the one degree grid cell at that location. Further, the user can select a subregion of the map with a rubberband box, and choose to summarize summaries of all grid cells within the box. This too is shown in a new window using the simple multivariate display.

2.1 Main map and control panel

The left panel of Figure 2 is a screenshot of the main L3View control panel. L3View uses Java Swing components to interact with users. The image displayed is constructed from information in the grid cells' clusters and combined with a GIF file containing continental outlines using Java image processing functions. L3View knows the position of the mouse in a graphic coordinate space native to the underlying Java object type, JPanel. L3View has methods to convert back and forth between this coordinate system, the 180×360 grid, and latitude and longitude. Latitude and longitude are displayed interactively as the mouse is moved, and the tool knows when the mouse is clicked, dragged, or leaves the map area. Clicking on a grid cell spawns a GraphView

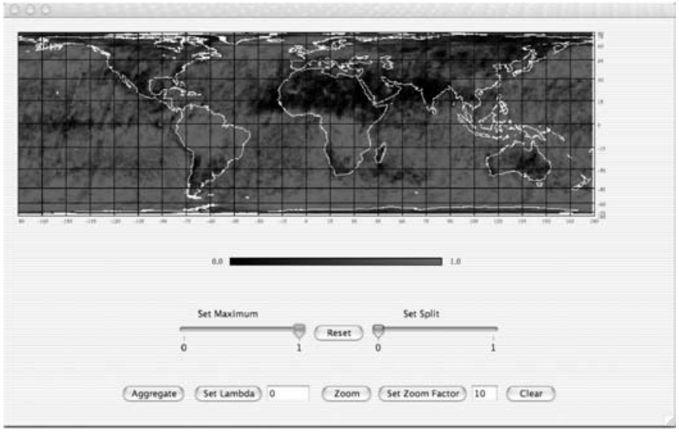

Figure 2: L3View main control panel showing MISR cloud fraction for March 2000.

window, which contains three graphics for visualizing the clusters representing that grid cell's data.

If the mouse is used to isolate a rectangular geographic region with a rubberband box, L3View calculates the corresponding geographic and index limits. These are subsequently used in two cases. First, if the Zoom button is pushed, a new window containing a magnified image of the isolated area is spawned. Second, if the Aggregate button is pushed, all clusters from all grid cells inside the box are summarized, and the result is displayed in a new GraphView window. The lambda text box accepts user specified values for a parameter of the summarization algorithm that specifies how much data reduction is applied. This is discussed in Section 3.

Finally, the Set Maximum and Set Split sliders are used to study spatial patterns in the cumulative distribution function of the display variable. Set Maximum truncates the upper end of the color scale so that all grid cells with display values at or above the maximum display white. Set split is similar: all values above the split value are displayed white, while all values below the split value display in black.

2.2 The GraphView window

The GraphView window is a simple, three panel multivariate visualization of a set of clusters. A typical GraphView window is shown in Figure 3. It includes two bar plots and a parallel coordinate plot. The bar plots are two instances of the same class, instantiated to display cluster counts and mean squared errors (distortions). Each has one bar per cluster, and bars are sorted in order of increasing cluster count. Actual values of counts and distortions

	Albedo	Height	Cloud Frac
max	0.841	10054.509	1.0
mean/sd	0.392/0.298	2582.843/3243.668	0.654/0.476
min	0.126	328.691	0.0

Figure 3: A GraphView window showing the summary of MISR albedo, height and cloud indicator for the grid cell with southwest corner 36°N, 98°W over northern Oklahoma. A zoom-in view of the parallel coordinate plot legend is shown in superimposed box.

relative to the norms of corresponding cluster representatives, are shown at the bars' left edges. Though not apparent in these black and white figures, bars are colored using a scheme that transitions smoothly from blue to red with increasing count.

The parallel coordinate plot occupies the right side of the window. Each line plot shows the representative values of albedo, scene height, and cloudiness for a single cluster on scales normalized using the global means and standard deviations. These are shown at the bottom of the parallel coordinate plot area. Lines are color coded to match bars in the other two panels so users can see which representatives belong to which clusters. In addition, clicking on any bar or any line highlights the bars and line in all plot corresponding to that cluster.

GraphView windows are spawned to visualize a set of clusters, either for a single grid cell or when a set of grid cells are to be summarized collectively. In the latter case, one could simply display the entire collection of clusters, but that would become more unwieldy for large areas as more clusters are included. Complexity of the parallel coordinate plots could grow to the point where it is impossible to resolve individual lines. Therefore, distributions represented by cluster sets must be summarized before they are displayed. The next section describes the theoretical rationale for this.

3 Hierarchical aggregation and quantization

Braverman [2] described how entropy–constrained vector quantization (ECVQ; [3]) is modified to function as a data reduction tool for large, spatial data sets. The basic idea is to partition these data into one degree spatial subsets, and use ECVQ to cluster the subsets in a coordinated way. ECVQ is a randomized, iterative algorithm similar to K-means, except it minimizes the expected value of the penalized loss function,

$$L_\lambda(\boldsymbol{X}, \alpha(\boldsymbol{X})) = \|\boldsymbol{X} - q(\boldsymbol{X})\|^2 + \lambda \left[-\log \frac{N_{\alpha(\boldsymbol{X})}}{N} \right]. \tag{1}$$

$\boldsymbol{X}$ represents a randomly drawn observation from the empirical distribution of the grid cell's data. $\alpha(\boldsymbol{X})$ is an integer that specifies the id number of the cluster to which $\boldsymbol{X}$ is assigned, and $q(\boldsymbol{X})$ is the corresponding cluster centroid. N is the total number of data points in the grid cell, $N_{\alpha(\boldsymbol{X})}$ is the number of data points assigned to the same cluster as $\boldsymbol{X}$, and the logarithm is base two. λ is a fixed parameter that specifies how important the second term on the right in Equation (1) is. For K-means, one must specify K, the number of clusters a priori. For ECVQ, one must specify K, the maximum allowable number of clusters, and λ. The algorithm then determines the number of clusters and the assignment of data points to them. We added a final step in which each data point is subsequently reassigned to the cluster with the nearest euclidian distance representative, and the representatives updated again. This ensures cluster representatives are centroids of cluster members, and mean squared errors between data points and their representatives are minimized. In [1] we introduced a further modification of ECVQ in which $\boldsymbol{X}$ is a random variable having the distribution of $q(\boldsymbol{X})$ rather than the original empirical distribution of the data. In other words, we allow realizations to have unequal mass. That is precisely the situation in which we find ourselves when summarizing sets of clusters formed by combining multiple grid cells.

Consider Figure 4. It shows a schematic representation of a one degree spatial grid. Each grid cell contains a summary instantiated as an L3Cell object. Figure 4 also shows a two degree grid cell superimposed, and suppose we want to summarize the four, one degree L3Cell's inside. Let $\boldsymbol{X}_{1uv}$ be a random variable having the distribution of the summary for the one degree grid cell with southwest corner at row u and column v. Suppose this grid cell is the lower-left most grid cell in the light box in Figure 4, and denote the other three grid cells' random variables by $\boldsymbol{X}_{1(u+1)v}$, $\boldsymbol{X}_{1u(v+1)}$, and $\boldsymbol{X}_{1(u+1)(v+1)}$. At coarser, two degree resolution the light box is represented by $\boldsymbol{X}_{2uv}$,

$$\boldsymbol{X}_{2uv} = \sum_{i=0}^{1} \sum_{j=0}^{1} \boldsymbol{X}_{1(u+i)(v+j)} 1[V = v_{(u+i)(v+j)}],$$

with

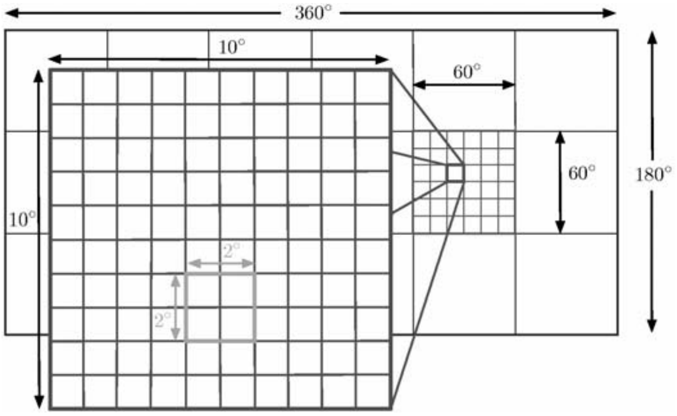

Figure 4: Schematic representation of a gridded map. The large rectangle represents a 180×360 array shown broken into 3×6 = 18, 60×60 arrays. Each of these is further subdivided into a 6 × 6 array. Each cell in the 6 × 6 array is a 10 × 10 arrangement of one degree grid cells. The lighter box illustrates how four one degree grid cells can make up a grid cell at coarser, two degree resolution.

$$P\left(V = v_{(u+i)(v+j)}\right) = \frac{N_{(u+i)(v+j)}}{\sum_{i=0}^{1}\sum_{j=0}^{1} N_{(u+i)(v+j)}},$$

and N_{ij} is the total number of data points represented by the summary of the corresponding grid cell. In other words, $\boldsymbol{X}_{2uv}$ is a mixture of $\boldsymbol{X}_{1uv}$, $\boldsymbol{X}_{1(u+1)v}$, $\boldsymbol{X}_{1u(v+1)}$, and $\boldsymbol{X}_{1(u+1)(v+1)}$ with weights equal to the proportions of the total count represented by $\boldsymbol{X}_{2uv}$ contributed by each one degree cell. The idea is illustrated on the left side of Figure 5, which shows the mixture distribution positioned directly above the four component distributions. Any nesting of fine-scale grid cells in a coarser grid can be represented in a similar way, and ensures mass, expectation, and mean squared error are all properly preserved between resolutions.

If data reduction were not a concern, we could proceed directly to visualizing mixture distributions like the middle layer in Figure 5. However, the greater the number of grid cells being aggregated, the greater the number of support points in the mixture, and the number of corresponding clusters. So, we compress the mixture distribution using a mass-weighted version of ECVQ described in [1], but implemented here in Java with the user specifying λ directly via the "Set Lambda" button and text box in the main control panel. K, the maximum number of clusters is nominally set to 10, and the default value of λ is zero, thus essentially implementing the K-means. If λ is changed to a positive value, the algorithm becomes ECVQ.

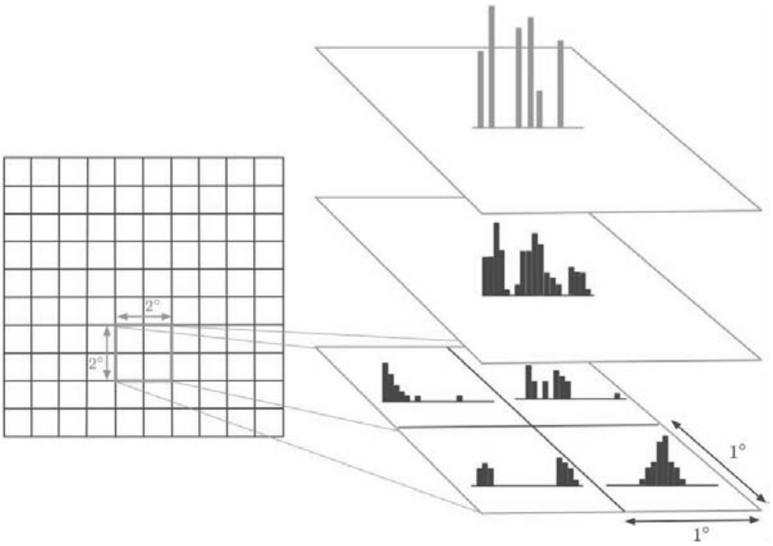

Figure 5: A hierarchy of distributions within a two degree spatial region. The bottom square on the right corresponds to the 2° × 2° area, and shows conceptual representations of cluster sets for constituent one degree grid cells as histograms. The middle layer on the right depicts the mixture distribution formed by the union of the cluster sets from the one degree cells. The top layer is the reduced distribution after summarization.

By first considering aggregated distributions for large areas, and then systematically summarizing subregions, we can begin to understand how the prevalence of various types of phenomena change spatially. The next section demonstrates how this can be done.

4 Visual data mining

As an example of how a scientist might use L3View for data exploration, we focus on an area in central Africa shown in Figure 6. The rectangular region extends from latitude 1°S to latitude 9°N, and from longitude 11°E to 31°E. The background L3View image shows cloud fraction. There is a clear difference between the northern and southern parts of this region, approximately demarcated by the horizontal dashed line in embedded, zoomed-in view. The southern area is very cloudy, and the northern area contains grid cells varying cloudiness. This is consistent with the climatological location of a persistent band of clouds called the Inter-Tropical Convergence Zone (ITCZ). The lower panel of Figure 6 shows the GraphView window of the summary of the entire 10 × 20 degree region.

	Albedo	Height	Cloud Frac
max	0.883	13912.022	1.0
mean/sd	0.392/0.256	2582.843/3243.868	0.654/0.476
min	0.1	614.597	0.0

Figure 6: Screenshots from L3View visualization of central Africa. Top: Main L3View map with embedded zoom of central Africa. Bottom: GraphView window for the entire, aggregated central area. All the parallel coordinate plots are annotated to show the cluster id numbers corresponding to the individual line plots.

The region contains 200 grid cells, with a total of 2,099 clusters. These represent 6,205,769 original MISR albedo–height–cloud indicator vectors. We begin by aggregating the whole region using the default value of $\lambda = 0$ and the number of clusters, K, set to 15. The resulting GraphView summary is shown in the lower panel of Figure 6. The figure is small making the graph labels difficult to see, but we can see from the bar chart of cluster counts that one cluster dominates in size. Using L3View interactively, we find that this is cluster 9, and it contains about 30 percent of the distribution's mass. Cluster 9 corresponds to one of two clear clusters, 6 being the other. Cluster 6 accounts for another eight percent of the distribution's mass. 9 and 6 have representatives with low albedo, low height, and are clear cloud indicators.

This is a dark, vegetated region of jungle. Areas to its north show significant numbers of low altitude, bright, clear scenes. This is the Sahara desert.

The remaining clusters have cloudy representatives, and form three subgroups. Clusters 8 and 4 constitute a subgroup with low albedo and below average height. Clusters 1, 2, and 7 form a second subgroup. Their heights are nearly one standard deviation above the mean, but their albedos range from nearly one standard deviation below to one standard deviation above average. The final subgroup is characterized by very large heights, two standard deviations above the mean at least. They too show a range of albedos similar to that of the second subgroup. These high clouds are likely the tops of thunderstorms prevalent in central Africa at this time of year, and the surrounding cloud formations. The first two subgroups are more mysterious. Clusters 1, 2, and 7 could be low and mid-level cumulus and stratus clouds. 8 and 4 are possibly dust, clear land surface misclassified as cloud, or simply dark, low clouds, as implied by the classification.

Noting the relatively sharp difference in cloud fractions between the northern and southern areas, we separately summarize them are shown in Figure 7. Signatures of southern region representatives look much like signatures for the region as a whole. The north's representatives also look roughly like those of the whole region except clusters similar to 0 and 4 are missing. The absence of clusters similar to cluster 0 in the lower panel is encouraging, since this cluster represents deep convective clouds. Corroborating sources indicate these are in fact absent in this region at this time.

These distributional differences are summarized in Table 1. Not surprisingly the joint distribution shows that the south is cloudier than the north. The fact that the south is dominated by low clouds while the north is dominated by mid-level clouds is less obvious but clear from the conditional distribution.

	Joint			Conditional	
Type	*North*	*South*	*Total*	*North*	*South*
Clear	0.330	0.064	0.394		
Low cloud	0.060	0.171	0.231	0.273	0.442
Mid-level cloud	0.094	0.114	0.207	0.426	0.295
High cloud	0.066	0.101	0.168	0.301	0.263
Total cloudy	0.220	0.386	0.606	1.000	1.000
Total	0.550	0.450	1.000		

Table 1: Joint and conditional distributions of cloud type/clear and location. Columns 2, 3, and 4 show the full, joint distribution. Columns 5 and 6 show the conditional distribution of cloud type given cloudy scene, and location.

The presence of low, dark clouds in both the north and the south at this time of year is something of a surprise. To see if these clouds can be

attributed to specific areas, we subdivided the north and south regions into east and west. We found no distributional differences related to east-west division for either the north or south. We then investigated areas along the prominent clear/cloudy boundary in Figure 6, and contrasted them to areas away from the boundary. We did this separately for east and west, but none of these visualizations revealed definitive distributional differences. We are therefore reasonably confident that Table 1 tells a complete story.

5 Discussion

The example of the previous section is a small scale, simple example of one way we think L3View may be useful for exploring spatial summaries of satellite data. Guided by the background map in the main L3View window, we focused on an area of interest, and hierarchically examined the data distribution summaries. We discovered that, in addition to the cloud fraction differences apparent from the background image, there is also a difference in the types of cloud present in the northern and southern parts of the region. We will have to perform many more exercises like this one to gain confidence that summarized data have enough detail to be scientifically useful, and to gain experience interpreting physically what we see in L3View.

Two main computational issues are brought to light in this exercise. First, L3View's implementation of ECVQ/K-means is not fast enough to summarize large geographic regions in reasonable time. One would ideally like to summarize whole hemispheres in the same sort of hierarchical exploration performed here. Second, we have not yet made use of the tool's ability to summarize the same data for different values of λ's. We would like to look at data at different quantization resolutions as well as different spatial ones. We believe there is important information in how distributions collapse as greater data reduction is imposed. To achieve greater interactivity both these issues must be addressed. We look forward to working on these and other improvements to L3View as it matures. We also eagerly anticipate working with our geoscience colleagues to better understand the connection between global physical processes and their expression through rich, Earth Observing System data sets.

GRAPHS FOR REPRESENTING STATISTICS INDEXED BY NUCLEOTIDE OR AMINO ACID SEQUENCES

Daniel B. Carr and Myong-Hee Sung

Key words: Letter sequences, graphics, layouts.

COMPSTAT 2004 section: Graphics.

Abstract: This paper develops coordinates and layouts for graphs that represent statistics indexed by repetitive letter sequences. The need for such graphics arises in a variety of applications. The examples in this paper concern sequences of nucleotides, such as AGTGGC, and sequences of amino acids.

1 Introduction

In contrast to maps that represent statistics indexed by geospatial coordinates, the development of graphics methodology for statistics indexed by repetitive letter sequences has been modest. One interesting exception is the sequence logo display [13] that can show a sequence of categorical frequencies. Statistical graphics methods for categorical data [7], [8] are relevant for relatively simple multivariate combinations but so far have seen little use in nucleotide and amino acid indexing examples.

Journal articles typically show short tables with one column giving the sequence of letters and one more column providing statistics. The rows are often sorted by one of the statistical columns. Both the one-dimensional linear ordering and the restriction to a modest number of rows reduce the opportunity to see patterns that may lead to new understanding. One-dimensional linear orderings produced by clustering, the first principal component, minimal spanning tree traversal, space filling curves or other methods do not exploit the human ability to see multivariate patterns based on 2-D and 3-D connectedness and proximity. Connectedness and proximity are among the most powerful of human perceptual grouping principles [18]. Thus this paper seeks to develop 2-D and 3-D coordinates for representing letter-indexed statistics.

The graphical design objectives include providing an overview along with interactive focusing and re-expression methods. For long sequences, combinatorics grow exponentially with sequence length and quickly lead to an overwhelming number of statistics. Overviews require substantial statistical summarization. The modest research here concerns developing representations for short sequences.

One approach not investigated here is the use of pixel oriented visualization [9]. It is possible to encode univariate statistics on all nucleotide sequences of length ten ($4^{10} = 1024 \times 1024$) in a pixel plot on a 1280×1024 monitor. Large high resolution prints will handle somewhat longer length sequences. Interactive pan and zoom methods can support layouts for longer sequences but showing all the values at once is problematic. The color of individual pixels is hard to identify with increased monitor resolution. The use of multiple monitors cannot keep up with the exponentially growing combinations.

Layout details are an issue. A convenient layout for a pixel plot may use lexicographic order for the first half (last half) of the sequence along the x-axis (y-axis). A following sectional on fractal coordinates provide another approach to layouts. In both cases indexing regularity help to keep the analyst oriented with interpreting the plots. However, indexing that is convenient for human memory may be poor at bringing out meaningful patterns. Maps often work well for showing geospatially-indexed statistics because geospatial attributes often have locally similar values. This applies to covariates as well as to the primary variables of interests. Proximity that reflects scientific relationships can be crucial to seeing meaningful patterns.

The layouts in this paper have limitations because they are primarily based on indexing regularity. However, the layouts provide some opportunities to rearrange letter order or axis placement either for perceptual simplification (such as reducing line crossings) or for incorporating physical/chemical properties (such as hydrophobicity) of the sequence constituents. Interestingly these two objectives can lead to the same display. Axes ordering problems are in general NP complete [1]. While many people prefer 2-D layouts, 3-D layouts not only allow better preservation of interpoint distances of higher dimensional points, they also provide more opportunities arranging axes. Thus the layout options are not as restrictive as might be assumed at first glance.

This paper develops three approaches to constructing coordinates while mentioning some alternatives along the way. Three different data sets motivate the development of the coordinates. Section 2 describes self-similar coordinates at different scales. Section 3 concerns self-similar coordinates at the same scale with focus on 3-D extension of parallel coordinates. The application shows cell statistics from a 4-D table. Section 4 illustrates the use of simple additive vector coordinates for showing all quadruples of amino acids (ignoring order). This approach can be useful despite some substantial overplotting problems. The section also hints at other 2-D layouts that avoid overplotting. Comments appear along the way about software and interactive tools used for rendering.

2 Self-similar coordinates, dimensionality, and fractals

The regularity of self-similar coordinates speeds learning and helps analysts devote short-term memory to other issues. A natural approach to developing multivariate coordinates encodes letters as integers and then uses Cartesian coordinate product sets with a coordinate for each position in the sequence. With A=1, C=2, G=3, and T=4 the sequence ATCG is located at (1, 4, 2, 3). The similar treatment of each position in the sequence and the same ordering of nucleotides for each axis motivates the description as a self-similar coordinate system. With coordinates in hand, multivariate glyphs can encode multivariate statistics associated with the sequence. The most immediate problem with this approach is that straightforward graphical representation of points is only available through three dimensions.

2.1 Rendering approaches and difficulties

There are many approaches to rendering multivariate data with more than three coordinates. As further mentioned in Section 4, nested coordinate plots provide one approach. Another approach encodes some coordinates as glyph features. For example with four coordinates the ray angle of a stereo-ray glyph can encode the value for the fourth coordinate [3]. Ray length and color can encode more coordinates. Good perceptual accuracy of extraction for the angle encoding and modest use of "ink" make glyph a good choice for revealing hyperplanes in 4-D data and other tasks. However in the current context all 3-D coordinate glyphs lose self similarity when rendering more than three coordinates.

Before developing 3-D coordinates to represent sequences longer than three, brief comments about limits and merits of 3-D graphics are appropriate. Many people prefer 2-D graphics to 3-D graphics. Common arguments for 2-D rendering are that people only see surfaces, occlusion is a problem in 3-D and that motion and/or binocular parallax depth cues are impossible or inconvenient to convey on a printed page. The position here is that many humans are endowed with the cognitive ability to see 3-D images based on motion and binocular parallax. They should be allowed to utilize this capability whenever it helps in dealing with difficult scientific challenges. Three dimensions provide a richer environment for conveying relationships and produce less distortion than 2D and 1D plots when scaling multivariate data into lower dimensions.

2.2 Weighted vector addition and fractals

Vector addition provides an enticing starting point for developing 3-D coordinates. For nucleotides, associate each letter with a vector from the origin to the vertices of a tetrahedron. Let A=(1,1,1), C=(1,-1,-1), G=(-1,1,-1), and T=(-1,-1,1). Then using of vector addition for each letter in a sequence produces a 3-D coordinate for representing the sequence. However, vector addition is commutative so all permutations of the same set of letters yield the same point. When the goal is to represent all hexamers (six letter sequences) the result should be $4^6 = 4096$ distinct plotting points but rather 84 points corresponding with the multinomial terms in multinomial $(\mathrm{A} + \mathrm{C} + \mathrm{G} + \mathrm{T})^6$.

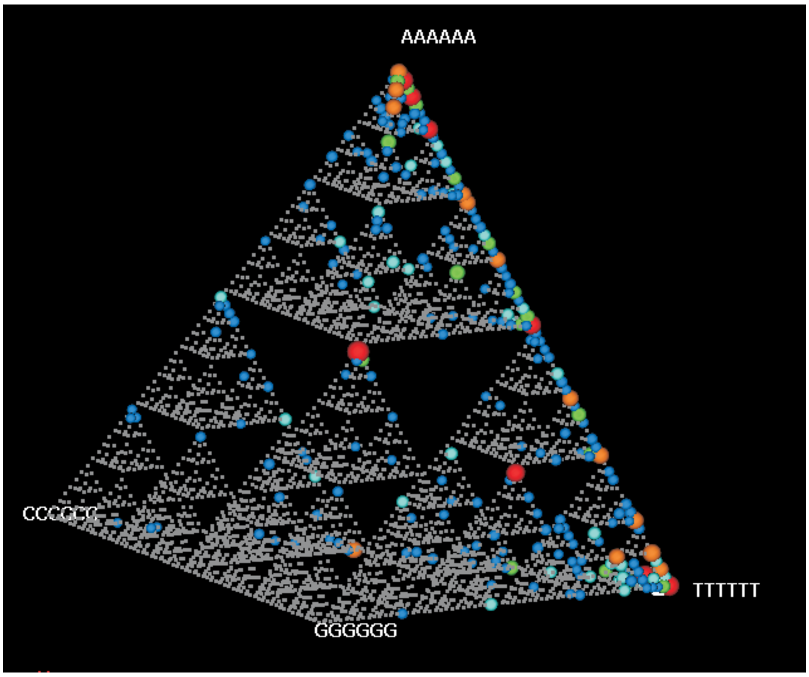

Figure 1: Fractal coordinates for nucleotide sequences. Sphere size (and color) show counts. Small rectangles show the plotting locations of low count spheres.

Weighted vector addition provides an approach that can produce unique points for plotting. Consider power of two weights $2^{(6-i)}/63$ where i is the position along the sequence and the weights sum to 1. The sequence ACGTTC then maps into the point (.555, .270, .206).

Rendering and rotating reveals the coordinates creating a Sierpinski Gasket similar to one shown in Mandelbrot [11]. The self-similarity provides means of decoding the indexing of a point based on its location. A point in the large tetrahedron toward the C attractor has C as the first letter. If a point within this C tetrahedron is as close as possible to the T attractor, then all the remaining letters are T. A tetrahedron zooming widget can reveal the sequence of conditioning letters. Similarly, zooming can be controlled by entering the first letters of the sequence.

A delight occurs when rotating the gasket. In some orthographic projections the appearance is a square lattice. Construction using a pair of coordinates indicated earlier makes this clear. However, this is not intuitive from looking at the gasket in other views. The 2-D layout is also self-similar and extends immediately to the 10-mer by 10-mer pixel display mentioned earlier.

The motivation for Figure 1 was an early effort to find transcription regulation docking sites for the Stanford yeast genes [5]. The study clustered genes based on their expression levels. This produced groups of seemingly co-regulated genes. For the genes in a group, the 300 (nucleotide)-letter regions upstream of the protein-coding regions of the genes were scanned with a sliding window of length six. This produced the basic statistics on the occurrence frequencies of the different hexamers encountered. The sphere glyphs in the plot encode counts using size and color. A glance reveals that most of the higher count hexamers appear along the AAAAAA to TTTTTT edge. Relatively little was known about transcription regulation when the Stanford yeast data was first made available and the statistics for Figure 1 was produced. Today many transcription regulation sites of various lengths have been identified and the regions as far as 800 nucleotides upstream are relevant for some genes. The plots could be improved by obtaining better data and by highlighting the hexamers known to be associated with transcription regulation.

Different kinds of software can produce figures similar to Figure 1. With a little work most standard statistical software can produce projected static views. Software that provides rotation, filtering and brushing, such as Xgobi and CrystalVision, provide better visualization environments. Efforts to produce multilayer 3-D visualization methodology similar to GIS software led to the development of software called GLISTEN (geometric letter-indexed statistical table encoding). GLISTEN supports point and path layers that are used in the graphs below.

Efforts to extend the fractal layout to amino acids were not very successful. One generalization used the 20 face centers of the icosahedron as attractors and adapted the weights so the clouds of points associated with each of the 20 attractors would be separated. Only three letter sequences were shown to restrict the view to $20^3 = 8000$ points. The high density of points for the smallest scale icosahedra and the occlusion, partly due to more points, made this layout less desirable.

2.3 Connecting coordinates for longer sequences

Paths that connect points can represent longer letter sequences. For example, a path through three points in Figure 1 can represent nucleotide sequences 18 letters long. The use of paths is advantageous since occlusion problems do not grow too quickly. Experimenting with translucent triangles and tetrahedra for showing triples and quadruples were not successful due to inability to see through much more than two layers.

Paths can encode statistics using path thickness and color. The path direction also needs to be encoded unless the sequence is explicit or intended to be reversible. There are limitations to this approach. If the data contains a large number of sequences, overplotting precludes providing an overview. Filtering widgets can then help to cope with very large databases. A second

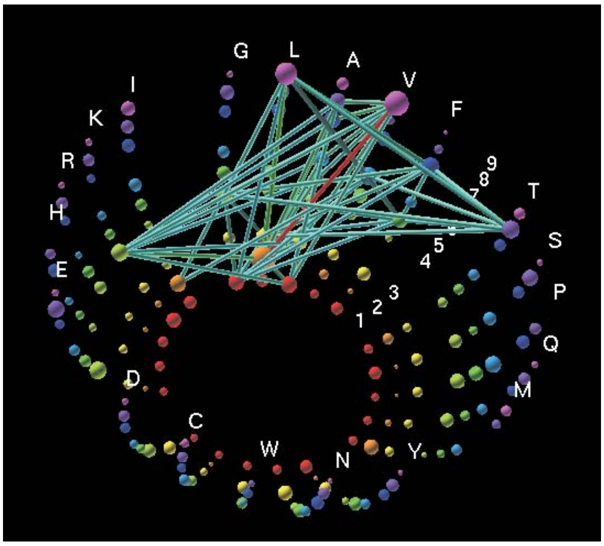

Figure 2: Capless hemisphere coordinates. Sphere size shows counts from 1-D table. Path thickness, color, and filtering enable focus on high counts from 2-D tables.

limitation is that a single coordinate system with each point representing a sequence of p letters does not accommodate sequence lengths that are not a multiple of p. A third issue that especially applies to fractal coordinates is that the apparent distance between paths is heavily influenced by the subset of coordinates receiving heavy weight. Fourth, there can be ambiguity when multiple paths go through the same point. Still, such displays can often turn up meaningful patterns that are otherwise missed.

3 Parallel coordinates escape the plane

Parallel coordinates (PC) plots also provide self-similar representations. Analysts are increasingly using these plots to show multivariate data and to provide interactive input in a multivariate context. A limitation of parallel coordinates is the lack of a natural way to connect non-adjacent axes. Figure 2 shows a capless hemisphere coordinate system that partially addresses the problem. The coordinate system encodes the 20 natural amino acids as longitude and nine positions along a sequence as latitude. The gap create perceptual groups that facilitate focusing on subsets. The path connecting L2 and L9 and the path between L2 and its neighbor L3 do not overlap due to the hemisphere curvature. The 3-D setting with curvature means the axes are not longer parallel, but there is a simple mapping to parallel coordinates.

The data motivating Figure 2 comes from a database of peptides [2], or in this case amino acid sequences of length 9 known to bind to important immune molecules called HLA. This binding reaction is crucial in initiating the recognition by the human body of peptides from 'foreign' sources such as viruses or cancer. When a T-cell finds the peptide-HLA combination on the target cell surface, it activates coordinated processes for the purpose of clearing the infected cells. The immune system is an incredibly complex 'search-and-destroy' system. Autoimmune diseases are examples of false positives, where the immunity is mistakenly directed toward normal tissue. An example of an immune system false negative is the inability to detect and clear certain infections. Bioinformatic prediction of peptides from pathogenic proteomes such as HIV has emerged as a valuable tool in vaccine development and cancer immunotherapy [16].

The data used in the example concerns peptides binding to the HLA A-2 molecule (a specific form among many different genetic versions of this HLA). Most of the binding peptides listed were 9-mers. Typical statistics would be just the counts of amino acid for each of the nine positions. Such can be represented by sequence logo displays or as sequence of bar charts. The sphere size and color (when not shown in gray level) in Figure 2 convey this information just as effectively. The paths in Figure 2 encode counts from the nine choose two (36) two-way (20×20) tables. A filtering widget removed all but the highest count cells. The counts are encoded by the line color (when not shown in gray level) based on a color ramp. The layout also requires some sorting considerations. Putting the hydrophobic amino acids adjacent to each other reduces line crossing.

Since paths can have more than one line segment, the capless hemisphere coordinate framework can also represent statistics from higher dimensional tables. The three-segment paths in Figure 3 show high count (frequency) cells from the nine choose four (126) four-way ($20 \times 20 \times 20 \times 20$) tables (see also [10]). The lowest count path shown goes through L2, A7, A8, and V9 as might be expected from the 1-D margin counts. There are large counts for L2 and V9. The rest of the high frequency paths shown go through G4. This is not apparent from the 1-D margins counts.

4 Additive vector coordinates and overplotting

When the ordering of letters in a sequence is not important, the additive vector coordinate approach mentioned in Section 2 is more appropriate. A 3-D tessellation application provides such data [15], [17]. The data arise from tessellating the space of proteins based on the location of their backbone Carbon alpha atoms. The Delauney tessellation yields tetrahedra indexed by the associated amino acid residues at the vertices. The ordering of the amino acids for a tetrahedron is not considered important. There are $(20 - 1 + 4)$ choose 4 or 8855 distinct tetrahedra (see [6] for a discussion of classical occupancy problems.)

Figure 4 provides an additive vector coordinate example with the vec-

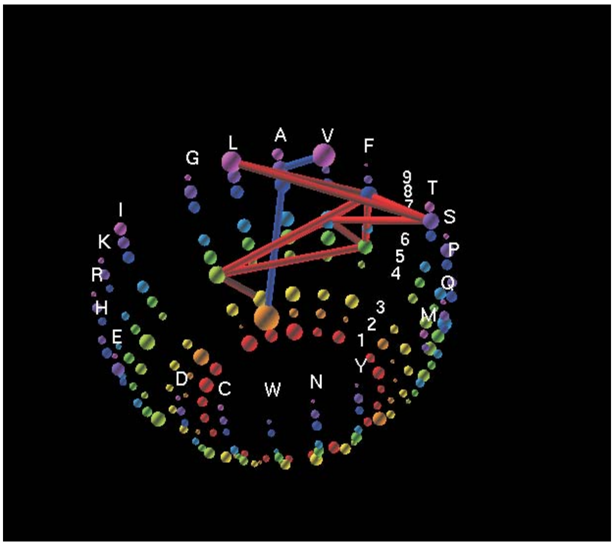

Figure 3: Paths with three segments show frequently occurring quadruples, i.e. high counts from 4-way tables.

tors point to twenty points evenly spaced around a circle. Again point size and color encode the counts, and dynamic filtering has removed low count tetrahedra. High count patterns jump out. One is a circle involving three Cysteins and one each of the amino acids.

While Figure 4 reveals a lot of structure, there are at least three problems worth noting. First, over some 2000 points are overplotted. This is partly related to symmetric construction with equal angles between vectors. Second, zooming reveals many points that to close together to see closer in a overview. Third, for over 4000 points involving four distinct amino acids the connection between plotting location and the indexing is almost impossible to untangle without mouseovers. Figure 4 is mostly useful for points in an outer annulus of the circle.

There are several possibilities for alternative views. It is possible to show a statistic encoded by color in a casement display of 204 = 160000 points [12]. In this example the casement display is a 20 × 20 layout of 20 × 20 matrices. However it remains desirable to study plots with a factor of 18 less points. The 8855 points can be placed in a 4-D simplex. (See also pentagonal numbers [4].) Space prohibits showing a layout composed of two-dimensional slices of the simplex. There is also a layout in the plane for all tetrahedra with 2 or more of the same amino acid. While this layout involves duplicates the regularity makes the layout easier to study. Such a layout can provide a starting point for drilling down to conditioned views of the 1-1-1-1 combinations.

5 Closing remarks

Just as map projections have been devised to serve different purposes, coordinates systems for encoding statistics can be developed to serve different purposes. A worthy goal is to develop coordinates systems with a regularity that minimizes memory burdens and helps analysts keep oriented with respect to the coordinates. A tension arises when one desires to show complex relationships faithfully in some abstract sense while keeping the relationships cognitively accessible. In many cases there are no easy answers and the graphics are a compromise. Still, analysts can make discoveries from imperfect graphs. It is worthwhile to consider graphics that lean toward the cognitive accessibility and work toward incorporating as much scientific structure as possible options. Accessible graphics enable analysts to look and, if they look, they have a chance to see.

MATRIX VISUALIZATION AND INFORMATION MINING

Chun-Houh Chen, Hai-Gwo Hwu, Wen-Jung Jang, Chiun-How Kao, Yin-Jing Tien, ShengLi Tzeng, Han-Ming Wu

Key words: Dimension free visualization, effect-ordered data display, generalized association plots, heat-map, matrix map, relativity of statistical graph, re-orderable matrix, sufficient statistical graph.

COMPSTAT 2004 section: Data visualization.

Abstract: Many statistical techniques, particularly multivariate methodologies, focus on extracting information from data and proximity matrices. Rather than rely solely on numerical characteristics, matrix visualization allows one to graphically reveal structure in a matrix. This article reviews the history of matrix visualization, then gives a more detailed description of its general framework, along with some extensions. Possible research directions in matrix visualization and information mining are sketched. Color versions of figures presented in this article, together with software packages, can be obtained from `http://gap.stat.sinica.edu.tw/`.

1 Introduction

The seminal work of Tukey [34] states a basic principle of Exploratory Data Analysis (EDA):

> *It is important to understand what you CAN DO before you learn to measure how WELL you seem to have DONE it.*

In his concept of EDA, Tukey would allow the data to speak for themselves prior to adoption of any standard assumptions or formal modeling. Much of this preliminary work can be achieved with graphics-oriented tools - the box and whisker plot, the scatterplot, etc.

Many visualization techniques have now been developed to assist us in looking at data. Much of this literature has been devoted to dimension reduction: multidimensional scaling [11], projection pursuit [20], self-organizing maps [24], and sliced inverse regression [26]. These techniques are very useful for exploring data structure when the number of variables is of moderate size and when structure is not too complex. Yet, with striking advances in computing, communication, and high-throughput biomedical instruments, the number of variables can easily reach tens of thousands, and the need for practical data analysis remains. Dimension reduction tools generally lose effectiveness when it comes to visual exploration for information structure embedded in very high dimensional data sets. On the other hand, matrix visualization, integrated with computing, memory, and display, has great potential for visually exploring the structure that underlies massive and complex data sets.

A brief review of matrix visualization is provided in Section 2. Section 3 introduces the general framework of matrix visualization and some extensions of it appear in Section 4. An outline of possible research directions is sketched in Section 5 and there are concluding remarks in Section 6.

2 Matrix visualization (MV)

The technique of matrix visualization discussed in this article is deemed dimension-free [3]. The only limitation of size for a given data set is the resolution of a computer display or the size of the printing device used. Matrix visualization is not a new technique but CPU speed, memory size, and display capability of modern computers give it a brand-new platform.

Given a data matrix, $X = [x_{ij}]_{n \times p}$, the idea is to graphically present all numerical values, x_{ij}, in a matrix map. With small values of n and p, this map can be the numerical matrix itself. Bertin [1] considered re-orderable or permutation matrices, Hartigan [19] introduced the direct clustering of a data matrix, Lenstra [25] and Slagel et al. [33] linked the traveling-salesman problem and shortest spanning path to matrix reordering, Wegman [35] proposed the idea of a color histogram, while Minnotte and West [30] implemented The Data Image package. The Cluster and TreeView packages by Eisen et al. [12] are probably the most popular visualization packages because of the wide application to gene expression profiling for cDNA microarray experiments. Heatmaps with classification tree partitioning are commonly used to summarize stock market structure (`http://www.smartmoney.com/marketmap/`). On the other hand, Carmichael and Sneath (taxometric maps [2]) and Ling [27] dealt with visualization of a proximity matrix, $D = [\rho_{ij}]_{n \times n}$, whose elements are measures of degree of relationship between pairs of a set of n objects. Murdoch and Chow [31] used elliptical glyphs to represent correlation matrices while Friendly [15] called them Corrgrams. Church and Helfman [9] developed Dotplot for exploring self-similarity in millions of lines of text and code. Chen [4], [5], [6] and Chang et al. [3] integrated visualization for data and proximity matrices into the framework of generalized association plots (GAP). We use matrix visualization (MV) to refer to all the aforementioned terminologies.

The basic principle of MV, then, is to effectively present a complete data or proximity matrix on a computer display or printout. We use the psychosis disorder data set described in Hwu et al. [22] to illustrate the framework of an MV analysis. Thirty-three Positive and Negative Syndrome Scales, PANSS [23], for one hundred and sixty-three schizophrenic patients were used in the original analysis. We randomly sampled 40 patients with 17 symptoms for our illustration. PANSS symptoms are rated on an ordinal scale from 1 (normal) to 7 (severe), but we treat them on a continuous scale for simplicity. Psychiatrists [22] have addressed three fundamental issues: the grouping structure among the symptoms, the clustering structure of patients, and the general behavior of every patient-cluster in each symptom-group. These three issues are closely related to the three major pieces of information contained in any multivariate data set: the linkage amongst n subject points in the p-dimensional space; the linkage between p variable vectors in the n-dimensional space; and the interaction linkage between the sets of subjects and variables. Factor analysis and clustering related methods are commonly applied to answer the first two issues, but there is no general technique for studying the interaction effects for subjects and variables. With appropriate presentation (permutation and color/shape coding) and integration for the raw data and proximity matrices, MV can be used to effectively display all three pieces of information with many types of data formats and sampling schemes.

3 Four components of matrix visualization

Most existing MV methods deal with data and proximity matrices separately. Chen [6] integrated them in a framework of generalized association plots with four major components. We focus our introduction on these four components.

3.1 Presentation of raw data matrix and selection of proximity matrices

The first task of MV is to convert a numerical matrix into a matrix map with a color dot (symbol) representing each entry. Then each row vector, call it a patient's symptom profile, is converted into a horizontal color band and every column vector, a symptom's patient distribution, is replaced by a vertical color strip. The information in a numeric matrix is thus comprehensively displayed in a matrix map (Figure 1a).

3.1.1 Color spectrum and variable transformation The selection of a suitable color spectrum is crucial in an MV analysis [1], [13]. With the PANSS symptoms, we need only find a color spectrum capable of expressing its ordinal nature, a rainbow spectrum in Figure 1a for example. For measurements with bi-directional structure, such as the logarithmic gene expression profiles used for cDNA microarray experiments, an integration of two monotonic color spectrums is needed (Figure 2).

For the PANSS example, the rainbow spectrum is the same for each symptom since they share the same scale. When variable structure becomes more complicated, transformation of variables may be necessary before the MV can effectively present the data structure. In particular, in order to make simultaneous visualization of multiple variables in MV meaningful, it is essential to standardize variables (sometimes for subjects) with different scales. When outliers are present, the relationship between outlying observations and

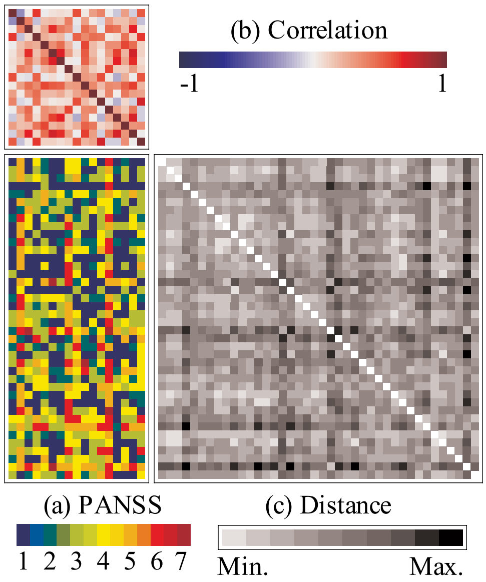

Figure 1: Presentation of the PANSS data matrix with proximity matrices.

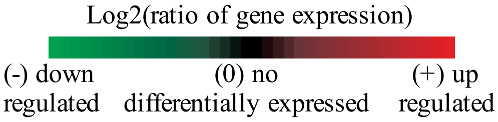

Log2(ratio of gene expression)
(-) down regulated
(0) no differentially expressed
(+) up regulated

Figure 2: Bi-directional color spectrum for gene expression profile.

the main body of the data set can exhaust the color spectrum and only the relative structure of outliers and the main body can be observed [3], [28]. A logarithm or similar transformation can be applied to variables or proximities to diminish the outlier effect. Transformation of variable (symptom), also termed the column conditioned transformation, is commonly practiced. Row (patient) and matrix conditioned transformations are used from time to time.

3.1.2 Selection of proximity measures The second important task is to identify appropriate measurements for representing between-variables and between-subjects association. The importance of this choice for proximity matrices is two-fold: it is used to directly assess the strength of variable-interaction with subject-relationship; it will be used to permute the raw data or proximity matrix. Suitable color spectrums are also needed to project numerical proximity matrices to matrix maps. Euclidean distance is used in the psychosis disorder example to measure the patient-to-patient dissimilarity so a uni-directional grey-scale spectrum (Figure 1c) is adopted, while a bi-directional blue-white-red spectrum is applied to illustrate the between symptoms correlation coefficients (Figure 1b). Appropriate transformations of variables before computing proximities, and of proximity measurements directly, are necessary for both numerical and visual considerations.

3.2 Seriation of proximity matrices and raw data matrix

Although Figure 1a has already converted three numerical matrices into MV format, not much information can be obtained from it since variables and subjects are randomly permuted in these matrices. In order for a statistical graph (including MV) to reveal structure embedded in the data being displayed it is necessary to place objects with similar (different) properties at closer (distant) positions in the graph. Chen [6] called this concept the relativity of a statistical graph. The corresponding mechanism in an MV display is to identify the best seriations (permutations) for the two proximity matrices. Friendly and Kwan [16] used a similar term, effect-ordered data display, for ordering information in general visual displays.

3.2.1 Robinson matrix Criteria are necessary to identify "good" seriations (permutations) for a given matrix. Seriation is a data analytic tool for finding a permutation or ordering of a set of objects using a data matrix (symmetric or asymmetric). Hubert [21] and Marcotorchino [29] discussed the seriation problem from the aspect of problem setting, methodology and algorithms. Two major considerations in permuting a matrix are global pattern identification and local cluster formation, see [6] and [16] for more detailed discussions. The global and local criteria usually conflict with each other unless the embedded structure has a simple uni-dimensional pattern. One familiar global criterion is the Robinson form [32], [8], and [6]. A matrix is said to be a Robinson (anti-Robinson) matrix if the elements in its rows and columns do not increase (decrease) when moving horizontally or vertically away from the main diagonal (Figure 3a). A permuted Robinson matrix is a pre-Robinson matrix (Figure 3b & c). A Robinson matrix satisfies both the relativity condition [6] and the effect-ordered requirement [16] and it is optimized for global and local criteria. A Robinson proximity matrix may be obtained from a raw data matrix with a monotonic structure for variables and/or for subjects. For our PANSS data, this monotonic structure can be a positive-neutral-negative pattern. Robinson form takes relative positions of any two columns and rows into consideration, so it focuses more on global consideration than on local structure. Visualization is usually more globally focused to reflect our ability to perceive the information in a given graph and organize it into a global pattern. There is no practical algorithm which optimizes the Robinson criterion because of its computing complexity.

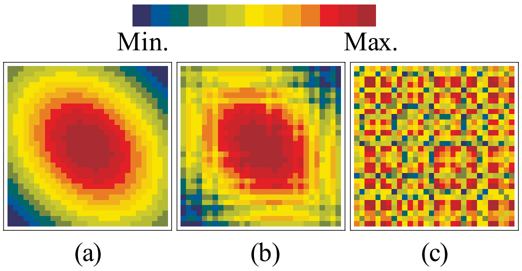

Figure 3: Robinson (a) and pre-Robinson (b & c) matrices.

The Iris data [14] is used to compare the performance of seriations with several commonly used sorting algorithms. The target proximity matrix is the Euclidean distance matrix of the 150 iris flowers on four variables. Using the convergence properties of a series of Pearson correlation matrices, Chen [6] proposed an elliptical seriation which identifies permutations with very good near-Robinson structure (Figure 4g & h).

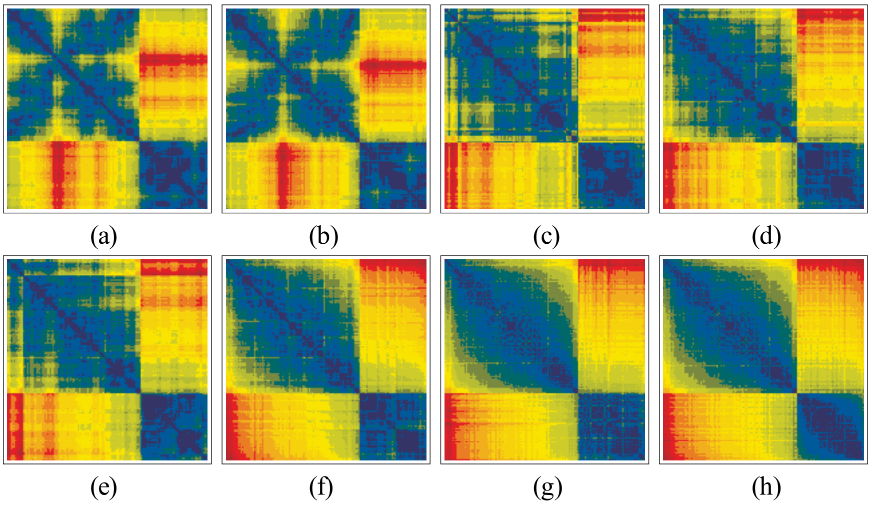

Figure 4: Permuted Euclidean distance maps for Iris data with eight seriation algorithms: (a) farthest insertion spanning; (b) nearest insertion spanning; (c) single linkage tree; (d) complete linkage tree; (e) average linkage tree; (f) GAP rank-one tree; (g) GAP rank-two ellipse; (h) GAP double ellipse.

3.2.2 Tree seriation Most of the seriation algorithms try to optimize some local properties. Travelling-salesman [25] and minimal spanning path [33] algorithms orient toward local optimization. Figure 4a & b show the distance matrix of the Iris data sorted by two minimal spanning algorithms. The hierarchical cluster analysis with a tree-architecture (dendrogram) is the most popular permutation fulfilling criteria for local optimization [27], [12] (Figure 4c, d, & e). Relative positions of the terminal nodes in the final tree grown are employed as the permutation to sort the input objects. The two dendrograms in Figure 5 are generated from the correlation matrix for symptoms and the distance matrix for patients in Figure 1. The two proximity matrix maps are permuted accordingly. The data matrix is two-way sorted using the corresponding permutations. After the permutations, relativity for both subjects and variables is satisfied. That is, patients with similar symptom profiles are placed in closer rows while symptoms with comparable patient distributions correspond to columns nearby each other. Patient-clusters and symptom-groups can now be easily identified using the sorted proximity matrix maps with the tree-architectures. These pieces of information are usually summarized through factor analysis for variables and clustering analysis for subjects. The two-way sorted data map in Figure 5a is actually a condensed version of two sets of scatter-plot matrix with $C(17, 2) = 136$ and $C(40, 2) = 780$ pair-wise plots each for studying the interaction of patient-clusters and symptom-groups.

One fundamental problem arises in applying the dendrogram for matrix permutation. There are $n - 1$ intermediate nodes for a dendrogram with n terminal nodes. Each of these $n - 1$ intermediate nodes can be flipped independently resulting in 2^{n-1} possible final permutations for a given dendrogram. Figure 6 shows the results of different flipping mechanisms for intermediate nodes applied to the same tree-architecture (dendrogram) for a given correlation coefficient matrix. As can be seen, different flipping mechanisms result in totally different visual perceptions and grouping effects. Figure 6a is the only permuted matrix map with perfect scores on both local and global criteria such as the minimum spanning and anti-Robinson scores [6]. It is also possible to use external and internal references [17], [36] for identifying desired flipping patterns.

3.3 Partitions of permuted matrix maps

The next step after the matrices have been permuted is to identify clusters in the resulting maps. This is a constrained clustering problem since the variables and subjects are sorted and listed in a one-dimensional manner. The goal becomes one of finding partitioning points on the two permutations. For a matrix map sorted with a dendrogram, the dendrogram structure can help in identifying suitable cutting points. Two purple lines are drawn in Figure 7b & c to partition the two dendrograms (and matrix maps) into three symptom-groups coded in (red, green, and blue) and four patient-clusters

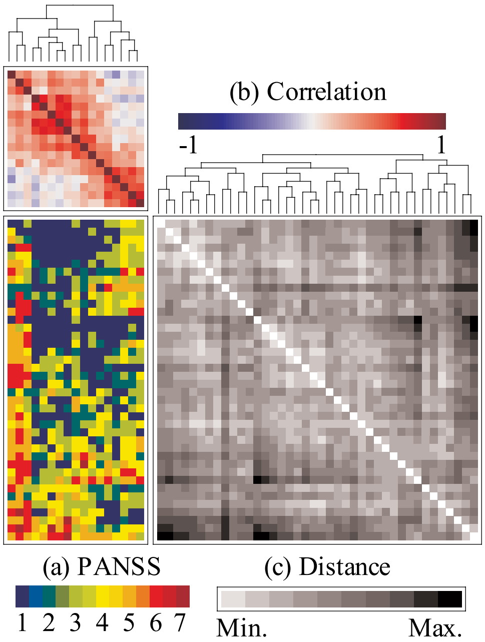

Figure 5: Proximity and raw data maps with dendrograms after permutation.

coded in (cyan, magenta, yellow, and grey). Without dendrograms, characteristics in a permuted data matrix (map) and in proximity matrices (maps) must be employed for identifying possible partitions. Chen [6] contains some discussion on matrix partition using a convergent sequence of Pearson correlation matrices.

3.4 Sufficient statistical graph

Symptoms and patients are partitioned into three groups and four clusters in Figure 7. These two partitions thus cut the correlation map, the distance map, and the raw data map into nine, sixteen, and twelve blocks accordingly. Blocks for proximity maps can be categorized as within-group blocks on the main diagonal and between-group blocks off the diagonal. Blocks for the raw data map have different combinations of symptom-groups and patient-clusters. Chen [6] proposed a concept of sufficient statistical graph for these partitioned blocks. The purpose is to comprehensively and effectively summarize information embedded in the raw data matrix and two proximity matrices with a simplified version of MV. Individual values within a block are replaced by a single summary statistic such as mean, median, or standard deviation to represent the information for that particular block. Figure 8

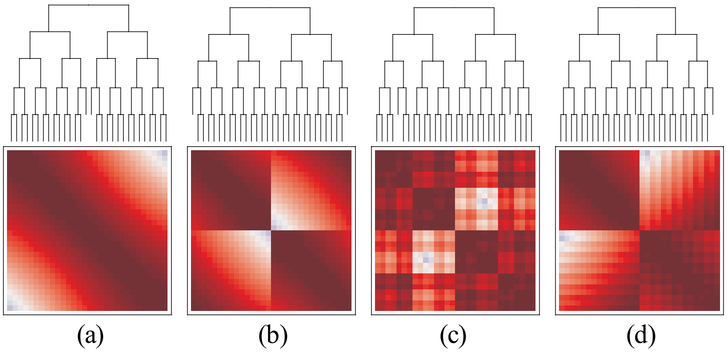

Figure 6: Results of different intermediate nodes flipping mechanisms applied to one tree-architecture (dendrogram) for a given proximity matrix.

displays the mean sufficient statistical graph for Figure 7. This presentation clearly illustrates the within-groups strength and the between-group relationship for symptoms and patients. More importantly, the sufficient graph for the raw data map effectively summarizes the interaction patterns of four patient-clusters on three symptom-groups. These three mosaic-displays of MV in Figure 8 can now easily reveal all three components of linkages for a given multivariate data set.

4 Generalization and flexibility of matrix visualization

Matrix visualization is very flexible and can be easily generalized for various purposes and situations. Two examples are illustrated in this section.

4.1 Sediment MV

Regular MV preserves the identity of each subject and variable, each dot in Figure 9a is the score of a specific symptom for a particular patient. It is possible to ignore symptom identity and sort the symptom profile for each patient according to severity. This results in the sediment MV for patients, as seen in Figure 9b, to express severity structure. One could also omit patients' identities and create the sediment MV for symptoms, as in Figure 9c. This is a side-by-side bar-chart and box-plot which displays the distribution structure for all symptoms simultaneously.

4.2 Sectional MV

The goal of a sectional MV is to display only those numerical values that satisfy certain conditions in the original MV display. Each sub-figure in Figure 10 exhibits correlation coefficients with p-values smaller than certain

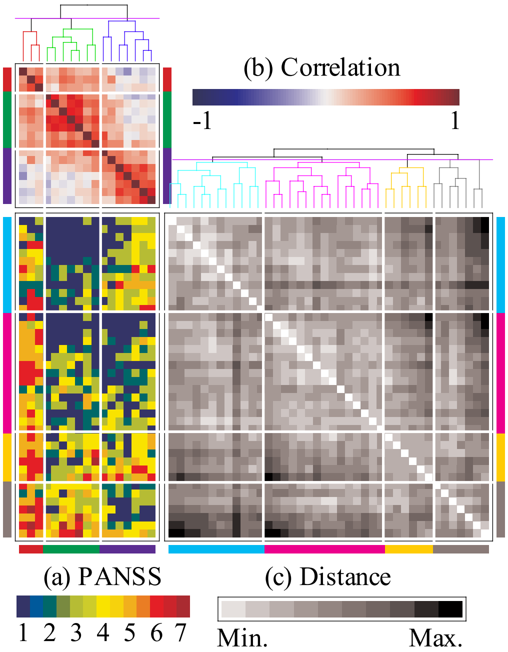

Figure 7: Partitions of permuted matrix maps with dendrograms.

significant levels for a student t-test. Figures with smaller p-values preserve more significant correlation coefficients along the main diagonal to reveal major (tight) symptom-groups, since the matrix maps have already been permuted.

5 Future directions

Matrix visualization is not a new research field but there are still many topics to be explored. All the available MV methods focus on seriation algorithms or coloring (shading) schemes for a data or proximity matrix with entries along a continuous scale. This is insufficient for exploring more complicated information structures in the statistical modelling of longitudinal, categorical, dependent or other complex data. We discuss several possible MV related issues in this section.

5.1 Categorical data

Two major difficulties arise in applying MV to categorical data (especially nominal): computing of proximities - given a categorical data matrix, it is necessary to define the proximity measure so that the numerical version of

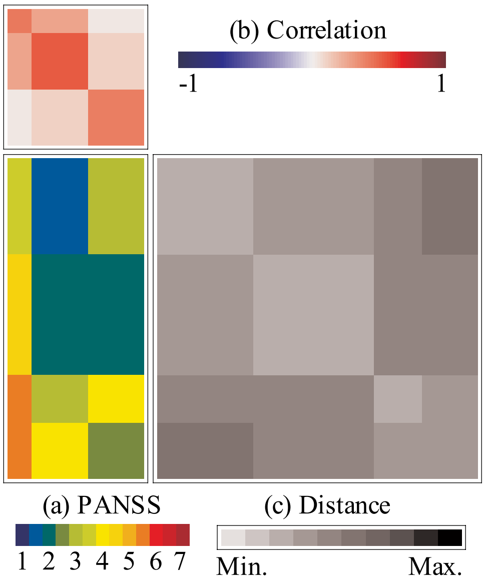

Figure 8: Sufficient statistical graph in GAP.

relativity is valid; selection of color spectrum - categories sharing similar (different) subject-distributions should be assigned with comparable (distinct) colors in order to satisfy the color version of the relativity concept. Chen [5] and Chang et al. [3] introduced a categorical version of GAP which can resolve these two difficulties.

5.2 Longitudinal multivariate data

The PANSS symptom profiles were collected when patients were admitted. There are also PANSS profiles collected at discharge and follow-ups. How to use a single or multiple MV displays to summarize and present the integration of structure for patients, symptoms, and time is a complicated and challenging task.

5.3 Multi-conditioned multivariate data

There are symptom tables other than PANSS in Hwu et al. [22] that can be analyzed simultaneously. The setup is similar to the longitudinal MV problem. Both data structures have identical sets of subjects across multiple time points or multiple tables. The longitudinal one has only one set of variables measured multiple times while the multi-conditioned one has various sets of variables. Statistical methods and theories from canonical correlation are discussed in Chen [5] and Chi [7] for multi-conditioned version of GAP.

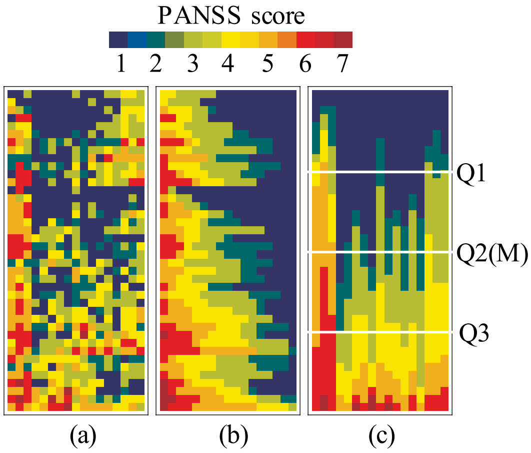

Figure 9: Sedimented MV for patients and symptoms.

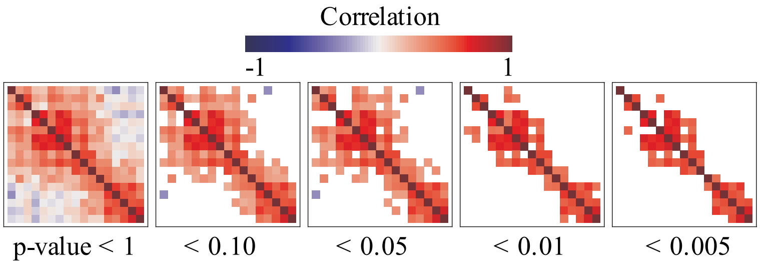

Figure 10: Sectional MV for the permuted correlation coefficient map.

5.4 MV with covariates adjustment

When effects of covariates such as gender or age are of concern in an MV analysis, covariate adjustment has to be taken into consideration. When gender acts as the covariate, it is not easy to create an MV display. One possibility is to decompose the correlation matrix into two component matrices, one for between-group (gender) structure, one for within-group pattern. The between-group correlation matrix can then be used to study the covariate effects on the original correlation matrix.

5.5 MV with dependent variables

The MV problems discussed so far do not include dependent variables. MV for a regression context with dependent variables is similar but not identical to MV with adjusting covariates. Sliced inverse regression by Li [26] is a natural staring point. The design matrix X can be row-wise sorted first by the magnitude of the dependent variable y with or without slicing. The proximity for variables can be the original one or the sliced version. Finally the reduced variables can be treated as the raw data and fed to the regular MV environment. There are certainly many different kinds of MV that can be developed for various regression problems.

5.6 Data with dependent (clustered) structure

When samples are collected with dependent structure, such as familial data for genetics studies, two difficulties emerge. First, it is numerically difficult to define the proximities with multi-levels of relationship and two issues must be addressed: the definition of between-cluster distance or similarity; whether or not within-cluster structure should be preserved while computing the between-cluster relationship. Second, it is graphically hard to display proximity and data maps simultaneously for the individuals' relationship and clusters' (families) structure. Generation of indexing variables for clusters may be necessary in forming MVs for data with dependent structure.

5.7 Mixed data

Categorical variables introduce difficulties in the computation of proximities and the selection of color spectrums. Problems get even more complicated when variables collected are mixed with quantitative, ordinal, binary, and nominal types. General similarity coefficients proposed by Gower [18] and general weighted two-way dissimilarity coefficients introduced by Cox and Cox [10] may aid the calculation of proximity matrices for variables and subjects in constructing the MV display with mixed data. Color coding for a data matrix with mixed data is a more difficult task.

5.8 MV for huge data

When data size (variable or subject) exceeds the limitations of computers used, such as thousands of variables and millions of subjects, burdens may come from the CPU speed, computer memory and display. Parallel and distributed computation with PC clusters may speed up computation time. When hardware support is not available, procedures from sampling techniques, sequential analysis, smoothing methods, and image processing all can be of help in creating MV for studying structures of huge data sets.

There are many interesting research areas not yet mentioned - MV for colorblind people, MV for spatial data, and MV with missing observations are good examples.

6 Conclusion

MV tools are not created to replace existing mathematical or statistical procedures. Instead, they can be applied in advance to obtain a general picture of the information structure and build up confidence for choosing and using more rigorous and appropriate mathematical and statistical operations. Of course it is possible that a good MV display alone can answer all the questions a user has in mind and reveal more comprehensive understanding about a data set than formal mathematical operations and statistical modellings.

st-apps AND EMILEA-STAT: INTERACTIVE VISUALIZATIONS IN DESCRIPTIVE STATISTICS

Katharina Cramer, Udo Kamps, and Christian Zuckschwerdt

Key words: Applied statistics, descriptive statistics, interactive visualizations, multimedia, teaching and learning environment, web-based.

COMPSTAT 2004 section: Teaching statistics.

Abstract: Within the "New Media in Education Funding Programme" the German Federal Ministry of Education and Research (bmb+f) has supported the project e-stat to develop and to provide a multimedia, web-based, and interactive learning and teaching environment in applied statistics called EMILeA-stat. After sketching the structure of EMILeA-stat, its scope and objectives briefly we focus on interactive visualizations in descriptive statistics as a specific and typical aspect of the system. Alternatively, the visualizations are available off-line as a graphical package called **st·apps**.

1 Introduction

Within the "New Media in Education Funding Programme" the German Federal Ministry of Education and Research (bmb+f) supports the project e-stat (project period April 2001 – June 2004) to develop and to provide a multimedia, web-based, and interactive learning and teaching environment in applied statistics called EMILeA-stat, which is a registered brand name. It is accessible via internet (`emilea-stat.uni-oldenburg.de`).

The project was set up by 13 partners at that time working at seven German universities: Bonn, Berlin (Humboldt-University), Dortmund, Karlsruhe, Münster, Oldenburg (leading university), and Potsdam. In test and evaluation phases of EMILeA-stat other universities are involved, too. The project is also supported by further partners in advice and it cooperates with economic partners such as SPSS Software, Springer-Verlag, MD*Tech Method & Data Technologies (XploRe-Software), and AON Re. Including the group of associated partners who are providing additional content, about 70 people are co-working in developing und realizing EMILeA-stat at the present time. For more detail about the project we refer to its web page `www.emilea.de`.

2 The system EMILeA-stat

Statistical and quantitative thinking and acting have become fundamental skills in several branches of natural sciences, life sciences, social sciences, economics, and engineering. Models, tools, and methods, which have been developed in statistics, are applied in modelling and data analysis, e.g., in business and industry, in order to obtain decision criteria and to gain more insight into structural correlations. Owing to these various applications and the necessity of using statistical methodology in so many fields, there have to be consequences for the processes of learning and teaching: Pupils, for example, should get to know elementary and application-oriented statistics. Therefore, statistics and data analysis, theoretically and practically, have to become part of teachers' studies at university and at in-service training courses. Moreover, students of many different disciplines with a statistics impact should be familiar with basic and advanced statistics. These goals gave the main impact to develop EMILeA-stat

- as one system suitable for teaching statistics at schools, universities, and in further vocational training,
- as one system which supports supervised and self-directed learning, and
- as one system which is accessible anywhere, anytime, and for anyone.

The basic concept offers on the one hand the opportunity to tailor individual courses covering specific learning needs. On the other hand, EMILeA-stat serves as an intelligent statistical encyclopaedia.

Basic statistical contents are presented on three levels of abstraction in order to take into account that different types of users have – owing to their individual mathematical and theoretical backgrounds – different needs. If sensible the contents are written on level

A (elementary level): presentation in a popular scientific way by assuming no or only a low previous (mathematical) knowledge,

B (basic level): like undergraduate courses in applied statistics for students, e.g., of economics, psychology, and social sciences, and

C (advanced level): containing deeper material and special topics within the broad field of statistics and applied probability.

Furthermore, user-oriented views and scenarios, which are near to real world applications, are integrated.

The following fields and subjects of quantitative methodology are or will be contained in EMILeA-stat: Descriptive and inductive statistics, exploratory data analysis, interactive statistics, graphical representations and methods, basic mathematics needed in statistics, probability theory, statistical methods in finance and insurance mathematics, modelling and prediction of data in financial markets, statistical methods in marketing, virtual productions and virtual company, experimental design, statistical quality management, and business games.

3 Interactive visualizations

The theoretical statistical content in EMILeA-stat is supplemented by interactive visualizations which are programmed as Java-Applets. By offering a variety of interactive options (for a detailed description see below) they support the learner in her/his learning process by offering the possibility to explore the explained method, to experiment with data, and to make own experiences with the discussed topic. Due to the fact that many places, e.g., at universities or schools, where teaching takes place still do not have access to the internet, these visualizations are not only part of the system but also realized as an off-line graphical package called **st·apps** . A German version of this tool – including an additional textbook with explanations, instructions, proposals for the use in teaching, etc. – is available via the publishing company Springer. An English edition is planned.

In the following we give an overview about the visualizations included in **st·apps** and present this tool by giving some examples. Finally the differences between the on-line version and the graphical package are briefly sketched.

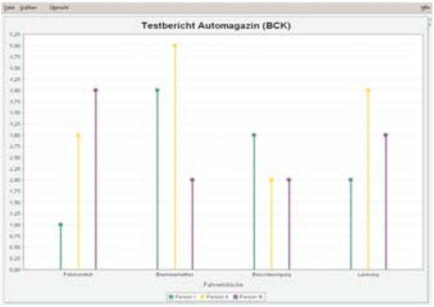
3.1 Types of visualizations

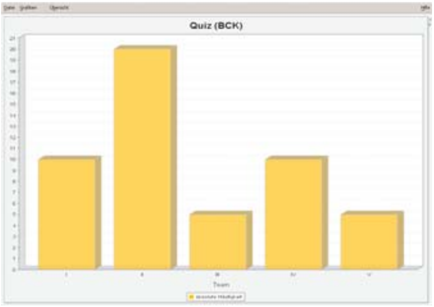
Due to their use the interactive visualizations are divided into two groups: The first one works like a simple statistical engine. It is used for analyzing own data and preparing presentations. The others are designed in the first place regarding didactical aspects in order to support the exploratory learning process for becoming familiar with the explained content or method. By offering many interactive elements the user is invited to experiment and explore the presented content by her/his own activity. Examples are given below.

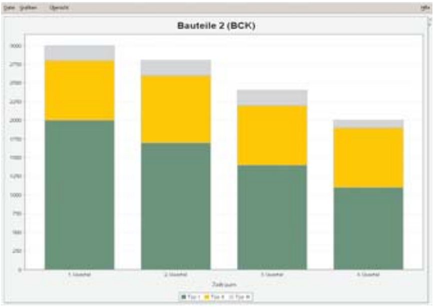
3.2 The range concerning descriptive statistics

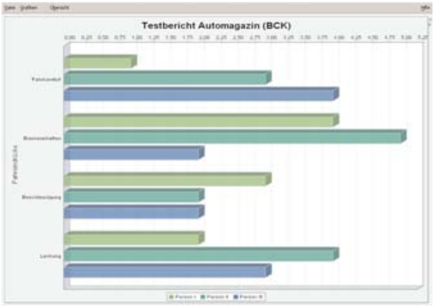
Starting with elementary visualizations like bar charts (vertical and horizontal), pie and ring charts, line charts, box plots, stem-and-leaf plots, histograms, and plots of the empirical and the approximate empirical distribution function, traditional measures like mean, standard deviation, quantiles, etc. are considered as well as measures of relationships between measurement or categorical variables. Methods for the description of economic data like price index numbers and measures of concentration, e.g., Lorenz curves and Gini coefficients, are also illustrated by this kind of interactive illustration. The field of univariate approaches is completed by regression and time series analysis. Furthermore, applets with scatterplots and scatter matrices are realized. All the mentioned visualizations are available on-line as part of EMILeA-stat, while in **st·apps** the following subjects focusing on analyzing and presenting data are included:

Bar charts

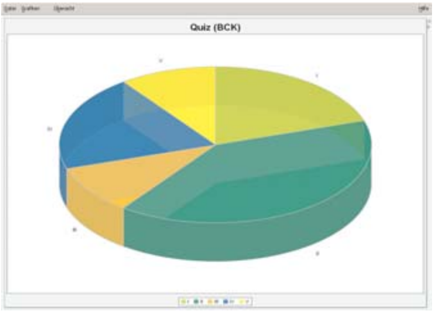


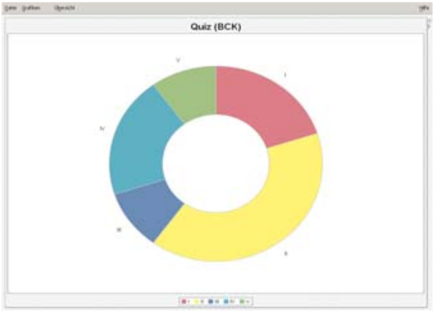




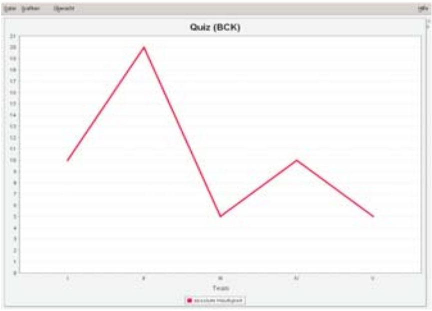


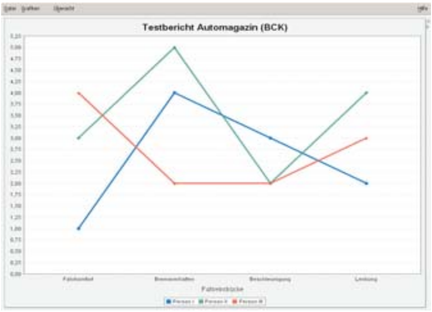
Pie and ring charts



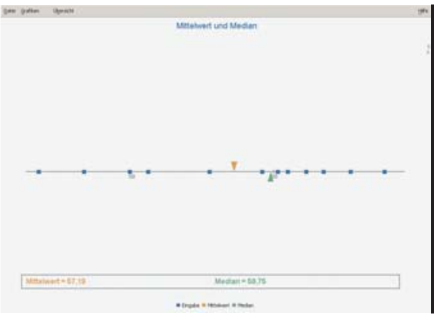


Line charts



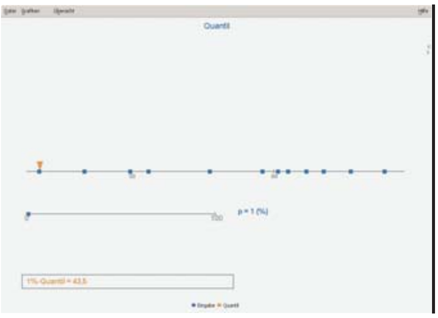


Location parameters



Mittelwert = 57,18 Median = 58,75

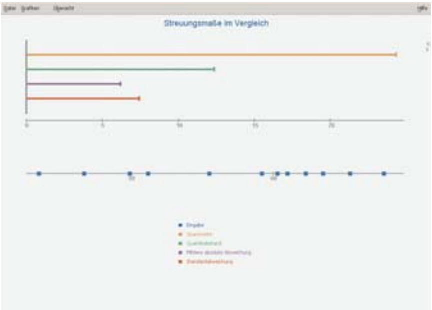
Mean and median



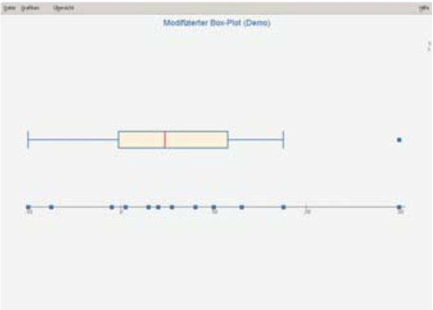
1%-Quantil = 43,5

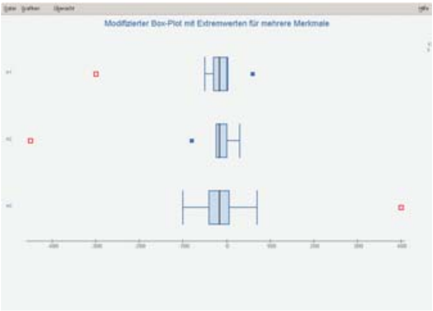
Quantiles

Scale parameters



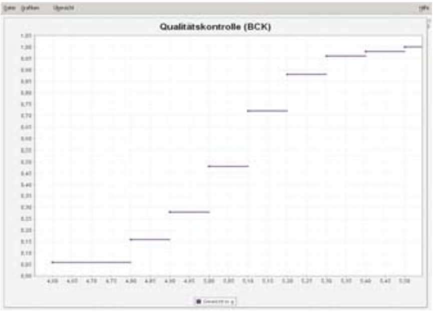
Box plots



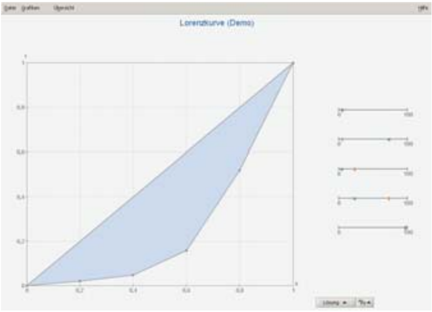


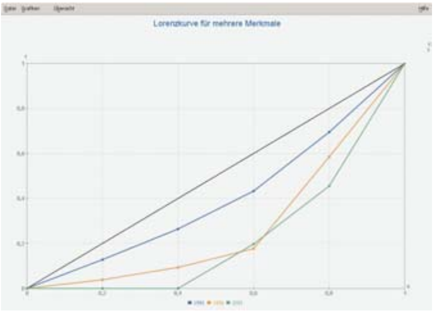
Modifizierter Box-Plot mit Extremwerten für mehrere Merkmale

Empirical distribution function

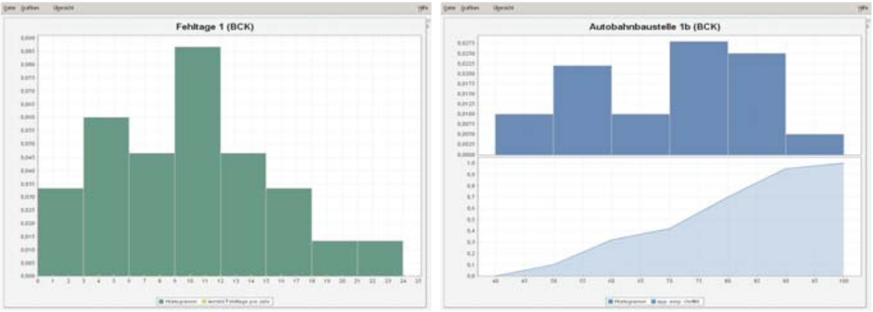


Lorenz curves

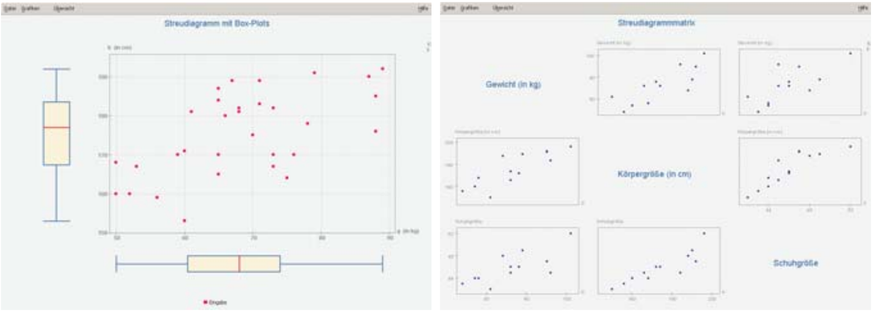




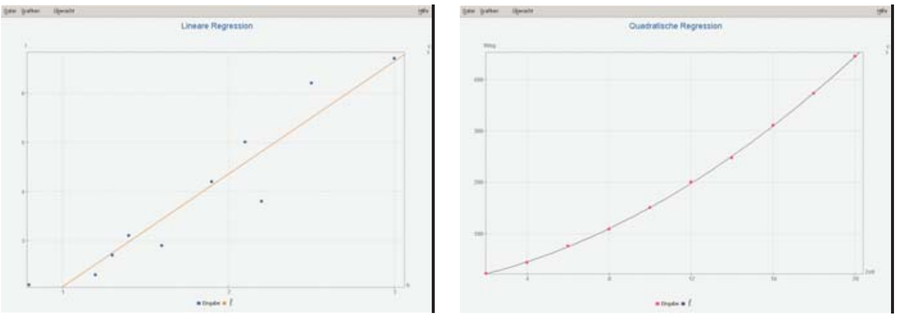
Histograms and approximate empirical distribution function



Scatter plot and scatter matrix



Regressions

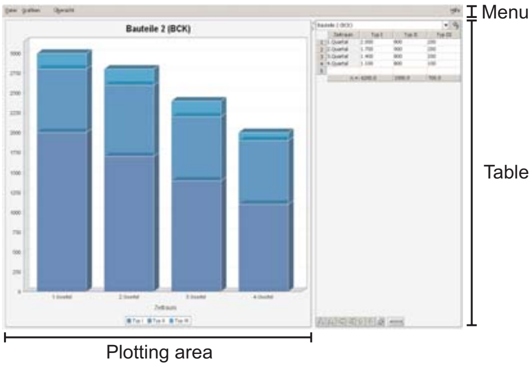


Linear regression

Quadratic regression

3.3 The structure

Each interactive visualization consists of three parts: the plotting area, a table for the data, and the menu.



When opening a visualization in **st·apps** a given data set is loaded automatically into the table and presented in the plotting area.

The size of the diagram and the table can be changed manually. Furthermore, it is possible to close one of these two components, a facility which is, e.g., useful for presentations.

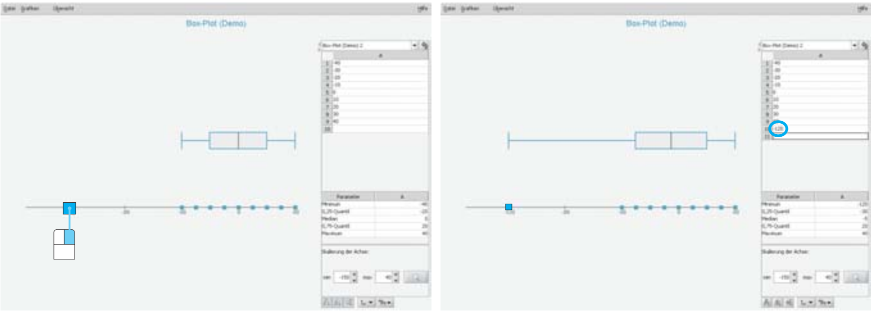
The "user interface" – the aspects of interactivity in the plot and the table or the menu – is standardized such that the frequent user should be able to work with a new visualization easily. Instructions accompanying the visualizations indicate the concept of learning by discovery enabled via the available interactivity.

Owing to the fact that the menu is organized similar to the menus of known standard software we will not go into details about this part while the plotting area and the table are described in more detail in the next paragraphs.

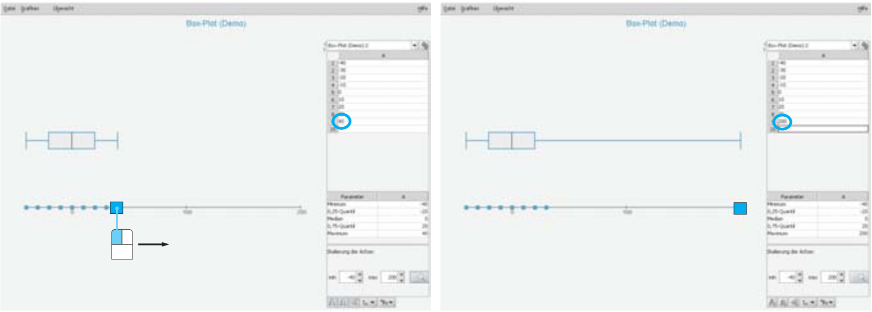
3.4 The diagram

Depending on the type of visualization different aspects of interactivity are implemented. Some of them will be explained in the following.

The automatically loaded data set can be modified by adding new data points. They can be given numerically by adding them in the table (see below) or by clicking the axis with the right mouse button.



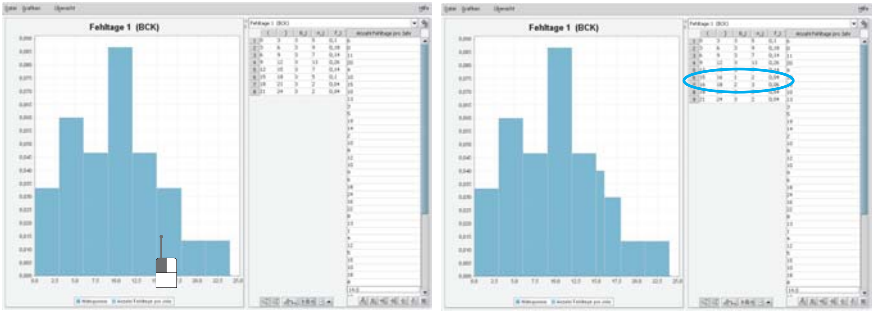
Moreover, existing data (points on the axis) can be moved to the right or left with the left mouse button. The axes are automatically rescaled.



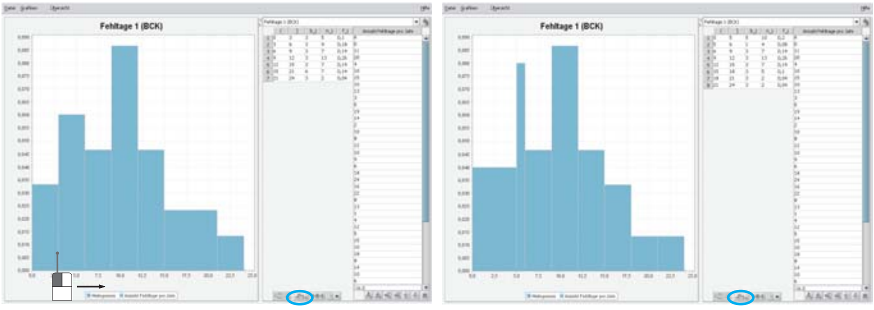
These options are included in many visualization such as those concerning location and scale parameters, box plots, scatter plots, regressions, histograms and the approximate empirical distribution function.

Furthermore, there are interactive aspects which are matched only with specific visualizations. Three examples are given in the following:

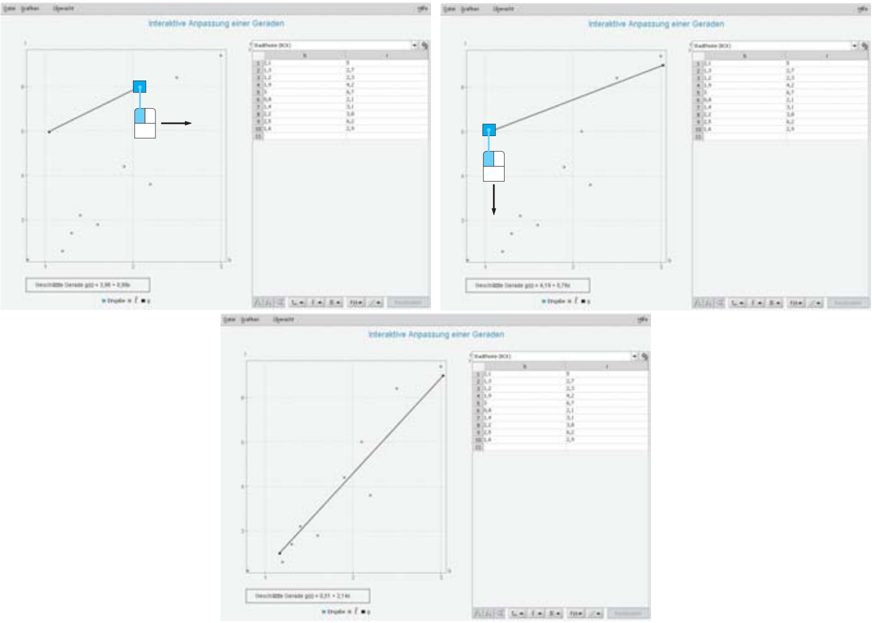
Histogram The histogram applet offers the most interactivity. Each bar can, for example, be split into two bars by clicking with the mouse into the respective bar.



By shifting the endpoints of the bars the width of the classes and eventually the number of classes change.

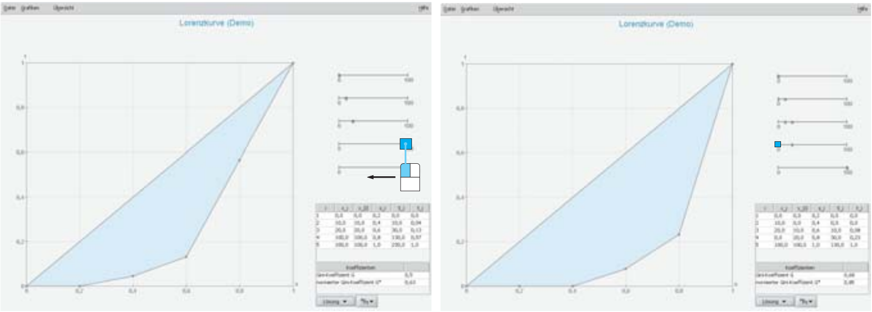


Fitting a straight line Concerning linear regression there is, e.g., one visualization available where a straight line has to be fitted manually to the data. The correct linear regression function obtained by least squares can also be added for checking the manually fitted line.



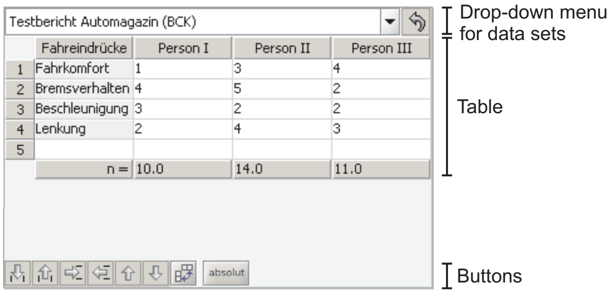
Interaktive Anpassung einer Geraden
Interaktive Anpassung einer Geraden
Interaktive Anpassung einer Geraden

Lorenz curve The Lorenz curve is offered in two interactive versions. In the applet shown in the illustration different market situations are modelled by shifting the marked buttons.



3.5 The table

The part which includes the table is composed of three parts:



Testbericht Automagazin (BCK)

	Fahreindrücke	Person I	Person II	Person III
1	Fahrkomfort	1	3	4
2	Bremsverhalten	4	5	2
3	Beschleunigung	3	2	2
4	Lenkung	2	4	3
5				
	n =	10.0	14.0	11.0

In some cases a fourth component with further information such as parameters or coefficients is realized.

In the drop-down-menu a selection of data sets suitable for visualization is offered. If a data set is loaded, the accompanying table can, e.g., be modified in the following ways:

Symbol	Action
⇩ ⇧	Add a column Delete the marked column(s)
⇨ ⇦	Add a row Delete the marked row(s)
⇧ ⇩	Shift the marked row(s) up Shift the marked row(s) down

An error in the table is indicated by (!) and ↶ restores the original data set. If a functionality makes no sense for the actual applet the corresponding button does not appear.

Depending on the specific visualization further buttons are offered. The button Korrelation ▲, for example, calculates the correlation coefficient in the regression applets while in the histogram applet ▅ generates a histogram with equidistant classes. Also the already mentioned optional fourth part with information about used parameters or coefficients is inserted by pushing a button, namely αβγ▲.

Some visualizations consist of two tables: one for the original data and one for the frequency table. The latter one depends on the first one. Therefore, it can only be modified as explained if the original data has been deleted.

3.6 Interactive visualizations available online

As already mentioned a wider range of applications, such as price index numbers or visualizations, e.g., concerning time series analysis, are offered online in EMILeA-stat. Moreover, in contrast to the off-line tool **st·apps** each interactive visualization is – similar to the theoretical content – available on three levels of abstraction. The elementary level A offers at least interactivity whereas on level C (advanced) the full range of functionality as described is accessible. Concerning the data sets loaded, this level dependent design means that the systems offers to a user working on level A only one data set (given by the teacher), while on level B she/he can choose between a wide range of data sets. On level C analyzing own data is possible. In other words the described "user interface" of the off-line tool is available only on level C to its full extent. On the other hand **st**·apps offers – because of these facilities – a variety of helpful and powerful tools for analyzing and presenting data which are also useable without an access to the internet.

COMPSTAT'2004 Symposium

THE CASE SENSITIVITY FUNCTION APPROACH TO DIAGNOSTIC AND ROBUST COMPUTATION: A RELAXATION STRATEGY

Frank Critchley, Michael Schyns, Gentiane Haesbroeck, David Kinns, Richard A. Atkinson and Guobing Lu

Key words: Combinatorial optimisation, convexity, diagnostics, Euclidean geometry, masking, multiple case effects, relaxation, robustness.

COMPSTAT 2004 section: Robustness.

Abstract: The present paper focuses on the case sensitivity function approach to diagnostics and robustness that are combinatorial by definition and hard to solve exactly. Attention is also given to the visual displays.

1 Overview and organisation

Central to both diagnostics and robustness are a range of optimisation problems that are combinatorial by definition and correspondingly hard to solve exactly. A variety of multiple case effects – such as masking – may be present, further complicating appropriate inference.

The present paper offers a computation-focused progress report on the case sensitivity function approach to diagnostics and robustness introduced in [4], on which we draw. A key idea here is that *relaxation brings benefits*. Specifically, the strategy outlined below shows how such high-dimensional ($O({}^nC_m)$) discrete optimisation problems can be embedded in low-dimensional ($O(n)$) smooth reformulations, in which both the insights of geometry and the power of analysis are available. In particular, informative plots become possible, while additional convexity and derivative information can be exploited.

Overall motivation for the case sensitivity function approach derives from considerations of (A) *unity*, (B) *insight* and (C) *innovation,* examples including – in order of appearance:

- (A1): an emphasis (throughout) on the connectivity of diagnostics and robustness,
- (A2): a single setting for a range of optimisation problems (Sections 3 and 4),
- (B1): visual displays affording insight into the nature and variety of multiple case effects (Section 5),
- (C1): new diagnostic methodologies (Section 6),

- (B2): insight into the performance of existing algorithms (Section 7), and:
- (C2): enhanced (potentially, encompassing) sets of algorithms for a class of robustness problems (Section 7).

A few preliminaries are established in Section 2.

2 Preliminaries

To gain focus, attention is restricted to one-sample contexts, with $\{z_i : i \in N\}$, $N := \{1, ..., n\}$ denoting a random sample of $n > 1$ cases from an unknown distribution F in $\dim(z)$ dimensions. The associated empirical distribution is $\widehat{F} := \sum_{i \in N} n^{-1} \widehat{F}_i$, where $\widehat{F}_i$ denotes the distribution degenerate at z_i. Throughout, analysis is conducted conditional on the observed $\{z_i\}$.

Assuming, as we do, that no further information is available about the observed cases, it is desirable that any analysis of these data should be invariant under permutation of the arbitrary labels attached to them. Given n, this invariance is achieved – without loss of information – by replacing $\{z_i : i \in N\}$ by $\widehat{F}$. In particular, every statistic of interest here is of the form $T[\widehat{F}]$, for some functional $T[\cdot]$. This may, for example, be (the observed significance level of) a test statistic, a parameter estimate, a prediction of future values of an observable, or a nonparametric density or regression function estimate. In particular, $T[\cdot]$ may be scalar, vector or function valued.

Let $Z := (z_i^T)$. In multivariate contexts where all the random variables in $\widetilde{z} \sim F$ are on the same footing, we put $\dim(z) = k$, $\widetilde{z} = \widetilde{x}$, $z_i = x_i$ and $Z = X$. In the usual linear model $y = X\beta + \epsilon$, we put $\dim(z) = 1 + k$, $\widetilde{z}^T = (\widetilde{y}, \widetilde{x}^T)$ and $z_i^T = (y_i, x_i^T)$, so that $Z = (y|X)$, (a constant term being assumed and accommodated by supposing that the distribution of the first element of $\widetilde{x}$ is degenerate at the value 1).

3 A combinatorial optimisation problem

Two integers $h > 0$ and $m > 0$ are called *n-complementary* if $h + m = n$, in which case:

$$A \in \mathbb{N}_h \Leftrightarrow A^c \in \mathbb{N}_m \tag{1}$$

where, for any integer $0 < a < n$, $\mathbb{N}_a := \{\varnothing \subset A \subset N : |A| = a\}$. In particular, $|\mathbb{N}_h| = |\mathbb{N}_m|$ or, in the familiar combinatorial identity, ${}^nC_h = {}^nC_m$.

Throughout, $\{H, M\}$ denotes a bipartition of N. That is, H and M are nonempty, complementary subsets of N. In particular, $|H|$ and $|M|$ are n-complementary. Of course, *holding onto* the cases labelled by H is the same thing as *missing* out those labelled by M. That is,

$$\widehat{F}_H = \widehat{F}_{-M} \tag{2}$$

where, for any $\varnothing \subset A \subset N$, $\widehat{F}_A := \sum_{i \in A} |A|^{-1} \widehat{F}_i$ and $\widehat{F}_{-A} := \widehat{F}_{A^C}$.

As is well-known, diagnostics and robustness meet at the influence function. The simple but general relations (1) and (2) provide a second, global connection between these two areas of statistics, as we now discuss. For brevity, each scalar *target* functional $t[\cdot]$ below is implicitly assumed to be defined wherever it is evaluated, and its possible dependence on $\widehat{F}$ or T suppressed notationally.

A general problem arising in diagnostics is to identify subsets M of given size m whose omission causes maximal changes $T[\widehat{F}] \to T[\widehat{F}_{-M}]$ in a statistic of interest, as measured by $t[\widehat{F}_{-M}]$ for some appropriate target functional $t[\cdot]$. A lead example is Cook's (squared) distance in the linear model. With $T[F] = \beta[F] := (\mathbb{E}_F(\widetilde{x}\widetilde{x}^T))^{-1}\mathbb{E}_F(\widetilde{x}\widetilde{y})$, $\widehat{\beta} := \beta[\widehat{F}]$ and $\widehat{\beta}_{-M} := \beta[\widehat{F}_{-M}]$, we have:

$$t_{Cook}[\widehat{F}_{-M}] := (ks^2)^{-1}(\widehat{\beta}_{-M} - \widehat{\beta})^T X^T X(\widehat{\beta}_{-M} - \widehat{\beta})$$

where s^2 is the usual estimate of error variance. Again, a range of robust estimates are defined in terms of subsets H of given size h which optimise a specified target functional $t[\widehat{F}_H]$. A lead example is minimum covariance determinant (MCD) estimation in multivariate analysis based on minimisation of $t_{MCD}[\widehat{F}_H] := \log(\det(\mathrm{cov}[\widehat{F}_H]))$. These two lead examples are developed below.

Summarising, a range of optimisation problems arising naturally in both diagnostics $(\mathcal{D})$ and robustness $(\mathcal{R})$ have *combinatorial* complexity and *entirely equivalent* $(\mathcal{D}) \leftrightarrow (\mathcal{R})$ forms expressed in Problem 3.1, in which h and m are given n-complementary integers:

Problem 3.1. *(Combinatorial optimisation problem)*
$(\mathcal{D})$ Optimise $t[\widehat{F}_{-M}]$ *over* $M \in \mathbb{N}_m$.
$(\mathcal{R})$ Optimise $t[\widehat{F}_H]$ *over* $H \in \mathbb{N}_h$.

We note in passing that a variety of other combinatorial problems, not necessarily linked to diagnostics and robustness, can also be formulated in this way.

This high-dimensional discrete problem can be embedded in a low-dimensional smooth one, as follows. It suffices to express such a relaxation strategy in, say, the $(\mathcal{D})$ form, that in the $(\mathcal{R})$ form following at once via (1) and (2).

4 A relaxation strategy

Throughout this section, h and m denote given n-complementary integers. Again, M denotes a general member of $\mathbb{N}_m$, and H its complement in N.

4.1 Probability vectors as labels for weighted empirical distributions

The first step in the relaxation strategy adopted here is to use probability vectors as labels for weighted empirical distributions.

For any $p \equiv (p_i) \subset \mathbb{P}^n :=$ {all probability n-vectors}, let $\widehat{F}(p) := \sum_{i \in N} p_i \widehat{F}_i$ denote the distribution attaching probability p_i to z_i, and $\widehat{\mathbb{F}} := \{\widehat{F}(p) : p \in \mathbb{P}^n\}$. For brevity, the $\{z_i\}$ are assumed distinct (this avoids an elaboration required in the general case). Accordingly, (indeed, equivalently),

$$p \leftrightarrow \widehat{F}(p) \text{ is a bijection between } \mathbb{P}^n \text{ and } \widehat{\mathbb{F}}. \tag{3}$$

In particular, every weighted empirical distribution corresponds to one and only one probability vector, which provides a convenient label for it. For example, $p_0 := (n^{-1})$ labels $\widehat{F}$.

Moreover, p_{-M} labels $\widehat{F}_{-M}$, where the i^{th} element of p_{-M} is zero if $i \in M$ and h^{-1} otherwise. That is, (3) specialises to:

$$p_{-M} \leftrightarrow \widehat{F}_{-M} \text{ is a bijection between } \mathbb{V}^n_{-m} \text{ and } \widehat{\mathbb{F}}_{-m},$$

where $\mathbb{V}^n_{-m}$ comprises the ${}^nC_m$ distinct probability vectors arising from permutation of $h^{-1}(0^T_m, 1^T_h)^T$ and $\widehat{\mathbb{F}}_{-m} := \{\widehat{F}_{-M} : M \in \mathbb{N}_m\}$ is the set of distributions optimised over in Problem 3.1.

The $(\mathcal{R})$ form is immediate, writing p_{-M}, $\mathbb{V}^n_{-m}$ and $\widehat{\mathbb{F}}_{-m}$ as p_H, $\mathbb{V}^n_h$ and $\widehat{\mathbb{F}}_h$ respectively. Of course, in the limit when $m = (n-1)$ (equivalently, $h = 1$), $\mathbb{V}^n_{-m}$ comprises the n unit vectors in $\mathbb{P}^n$ which label the degenerate distributions $\{\widehat{F}_i\}$ in the obvious way.

Again, with $0 < \lambda_a := a/n < 1$ denoting the proportion of cases in $\varnothing \subset A \subset N$, the identity:

$$\widehat{F} = (1 - \lambda_a)\widehat{F}_{-A} + \lambda_a \widehat{F}_A \tag{4}$$

has an exactly analogous probability vector form:

$$p_0 = (1 - \lambda_a)p_{-A} + \lambda_a p_A. \tag{5}$$

Finally, let $T[\cdot]$ denote any statistic of interest. Following [4], perturbation is defined here as movement $p \to p^*$ between probability n-vectors, with primary effect (corresponding to the identity functional T) the induced change $\widehat{F}(p) \to \widehat{F}(p^*)$ in distribution, and general effect $T[\widehat{F}(p)] \to T[\widehat{F}(p^*)]$.

4.2 Size and direction of perturbations

Again following arguments set out in [4], the second relaxation step embeds $\mathbb{P}^n$ in n-dimensional Euclidean space $\mathbb{E}^n$, this choice of geometry assigning both *size* and *direction* to perturbations.

In particular, the size $r^{(n)}_{-m} \equiv r^{(n)}_h = \sqrt{m/(nh)}$ of the perturbation $p_0 \to p_{-M}$ (*not*, note, of its primary effect $\widehat{F} \to \widehat{F}_{-M}$):

(i) does not depend on which m cases are deleted,
(ii) increases with m for fixed n, and
(iii) decreases with n for fixed m,

each of which is intuitive.

Again, for any nonzero vector v in $\mathbb{E}^n$, let $d(v) := v/\|v\|$ denote its direction. Then, for any $\varnothing \subset A \subset N$, $d_A := d(p_A - p_0)$ and $d_{-A} := d_{A^c}$ are the directions of the perturbations (from p_0) which *hold onto* and *miss out* A, respectively. In particular, (4) and (5) can be tellingly re-expressed as $d_A = -d_{-A}$. In words, *for any nonempty proper subset of cases, the perturbation which holds onto it is in the* ***opposite*** *direction to that which misses it out.*

Finally, let $\{M_r : r = 1, 2, 3\}$ denote a tripartition of N. Then it is easy to see that the perturbations $\pm d_{M_1}$ (from p_0) holding onto and missing out M_1 are *orthogonal* to those, $\pm d(p_{M_2} - p_{M_3})$, which trade probability weight between the cases labelled M_2 and M_3, exactly similar relations holding under cyclic permutation of subscripts.

4.3 Convexification of the feasible region

Recalling that $\mathbb{V}^n_{-m}$ labels the distributions over which an optimum is sought, the third relaxation step is to embed $\mathbb{V}^n_{-m}$ in its convex hull, $\mathbb{P}^n_{-m}$ say, this larger set serving (below) as the feasible region for the smooth embedding of Problem 3.1.

It follows that $\mathbb{P}^n_{-m} = \{p \in \mathbb{P}^n : p_i \leq h^{-1} \ (i \in N)\}$, a closed convex polyhedron of maximal dimension $(n-1)$ in $\mathbb{E}^n$. And, dually, that $\mathbb{V}^n_{-m}$ is the set of all *vertices* (extreme points) of $\mathbb{P}^n_{-m}$. That is, all those members of $\mathbb{P}^n_{-m}$ which cannot be written as a strict convex combination of two other members. Geometrically, all those points in $\mathbb{P}^n_{-m}$ which do not lie in the interior of a line segment joining two others. Again, we have:

$$\{p_0\} = \{p \in \mathbb{P}^n : p_i \leq n^{-1} \ (i \in N)\} \subset \mathbb{P}^n_{-1} \subset \mathbb{P}^n_{-2} \subset \ldots \subset \mathbb{P}^n_{-(n-1)} = \mathbb{P}^n \quad (6)$$

while, writing $\mathbb{P}^n_{-m}$ as $\mathbb{P}^n_h$, the $(\mathcal{R})$ form is immediate.

4.4 Examples

Figure 1 illustrates the $n = 3$ case. $\mathbb{P}^3 = \mathbb{P}^3_{-2}$ is the outer equilateral triangle, whose vertices $\mathbb{V}^3_{-2}$ are the unit vectors. $\mathbb{P}^3_{-1}$ is the inverted, inner equilateral triangle, whose vertices $\mathbb{V}^3_{-1}$ are the midpoints of the sides of $\mathbb{P}^3$. Both triangles are centred on p_0. All perturbations (from p_0) which miss out a single case are the same size, and smaller than all which miss out two. Again, each perturbation (from p_0) that holds onto a given case is in the opposite direction to that which misses it out, and orthogonal to that which trades weight between the other two.

The $n = 4$ case is illustrated in the 3-D polyhedra of Figure 2. The leftmost of these is the regular triangular pyramid $\mathbb{P}^4 = \mathbb{P}^4_{-3}$, whose vertices $\mathbb{V}^4_{-3}$ (again, the unit vectors) are shown as solid circles. The four square symbols shown there are the vertices $\mathbb{V}^4_{-1}$, each $p_{-\{i\}}$ being the centroid of the face of $\mathbb{P}^n$ opposite to $p_{\{i\}}$, (a result that holds for any $n > 1$). Again, the six oval symbols at the mid-points of the edges of $\mathbb{P}^4$ are the vertices $\mathbb{V}^4_{-2}$.

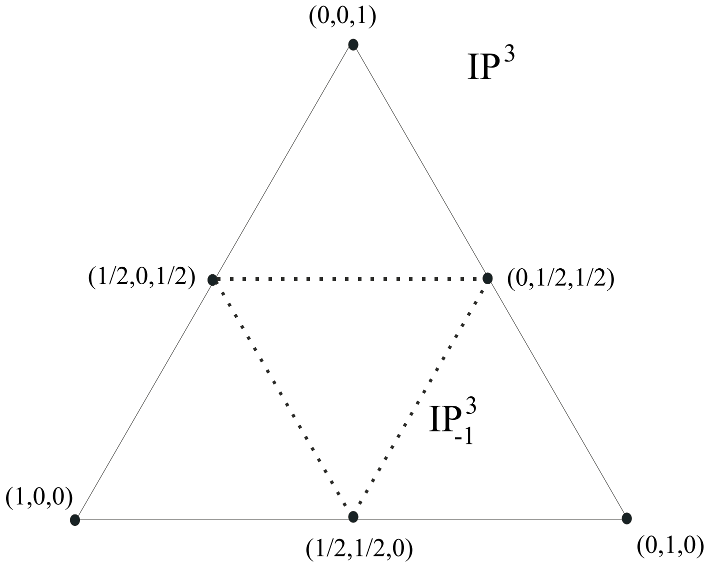

Figure 1: $\mathbb{P}^3$ and some of its key features.

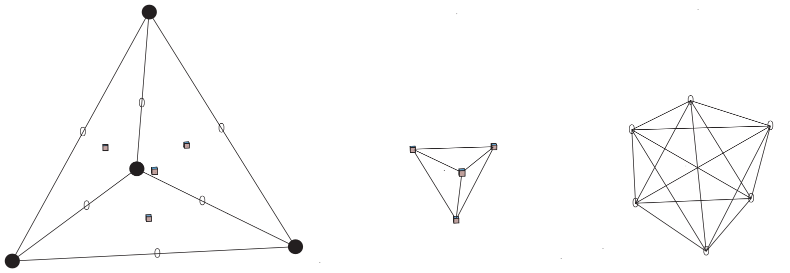

Figure 2: $\mathbb{P}^4$ and some of its key features.

The convex hulls $\mathbb{P}^4_{-1}$ and $\mathbb{P}^4_{-2}$ of these two vertex sets comprise the other two polyhedra shown, all three being centred on p_0. The inclusions (6) are clear.

Overall, the three sides of $\mathbb{P}^3$ are scaled copies of $\mathbb{P}^2$, each being the region where zero weight is attached to a given case. For the same reason, the four faces of $\mathbb{P}^4$ are scaled copies of $\mathbb{P}^3$, similar results holding in general.

4.5 A smooth reformulation

Now, exploiting (3), we define the *case sensitivity function* $T(\cdot)$ for the statistic $T[\cdot]$ via $T(p) := T[\widehat{F}(p)]$. Similarly, we define the *smooth* target function $t(\cdot)$ via $t(p) := t[\widehat{F}(p)]$. In particular, $t_{MCD}(p) = \log(\det(\text{cov}[\widehat{F}(p)]))$, while

$t_{Cook}(p) = (ks^2)^{-1}(\widehat{\beta}(p) - \widehat{\beta})^T X^T X(\widehat{\beta}(p) - \widehat{\beta})$, where $\widehat{\beta}(p) := \beta[\widehat{F}(p)]$.

The final relaxation step is to embed Problem 1 in:

Problem 4.1. *($O(n)$ smooth reformulation of Problem 3.1)*
Optimise $t(p)$ over $p \in \mathbb{P}^n_{-m} \equiv \mathbb{P}^n_h$.

It follows at once that any concave (respectively, convex) smooth target function $t(\cdot)$ attains its minimum (respectively, maximum) over the feasible region $\mathbb{P}^n_{-m} \equiv \mathbb{P}^n_h$ of Problem 4.1 at a member of the feasible region $\mathbb{V}^n_{-m} \equiv \mathbb{V}^n_h$ of Problem 3.1 and, in the strict case, only at such a vertex.

In particular, [7] show that $t_{MCD}(\cdot)$ is concave, exploiting this in their *smooth*-MCD algorithms. Although its convexity in a neighbourhood of p_0 need not extend to the whole feasible region of Problem 4.1, [4] present numerical results which support the conjecture that p-generalised Cook's distance $t_{Cook}(\cdot)$ enjoys similar extremal properties (as they note, it would be helpful to have either a proof of – or counterexample to – such a conjecture). We note, in passing, that further positive evidence for it turns up in Figure 3 of the following section.

5 Visual displays of multiple case effects

One outcome of the above relaxation strategy is the availability of visual displays offering insight into the nature and variety of multiple case effects that can occur in different contexts. We focus here on graphs of $t_{Cook}(\cdot)$ in the linear model, following [10] from which Figure 3 is taken.

For all but the smallest values of n, direct visualisation of the graph of any smooth target function $t(\cdot)$ over $\mathbb{P}^n$ – or one of its subsets $\mathbb{P}^n_{-m}$ – is prevented by the fact that each has dimension $(n-1)$. Instead, the approach adopted here uses tripartitions of N as devices providing informative triangular subsets of $\mathbb{P}^n$, over which the graph of $t(\cdot)$ can then be displayed. The key idea is to attach *equal* probability weight to cases in the same member of a tripartition. This turns out to be a rich enough structure to provide insight into a range of multiple case effects – allowing us, in effect, to *see* the nature of each, and their variety.

5.1 Tripartitions

Suppose then that $\mathcal{M} := \{M_r : r = 1,2,3\}$ is a given partition of N into three disjoint subsets, with $m_r := |M_r| > 0$ and $\sum_r m_r = n$, and let

$$\mathbb{T} = \mathbb{T}(\mathcal{M}) := \{p \in \mathbb{P}^n : [i \in M_r,\, j \in M_r] \Rightarrow p_i = p_j\}.$$

It follows that $\mathbb{T}$ is the convex hull of $\{p_{M_r} : r = 1,2,3\}$. That is, $\mathbb{T}$ is the triangle which has these three points as vertices which, when convenient, we abbreviate to $\{M_r\}$. Otherwise said, $p \in \mathbb{P}^n$ belongs to $\mathbb{T}$ if and only if, for some $\pi \equiv (\pi_r) \in \mathbb{P}^3$, $p = \sum_r \pi_r \, p_{M_r}$. In this case, $\pi = \pi(p)$ is *unique*, $\pi_r(p)$ being the total probability assigned (equally) by p to the m_r cases in M_r.

Accordingly, we may identify $\mathbb{T}$ with $\mathbb{P}^3$ via the bijection $p \leftrightarrow \pi(p)$. For example, $p_0 \leftrightarrow (\kappa_r)$, where $\kappa_r := m_r/n$ is the proportion of cases in M_r. However, whereas $\mathbb{P}^3$ is a fixed equilateral, the shape and size of $\mathbb{T}$ vary with the $\{m_r\}$. Nevertheless, important inclusions, collinearities and orthogonalities in $\mathbb{P}^3$ survive in $\mathbb{T}$ for every $\mathcal{M}$.

Two obvious cyclic permutations applying, the identity:

$$p_{-M_1} = (1 - \kappa_1)^{-1}(\kappa_2 p_{M_2} + \kappa_3 p_{M_3})$$

shows that p_{-M_1} lies on the M_2M_3 side of $\mathbb{T}$, being closer to whichever vertex labels the larger number of cases. In particular, writing $p_r(\lambda) := (1 - \lambda)p_{-M_r} + \lambda p_{M_r}$, the line segment $\mathbb{L}_r := \{p_r(\lambda) : \lambda \in [0, 1]\}$ lies in $\mathbb{T}$, all three such meeting at p_0 by (5). Again, using Section 4.2, each $\mathbb{L}_r$ is orthogonal to the side of $\mathbb{T}$ containing p_{-M_r}, $\mathbb{S}_{-r}$ say, along which probability weight is traded between the other two subsets. Thus, the probability attached to M_r increases linearly along $\mathbb{L}_r$ from zero at the p_{-M_r} end to unity at the other. Indeed, for each $\lambda \in [0, 1]$, this probability is constant at the value λ for all points in $\mathbb{T}$ on the line through $p_r(\lambda)$ parallel to $\mathbb{S}_{-r}$. In particular, it vanishes on $\mathbb{S}_{-r}$.

5.2 Four multiple case effects in the linear model

[3] and [11] discuss a variety of possible effects that a pair of cases may have on Cook's distance. Here, with M_3 representing a convenient 'null' data set, and restricting ourselves to the special case $m_1 = m_2 = 1$ (for a fuller account, see [10]), we consider four effects defined in the table below, and illustrated in the corresponding rows of Figure 3:

	Effect	**Joint presence of M_1 and M_2 ...**
(a)	Masking	. . . conceals presence of either
(b)	Cancellation	. . . has no effect on fitted line
(c)	Swing	. . . swings fitted line, (intercept ∼ unchanged)
(d)	Raise & Lower	. . . translates fitted line, (slope ∼ unchanged)

For clarity, stylised simple linear regression data sets are used, shown in the middle column of Figure 3. In each case, M_3 contains $m_3 = 20$ points, comprising five replicates at each corner of the square $\{\pm 1\}^2$, whose fitted line is the horizontal axis. Both M_1 and M_2 consist of a single point at the corner of $\{\pm 4\}^2$ indicated.

The righthand column of Figure 3 gives the corresponding graph of $t_{Cook}(\cdot)$ over $\mathbb{T}$, limits being used where needed (since, of course, a line cannot be fitted to a single case). Some linear rescaling between plots has been applied, both vertically and horizontally, to enhance their visual clarity (a minor cost being some loss of visual perception that the angle at M_3 exceeds 87°). Note that p_0 (corresponding to $\widehat{F}$) is close to M_3, being just one-eleventh of the way along the line $\mathbb{L}_3$ joining M_3 to the midpoint of the opposite side. The

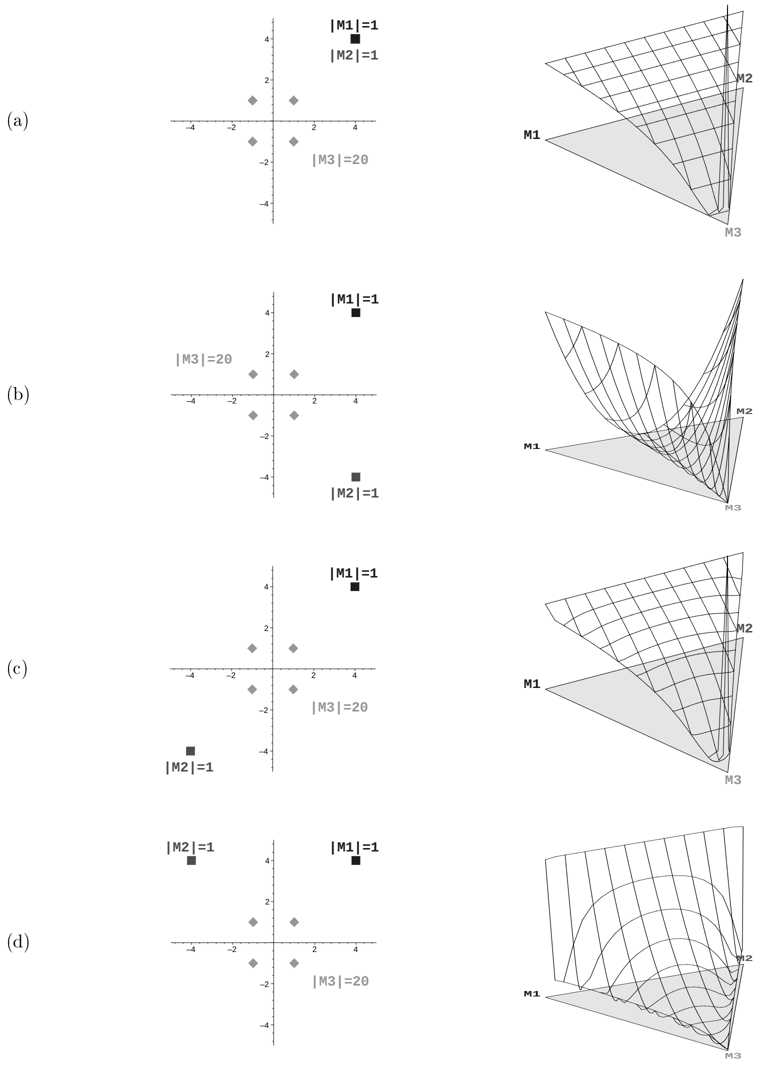

Figure 3: Four multiple case effects in the linear model: (a) masking, (b) cancellation, (c) swing and (d) raise & lower.

inbuilt $M_1 - M_2$ symmetry is evident throughout. Overall, the four graphs have visibly different *shapes*, discussed next:

(a) Masking. The ‘spike’ at M_3 reflects the dominant effect of removing both M_1 and M_2, while the parallelism of the contours to $\mathbb{S}_{-3}$ corresponds to the fact that there is, of course, no effect here in trading weight between these sets.

(b) Cancellation. The contours of $t_{Cook}(\cdot)$ here are straight lines fanning out from M_3. In particular, $\mathbb{L}_3$ is the zero height contour, since varying π_3 while keeping $\pi_1 = \pi_2$ has no effect on the fitted line. Trading weight between M_1 and M_2 now has a quadratic, globally dominant, effect.

(c) Swing. The overall shape of the surface here is very similar, but not identical, to that in the masking case. The 'spike' at M_3 remains dominant, but the surface contours are no longer parallel to $\mathbb{S}_{-3}$.

(d) Raise & Lower. This is perhaps the most interesting graph. As is intuitive from the data, the dominant global effect occurs along $\mathbb{S}_{-3}$. Looking at the surface, we see two 'troughs'. These run along $\mathbb{L}_1$ and $\mathbb{L}_2$, showing that varying the weight on one of these subsets alone has little effect. The contours of $t_{Cook}(\cdot)$ are parallel to $\mathbb{S}_{-3}$ when there is little weight on M_3, but become more curved as π_3 increases. Locally to p_0, trading weight between M_1 and M_2 produces the largest effects.

6 A relaxed diagnostic approach to detecting heavy mutual masking

Multiple case effects can be strong and yet intrinsically hard to detect with standard diagnostic procedures, while the burden of full enumeration increases combinatorially with m. Heavy mutual masking is a well-known example, challenge data sets comprising 60% of cases from one distribution and 40% from a second, suitably remote from the first. [4] present a widely applicable, relaxed, two-stage approach to detecting such effects (cf. [2]), briefly reviewed here.

Adopting the standard assumption in the literature that at most half the cases are discordant from a common pattern followed by the rest, Stage I consists on maximising (say) a suitable target function $t(\cdot)$ over $\mathbb{P}^n_{-m}$, with m the integer part of $n/2$, the optimum being known or assumed to occur at a vertex. This corresponds precisely to missing out a specified subset $\widehat{M}$ of m cases. The (in)equality constraints defining $\mathbb{P}^n_{-m}$ being linear, this relaxed optimisation can be carried out with standard software (or some alternative, as indicated in Section 7). The assumed internal consistency of the cases in $\widehat{H} := \widehat{M}^c$ may also be checked.

Stage II back-checks for swamping. That is, for cases in $\widehat{M}$ which are *not* inconsistent with the pattern followed by the majority. [4] envisage doing this *separately* for each case in $\widehat{M}$, although a *sequential* approach is possible. Having augmented $\widehat{H}$ with any such cases, a final check on their internal consistency can be made while, if required, the possibility of further structure within the cases in $\widehat{M}$ may be made.

[4] report encouraging results for this general strategy, using regression as a test problem and several forms of challenge data set. Specifically, they maximise $t_{Cook}(\cdot)$ in Stage I, using the mean shift outlier test in Stage II.

Finally, a remark on local maxima. On those occasions when the final check for a common pattern fails, the possibility that this is because omission of $\widehat{M}$ is a particular form of non-trivial local maximum can be easily explored as follows. The value of $t(\cdot)$ there can be compared to that where $\widehat{M}$ is held onto. If this is greater, replacing $\widehat{M}$ by its complement, and then continuing as before, is indicated. On the relatively few occasions where it was needed in their regression study, [4] report that this simple strategy was successful. The original $\widehat{M}$ containing no mutually masked cases, moving to its complement produced a large increase in t_{Cook} and led again to correct identification of the structure in the data.

7 Developments in relaxed robust computation

Consider now minimisation over $\mathbb{P}_h^n$ of the particular function $t(\cdot) = t_{MCD}(\cdot)$ as an exemplar of the class of robust estimation procedures that can be defined in this way. Algorithms for the MCD problem include those reported in [1], [8], [9] and [12]. These are all *discrete* in the sense that they address Problem 3.1, iteratively 'jumping' between members of $\mathbb{V}_h^n$.

We briefly sketch here some of the work reported in [6] and, more fully, in [7], recalling that these papers show that $t_{MCD}(\cdot)$ is, indeed, concave. Collectively, the new approaches reported therein are referred to as *smooth*-MCD algorithms.

Figure 4 shows two views of the same t_{MCD} surface over $\mathbb{P}_2^3$ for univariate data. This simple example offers some general geometric insight: the graph of t_{MCD} contains multiple local minima, separated by hills, with corresponding limitations for any purely descent algorithm. In particular, it motivates the use of *swapping* strategies aimed at 'getting you over a hill to a lower valley'. At the same time, the swapping strategy employed by the feasible subsets algorithm – while optimal in its own terms – is relatively expensive to perform and may not always be needed, in the sense that not every vertex is a local minimum.

Again, [4] note the benefits of using explicit gradient information, when this is available. [5] develop local *projected* (here, *centred*) Taylor expansions in generality. They show that such expansions are possible even when, as here, one or more constraints (here, $p^T 1_n = 1$) imply that there are *no* open sets in a function's domain (here, a subset of $\mathbb{P}^n$). Indeed, they exist uniquely under mild conditions and can be used to guide algorithms downhill, in the usual way. They also provide also a useful necessary and sufficient condition for a vertex in $\mathbb{V}_h^n$ to be a local minimum, for any t. In the t_{MCD} case, it is shown that these are precisely the points where the C-steps of FAST-MCD converge.

Now, conditional on robustness, there are two key performance criteria in any problem such as this: speed and optimality. Perfection (*i.e.* instant, global optimality!) being unachievable, different algorithms aim for it, while striking different trade-offs between these criteria. Accordingly, the state-of-

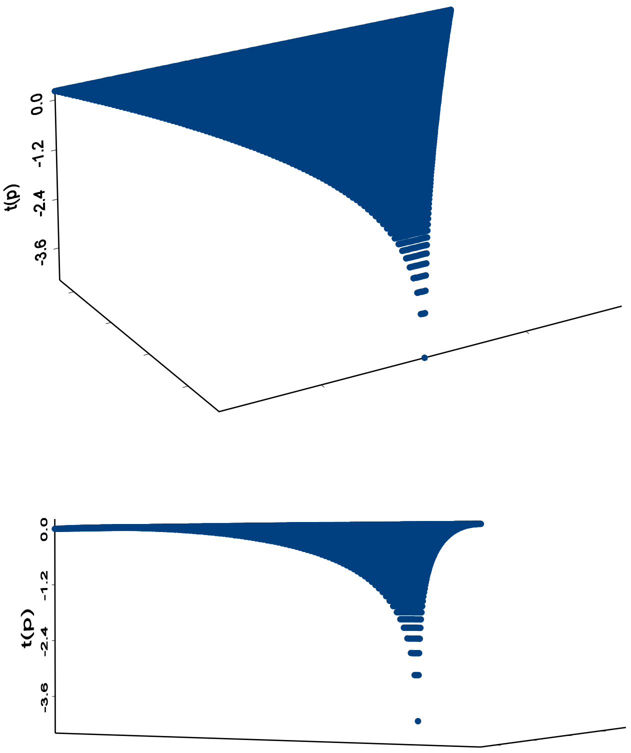

Figure 4: Two views of a t_{MCD} surface ($n = 3$; $k = 1$).

the-art can be thought of as a boundary of limiting speed/optimality trade-offs that are currently feasible, the different algorithms appearing at different points along it.

[6] and [7], to which the reader is referred for further details, exploit features of the case sensitivity function approach – in particular, insights from (convex) geometry, the power of analysis, and a unifying structure – both to understand better *why* current algorithms occur where they do along this boundary, and to add new algorithms that fill it out and/or nudge it nearer to perfection.

COMPSTAT'2004 Symposium

ON THE BOOTSTRAP METHODOLOGY FOR FUNCTIONAL DATA

Antonio Cuevas and Ricardo Fraiman

Key words: Bootstrap validity, bootstrap consistency, bounded Lipschitz metric, differentiable functionals, functional data analysis.

COMPSTAT 2004 section: Functional data analysis.

Abstract: The current theory of statistics with functional data provides only a few results [21] of asymptotic validity for the bootstrap methodology. Roughly speaking, these validity results guarantee that the bootstrap versions of the sampling distribution of a statistic tend (as the sample size increases) to the same limit as the true sampling distributions. From a computational and practical point of view, such results have an special interest when dealing with functional data, as the distributional properties of the statistics are usually difficult to handle in this setup. Of course, the point is that while the true sampling distributions are usually very difficult to handle, the corresponding bootstrap versions can be approximated with arbitrary precision.

In this work, a uniform inequality is obtained for the Bounded Lipschitz distance between the empirical distribution of a function-valued random variable and the corresponding underlying distribution that generates the sample. As a consequence, a result of bootstrap validity (consistency) is obtained for functional statistics defined from differentiable operators.

Our proof is based on the use of a differential methodology for operators, similar to that used by Parr [19], and relies also on a result of empirical processes theory proved by Yukich [29].

1 Introduction

We deal here with the statistical setups where the available sample information consists of (or can be considered as) a set of functions. Depending on the approach and on the assumed structure of the data (which come often in a discretized version) this statistical field is called "longitudinal data analysis" or "functional data analysis" (FDA). We will follow here a purely functional approach which entails to consider the available data as true functions and, as a consequence, to define and motivate the methods in a functional framework.

The books by Ramsay and Silverman [22], [23] have greatly contributed to popularize the FDA techniques among the users, offering a number of appealing case studies and practical methodologies. Simultaneously, this increasing popularity motivates the need of a solid theoretical foundation for the FDA methods, as many basic issues (concerning, e.g., the asymptotic behavior) are often rather involved in the FDA setup.

In general terms, the FDA theory is still incomplete as many topics remain unexplored from the mathematical point of view. Some theoretical developments with functional data have been made in fields as principal component analysis ([5], [11], [17], [20], [25]), linear regression ([6], [7], [8], [9], [13]), data depth [14], clustering [1] and anova models ([12], [18], [10]).

An important issue in this field has to do with the asymptotic validity (usually called consistency) of bootstrap procedures for functional data. This looks as an interesting research line since the exact calculation of sampling distributions in FDA problems presents an obvious difficulty so that the bootstrap methodology turns out to be often the only practical alternative. Of course, the point is that while the sampling distribution of a function-valued statistic can be formally defined in the same way as the analogous concept for a real-valued statistic, the effective calculation and handling of such "functional" sampling distributions is usually very difficult since they are in fact probability measures defined on function spaces. Thus the case for using bootstrap versions is quite strong as they are discrete measures which can be in turn approximated by resampling with arbitrary precision. An example of the use of resampling methods in a functional data framework can be found in [10].

The classical works by Bickel and Friedman [3], Singh [26] and Parr [19], among others, have established the validity of the bootstrap methodology, in the case of real variables, for a number of useful statistics, including the sample mean and those generated by differentiable statistical functionals. The functional counterpart of this theory is much less developed. However, Giné and Zinn [15] have proved, in a very general setup, a bootstrap version of Donsker theorem for the empirical processes. A partial extension of this result is given in [24]. Politis and Romano [21] have proved the consistency of the bootstrap for the sample mean in the case of uniformly bounded functional variables taking values in a separable Hilbert space imposing very general assumptions on the dependence structure which include the independent case to be considered here. The main purpose of this paper is to partially extend this consistency result to (function-valued) statistics defined from differentiable operators. So we are concerned here with a functional version of some classical validity theorems, as those in [19] or [2], where the methodology based on functional differentiation plays a relevant role.

More precisely, we want to get a bootstrap validity result for statistics of type $T(P_n)$ where T is a differentiable operator (taking values in a functional space) and P_n is the empirical distribution associated with a sample $X_1, \ldots, X_n$ of n functions drawn from a common distribution P. In practical terms, this result will establish that the distribution of $\sqrt{n}(T(P_n) - T(P))$ can be approximated by its corresponding bootstrap version in $\sqrt{n}(T(P_n^*) - T(P_n))$, where P_n^* is the empirical distribution based on an artificial (bootstrap) sample drawn from the original sample. Our approach is much in the spirit of Theorem 4 in [19] although the fact that we are dealing with functional data entails some additional technical complications.

Our main result establishes that $\sqrt{n}(T(P_n) - T(P))$ and $\sqrt{n}(T(P_n^*) - T(P_n))$ converge (weakly) to the same limit. It is proved in Section 3 below. An essential auxiliary step in the proof of this theorem is a uniform (universal) bound, similar to the classical Dvoretzky-Kiefer-Wolfowitz (DKW) inequality (see, e.g., [27]), for the distance $d(P_n, P)$ between P_n and P. It will be established in Section 2. This bound is universal in the sense that it does not depend on the underlying distribution P; this is crucial in a bootstrap setup as the bound for $d(P_n, P)$ will also hold for its bootstrap counterpart $d(P_n^*, P_n)$. Let us recall that P stands here for a probability distribution in a function space so that in order to establish a DKW-type inequality we would need a distance $d(P_n, P)$ compatible with the weak convergence and making sense in a functional framework. We will use the so-called Bounded Lipschitz metric defined by

$$d(P_n, P) = \sup_{f \in \mathcal{F}} |\int f\, dP_n - \int f\, dP|, \tag{1}$$

P being a probability on a normed space $\mathcal{X}$, P_n a empirical drawn from P and

$$\mathcal{F} = \{f : \mathcal{X} \longrightarrow \mathbb{R} :\ f \text{ is Lipschitz with } \|f\|_\infty \leq 1 \text{ and Lipschitz constant } 1\}. \tag{2}$$

2 A uniform inequality for the Bounded Lipschitz metric

Let P be a probability on a Banach space $\mathcal{X}$ whose support is included in the ball $B(0, r) \subset \mathcal{X}$. Let P_n be the empirical distribution associated with a sample $X_1, \ldots, X_n$ drawn from P. Let d denote the Bounded Lipschitz metric defined in 1). We next show a version of the DKW inequality for $d(P_n, P)$.

Theorem 2.1. *For all $\epsilon > 0$ there exists $K = K(\epsilon)$ such that*

$$\mathbb{P}\left\{\sqrt{n}\, d(P_n, P) > K\right\} < \epsilon, \text{ for all } n, \text{ for all } P \text{ with support in } B(0, r). \tag{3}$$

Proof: This will result as a direct consequence of a exponencial bound obtained by Yukich ([29], Theorem 1) by a empirical process methodology.

Define the ϵ-entropy $N(\epsilon, \mathcal{F})$ by

$$N(\epsilon, \mathcal{F}) = \min\{m : \text{there exist } f_1, \ldots, f_m \in \mathcal{F} \text{ such that } \sup_Q \min_i \|f - f_i\|_Q^2 < \epsilon^2,\ \forall f \in \mathcal{F}\}, \tag{4}$$

where the supremum on Q is taken on the set of all the probability distributions with finite support and $\|f\|_Q^2 = \int f^2 dQ$ is the $L^2(Q)$-norm.

Yukich's Theorem establishes that if the envelope function $F := \sup\{|f(x)| : f \in \mathcal{F}\}$ fulfills $F \leq 1$ and there are constants $0 < \epsilon_0 \leq 1$, $0 < \delta < 1$, and $C \geq 1$ such that

$$N(\epsilon, \mathcal{F}) \leq \exp(C/\epsilon^{2-\delta}),\ \forall \epsilon,\ 0 < \epsilon \leq \epsilon_0, \tag{5}$$

then

$$\mathbb{P}\left\{\sqrt{n}\, d(P_n, P) > M\right\} \leq 8 \exp(-M^2/5)\ \forall n \geq 1, \tag{6}$$

for all M greater than, or equal to, some constant $M(\delta, C, \epsilon_0)$ whose explicit expression is given in the statement of Theorem 1 in [29].

In fact, the proof will be more simple and intuitive by replacing the distances $\|f - f_i\|_Q^2$ in (5) by the supremum distances $\|f - f_i\|_\infty$. As a consequence, we will prove a stronger version of condition (5), by taking the supremum in (5) over all the possible probability measures (instead of just considering those of finite support). The reason is that we in fact will provide a bound for $\|f - f_i\|_\infty$ and, as the Q's are probability measures and the f's are bounded, we will also get bounds for the $L^2(Q)$ norms.

Given $0 < \epsilon < 1$, divide the interval $[-1, 1]$ (where the functions $f \in \mathcal{F}$ take values) into $q = [2/\epsilon] + 1$ subintervals with extreme points in the set

$$R_\epsilon = \{0, \epsilon, -\epsilon, 2\epsilon, -2\epsilon, \ldots, -1, 1\}.$$

Let us also consider a finite sequence of q_1 balls defined by

$$B(0, \epsilon) \subset B(0, 2\epsilon) \subset \ldots \subset B(0, r)$$

Observe that q_1 is either r/ϵ or $r/\epsilon + 1$.

Let $\mathcal{F}_m = \{f_1, \ldots, f_m\}$ be a class of functions taking values in R_ϵ such that every f_i is constant on the domains $B(0, \epsilon)$, $B(0, 2\epsilon) \setminus B(0, \epsilon)$, $B(0, 3\epsilon) \setminus B(0, 2\epsilon)$,... and the differences between the values of f_i on two adjacent domains (for example on $B(0, \epsilon)$ and $B(0, 2\epsilon) \setminus B(0, \epsilon)$) is at most ϵ. Note that $\#(\mathcal{F}_m) = m \leq q3^{q_1}$.

We have that for every $f \in \mathcal{F}$ there exists $i \in \{1, \ldots, m\}$ such that $\|f - f_i\|_\infty \leq 2\epsilon$. Indeed, given $f \in \mathcal{F}$, there exists $y_0 \in R_\epsilon$ such that $|f(0) - y_0| < \epsilon$. Now let $\mathcal{G}_0$ be the set of all functions f_i in $\mathcal{F}_m$ such that $f_i(0) = y_0$. As f has Lipschitz constant 1, we have $\sup_{x \in B(0,\epsilon)} |f(x) - g(x)| \leq 2\epsilon$. On the other hand, as

$$\sup_{x \in B(0,\epsilon)} f(x) \leq f(0) + \epsilon \text{ and } \inf_{x \in B(0,\epsilon)} f(x) \geq f(0) - \epsilon,$$

the class $\mathcal{G}_1$ of all functions $g \in \mathcal{G}_0$ such that $\sup_{x \in B(0,2\epsilon)} |f(x) - g(x)| \leq 3\epsilon$ is not empty. In a similar way, by the Lipschitz property of f, we can choose a non-empty class $\mathcal{G}_2 \subset \mathcal{G}_1$ such that $\sup_{x \in B(0,3\epsilon)} |f(x) - g(x)| \leq 3\epsilon$, for all $g \in \mathcal{G}_2$. By recurrence, define the (non-empty) class $\mathcal{G}_{q_1 - 1}$ of functions such that $\sup_{x \in B(0,r)} |f(x) - g(x)| \leq 3\epsilon$ for all $g \in \mathcal{G}_{q_1 - 1}$.

Thus we have shown

$$N(3\epsilon, \mathcal{F}) \leq q3^{q_1} \leq \left(\frac{2}{\epsilon}+1\right)3^{r/\epsilon+1} \leq \exp\left(\frac{C}{\epsilon^{1+\eta}}\right), \tag{7}$$

for all $\eta \in (0,1)$, and $C=(2r)^{1+\eta}\log 3$. Finally, using Yukich's [29] Theorem 1, (observe that $2-\delta$ in (5) has been denoted $1+\eta$ in (7)), we conclude (6).

3 A bootstrap validity result for functional data

We establish now a validity result for function-valued statistics defined on functional data. The methodology will be based on differentiability arguments very much in the line of [19]. As pointed out in the introduction, the functional version of the DKW-inequality obtained in the previous section will be a crucial step in the proof.

Theorem 3.1. *Let $\mathcal{H}$ be a bounded set in a Banach space (endowed with the Borel σ-algebra). Let $\mathcal{P}(\mathcal{H})$ be the set of all probability measures whose support is included in $\mathcal{H}$. Let T be an operator defined in $\mathcal{P}(\mathcal{H})$ with values in another Banach space $\mathcal{C}$. Denote by P_n the empirical measure corresponding to i.i.d. $\mathcal{H}$-valued variables with distribution P. Let P_n^* be the corresponding empirical associated with a bootstrap sample $X_1^*,\ldots,X_n^*$.*

(a) Assume that T satisfies the following differentiability condition for some given $P \in \mathcal{P}(\mathcal{H})$,

$$T(Q)=T(P)+T'_P(Q-P)+o(d(Q,P)), \tag{8}$$

where the remainder term $o(d(Q,P))$ denotes, as usual, an operator such that

$$\lim_{Q\to P}\frac{o(d(Q,P))}{d(Q,P)}=0,$$

and $T'_P : \mathcal{P}(\mathcal{H}) \longrightarrow \mathcal{C}$ is a linear (not necessarily continuous) operator for which is valid the bootstrap for the sample mean in the sense that

$$\sqrt{n}T'_P(P_n^*-P_n) \text{ converges weakly a.s. to the same limit as } \sqrt{n}T'_P(P_n-P). \tag{9}$$

Then,

$$\sqrt{n}\,(T(P_n^*)-T(P_n)) \xrightarrow{w} Z, \tag{10}$$

Z being the weak limit of $\sqrt{n}\,(T(P_n)-T(P))$.

(b) Assume that the operator T takes values in a separable Hilbert space $\mathcal{C}$ and it is differentiable in the sense (8). If the function $\Psi(x)=T'_P(\delta_x-P)$ is bounded (δ_x being the degenerate distribution at x), then condition (9) is fulfilled and therefore (10) holds.

Proof: (a) The result is a simple consequence of Theorem 2.1. Indeed, using the differentiability assumption (8),

$$T(P_n) = T(P) + T'_P(P_n - P) + o(d(P_n, P))$$

and

$$T(P_n^*) = T(P) + T'_P(P_n^* - P) + o(d(P_n^*, P)).$$

Hence

$$\sqrt{n}\,(T(P_n^*) - T(P_n)) = \sqrt{n}T'_P(P_n^* - P_n) + \sqrt{n}o(d(P_n^*, P)) + \sqrt{n}o(d(P_n, P)). \tag{11}$$

The first term in the right-hand side tends, by assumption (9), to the same limit as $\sqrt{n}\,(T(P_n) - T(P))$. Also, from the triangle inequality, $\sqrt{n}d(P_n^*, P)$ is bounded in probability (uniformly on P), as both $\sqrt{n}d(P_n^*, P_n)$ and $\sqrt{n}d(P_n, P)$ are. Therefore the remainder terms in (11) tend to zero in probability almost surely, which concludes the proof of (a).

(b) Since the operator T'_P is linear,

$$\sqrt{n}T'_P(P_n^* - P_n) = \sqrt{n}\left(\sum_{i=1}^{n} \Psi(X_i^*) - \Psi(X_i)\right).$$

Then, we may apply Theorem 3.1 in [21] to conclude that (9), and therefore (10), holds in this case.

Some final remarks:

(i) The hypothesis of uniform boundedness is not very restrictive in practice. It is in some sense similar to the assumption of compact support in nonparametric estimation. If one is willing to renounce to the usual gaussian models (which is also the case in nonparametrics) the hypothesis of boundedness looks quite natural as every observable phenomenon provides in fact observations taking values in a bounded domain (whose limits are imposed by the measurement instruments). From a technical point of view, boundedness is required for Theorem 2.1 (in order to be able to apply the entropy argument involved in the proof) and also for the result by Politis and Romano ([21], Theorem 3.1) used in the proof of part (b). Note also that the boundedness condition must be fulfilled in the metric of the space where the random elements X_i take values. For example, if this space is $L^2[a,b]$ the assumption that $X_i \in \mathcal{H}$, where $\mathcal{H}$ is bounded in $L^2[a,b]$, does not entail that the realizations of X_i have to be bounded in the supremum sense.

(ii) The above theorem can be applied, for example, to show the validity of the bootstrap for statistics of type $g(\bar{X})$ which may arise in different problems theoretical and applied. In particular, this type of statistics could appear if we are looking for robust alternatives (similar to M-estimators) for the sample mean in a functional data setup. Such functional statistics are often called Z-estimators; see [28], ch. 3.3. Since they are usually defined in an implicit way (as the solution of a functional equation) the effective use of our validity theorem for them would require an additional result in order to ensure that the required differentiability conditions are fulfilled. A detailed study on the asymptotic behavior of Z-estimators can be found in [30].

(iii) As an example of a differentiable operator $T = T(P)$ let us consider the variance operator

$$T(P)(t) = \int X^2(t,\omega)dP(\omega) - \mu_P^2(t),$$

where $X(t) = X(t,\omega)$ is a process with distribution P and mean function $\mu_P(t)$. It can be easily seen that the differential T'_P is the linear operator given by

$$T'_P(Q)(t) = \int X^2(t,\omega)dQ(\omega) - \mu_P^2(t).$$

A NOVEL APPROACH TO PARAMETRIZATION AND PARAMETER ESTIMATION IN LINEAR DYNAMIC SYSTEMS

Manfred Deistler, Thomas Ribarits and Bernard Hanzon

Key words: Identification, parametrization, multivariate state space systems.

COMPSTAT 2004 section: Time series analysis.

Abstract: We describe a novel approach, called data driven local coordinates (DDLC), for parametrizing linear systems in state space form, and we analyze some of its properties which are relevant for e.g. maximum likelihood estimation. In addition we describe how this idea can be used for a concentrated likelihood function, obtained by a least squares type concentration step, which gives the so called sls (separable least squares) DDLC approach. Both approaches give favourable results in numerically optimizing the likelihood function in simulation studies.

1 Introduction

Despite the fact that identification (in the sense of model selection and parameter estimation) of linear dynamic systems is a quite mature subject now, there still exist severe problems in applying identification procedures, in particular in the multivariable case.

As is well known, one of the major problems is the 'curse of dimensionality'; in the (linear) multivariable case the dimension of the parameter space is a quadratic function of the number of outputs, unless additional restrictions, e.g. of factor analysis – or reduced rank regression type or of 'structural' type are imposed.

In this contribution our main focus will be on another important issue. For simplicity of notation, we only consider linear systems with unobserved white noise inputs. Then the most common models are AR, ARMA and state space (StS) models. In applications AR models still dominate, mainly for two reasons:

(i) The structure of parameter spaces for AR models is much simpler than in the case of ARMA and StS models. In particular, in the most common parametrization of AR(p) models (where the coefficient matrix of the present output is the identity) the entries of all other coefficient matrices are free parameters (of course satisfying the stability condition) and identifiable, including the parameters corresponding to the lower dimensional systems.

(ii) The maximum likelihood method gives least squares-type estimators, which are asymptotically efficient and numerically robust and fast; in other words parameter estimation is simple.

On the other hand ARMA and StS systems are more flexible and thus in many cases less parameters may be required.

As is well known every causal (stable) rational transfer function (describing the input-output behaviour of a linear system) can be described by an ARMA or a StS system; in this sense ARMA and state space system are equivalent. However, when embedded in 'naive' parameter spaces, typically the classes of observational equivalence are larger in the state space case. For instance, in the univariate case, for ARMA (n, n) systems, the equivalence classes are singletons in $\mathbb{R}^{2n}$ for the ARMA case (unless common factors occur), whereas they are n^2 dimensional manifolds for (minimal) state space systems in the embedding $\mathbb{R}^{2n+n^2}$. Identifiability is obtained by selecting representatives from equivalence classes and the advantage of large equivalence classes lies in the possibility to select (in some sense) better representatives. This is the reason why we here restrict ourselves to StS systems.

Both, typical ARMA and StS model classes suffer from the fact that the parametrization problem is non-trivial and that in general no explicit formula for the maximum likelihood estimator exists. For instance, in general, the boundary of the identifiable parameter spaces contains lower dimensional systems, which are not identifiable and algorithmic problems occur if the true system is close to the boundary. Some of these problems cannot be fully understood in the framework of the usual asymptotic analysis or are even better reflected by numerical rather than by statistical analysis. In a certain sense, asymptotic properties are parametrization independent, to be more precise:

(i) Under general assumptions, consistency can be shown for transfer functions in a coordinate-free way (see e.g. [2]); if we have identifiable parameter spaces and the function attaching parameters to transfer functions is continuous, then the corresponding parameter estimates are consistent, independent of the choice of the particular parametrization.

(ii) Under certain conditions the asymptotic variances of the maximum likelihood estimators change in a well defined way.

On the other hand a number of numerical properties are parametrization dependent. Numerical problems may arise for instance if the grid is too coarse in relation to the curvature of the likelihood function or if the likelihood function has 'long valleys' in relevant parts of the parameter space. It can be shown (see e.g. [4], [8]) that the choice of the parametrization has a severe impact on e.g. success rates or the number of iterations in numerical optimization of the likelihood function.

In the following we present two 'data driven' parametrizations as a contribution to the aim of increasing the 'market penetration' for state space modelling in applications.

2 Parametrization by state space systems

A common approch is to commence from the model class U_A of all causal and rational $s \times s$ transfer functions

$$k(z) = \sum_{j=0}^{\infty} K_j z^j \tag{1}$$

For a number of reasons, e.g. in order to obtain finite dimensional parameter spaces, U_A has to be broken into bits, where each bit is parametrized separately. In many cases, in a first step, the subclasses $M(n)$ of all transfer functions of order n are considered. Here we deal with parametrizations of $M(n)$ via state space systems (in innovations form):

$$\begin{aligned} x_{t+1} &= Ax_t + B\varepsilon_t && (2)\\ y_t &= Cx_t + \varepsilon_t && (3) \end{aligned}$$

where y_t is the s-dimensional observed output, x_t is the n-dimensional state and ε_t is (unobserved) s-dimensional white noise with $E\varepsilon_t\varepsilon_t' = \Sigma > 0$.

Usually it is assumed that

$$|\lambda_{\max}(A)| < 1 \quad \text{(stability)} \tag{4}$$

and

$$|\lambda_{\max}(A - BC)| < 1 \quad \text{(strict minimum phase assumption)} \tag{5}$$

hold. Here $\lambda_{\max}(D)$ denotes an eigenvalue of D of maximal modulus. However, mainly for the sake of notational simplicity, we here do not impose (4) and (5). For the stable case, the steady state solution of (1) is given by

$$y_t = \sum_{j=1}^{\infty} K_j\varepsilon_{t-j} + \varepsilon_t, \quad K_j = CA^{j-1}B \tag{6}$$

Let $S(n)$ denote the set of all $(A, B, C) \in \mathbb{R}^{n^2+2ns}$ (we identify (A, B, C) with $(vecA', vecB', vecC')'$). Clearly, $S(n) = \mathbb{R}^{n^2+2ns}$ and it can be shown that the set $S_m(n) \subseteq S(n)$ of all minimal (A, B, C) is open and dense in $\mathbb{R}^{n^2+2ns}$. Let us endow U_A with the pointwise topology, i.e. the topology corresponding to the product topology in the space $(\mathbb{R}^{s\times s})^N$ of power series coefficients $(K_j|j \in N)$ of the transfer functions. As can be shown, the closure $\bar{M}(n)$ of $M(n)$ satisfies $\bar{M}(n) = \cup_{i=1}^{n} M(i)$.

Finally, we define the mapping

$$\pi : S(n) \rightarrow \bar{M}(n) \tag{7}$$

by

$$\pi(A, B, C) = C(z^{-1}I - A)^{-1}B = k(z) \tag{8}$$

For describing $M(n)$ by state space systems the following approach (see e.g. [1] and [5]) may be used:

(i) Full state space parametrizations, i.e. $M(n)$ is described by $S_m(n)$. The drawback of this approach is that $S_m(n)$ is non-identifiable. The classes of observational equivalence are given by

$$\mathcal{E}(A, B, C) = \{(TAT^{-1}, TB, CT^{-1} | T \in GL(n)\} \tag{9}$$

and are real analytic manifolds of dimension n^2. Thus there are n^2 unnecessary parameters.

(ii) $M(n)$ can be shown to be a real analytic manifold of dimension $2ns$, which in general cannot be described by one coordinate system. One approach is to use socalled overlapping parametrizations, an alternative approach is the use of canonical forms, such as echelon form. In both cases a model selection procedure has to be applied in order to select a subclass of $M(n)$ from a fixed finite number of subclasses.

(iii) The approach described here, namely data driven local coordinates DDLC, (see [3], [4]) is as follows: We commence from an initial (minimal) $(A, B, C) \in S_m(n)$ and the tangent space to the equivalence class $\mathcal{E}(A, B, C)$ at (A, B, C). (A, B, C) may be obtained by an initial estimate, using e.g. a subspace or an instrumental variable estimation method. Then we take the orthocomplement (in $S(n)$) to the tangent space as (preliminary) parameter space: Let $Q^{\perp}$ denote a $(n^2 + 2ns) \times 2ns$ matrix whose columns form a basis for this orthocomplement. Then we have the parametrization:

$$\begin{aligned} \varphi_D : \mathbb{R}^{2ns} &\rightarrow S(n) \\ \tau_D &\mapsto \begin{pmatrix} vecA(\tau_D) \\ vecB(\tau_D) \\ vecC(\tau_D) \end{pmatrix} = \begin{pmatrix} vecA \\ vecB \\ vecC \end{pmatrix} + Q^{\perp} \cdot \tau_D \end{aligned} \tag{10}$$

The corresponding parameter space $T_D \subseteq \mathbb{R}^{2ns}$ is defined by removing the non-minimal systems and the corresponding space for transfer functions is $V_D = \pi(\varphi_D(T_D))$.

The intuitive motivation behind the $DDLC$ approach is that, due to orthogonality to the tangent space, the numerical properties of optimization based estimators, such as the maximum likelihood estimator, are at least locally favourable. Comparisons with other parametrizations corroborate this notion (see e.g. [4] and [8]). In particular these comparisons show that echelon forms (whose parameters correspond to the usual ARMA parameters) are clearly outperformed. $DDLC$ is now the default option in the system identification toolbox in $MATLAB6.x$. The success of $DDLC$ was the motivation for a careful investigation of the topological and geometrical properties of $DDLC$ relevant for estimation, described in the next section.

3 Topological and geometrical properties of DDLC

Important properties of $DDLC$ are summarized in the following theorem: see [5], [9].

Theorem 3.1. *Let an initial minimal system* (A, B, C) *be given. Then the parametrization by* $DDLC$ *as given in (10) has the following properties:*

(i) T_D *is an open and dense subset of* $\mathbb{R}^{2ns}$*.*

(ii) There exist open neighborhoods $T_D^{loc} \subseteq T_D$ *of* $0 \in T_D$ *and* V_D^{loc} *of* $\pi(A, B, C)$ *in* $M(n)$ *such that* T_D^{loc} *is identifiable,* $V_D^{loc} = \pi(T_D^{loc})$ *and the mapping* $\psi_D^{loc} : V_D^{loc} \to T_D^{loc}$ *defined by* $\psi_D^{loc}(\pi(\tau_D)) = \tau_D$ *is a homeomorphism.*

(iii) For $n > 0$, $\pi(\bar{T}_D)$ *contains transfer functions of lower McMillan degree.*

(iv) There exists an open and dense subset V_D^{fin} *of* V_D *such that for every* $k \in V_D^{fin}$*, the corresponding equivalence class in* T_D *consists of a finite number of points.*

(v) V_D° *is dense in* V_D*, where* V_D° *denotes the interior of* V_D *in* $\mathbb{M}(n)$*. Additionally,* V_D *is open (and trivially dense) in* $\pi(\bar{T}_D)$*, but not necessarily open in* $M(n)$*.*

(vi) $\pi(\bar{T}_D) \subseteq \bar{V}_D$*, where equality can hold, but the inclusion may also be strict.*

In a certain sense this theorem is an analogue to the theorems given in [2] for the overlapping description of $M(n)$ and for echelon forms. We give a short discussion of the consequences of the results of Theorem 3.1:

(i) Openness means that the parameters are free and in particular not restricted to a thin subset of $\mathbb{R}^{2ns}$. This is an important requirement for gradient-type optimization procedures to work properly. Note that openness also holds if the stability assumption (4) and the miniphase assumption (5) are imposed. Clearly then denseness will not hold.

(ii) states that there exist neighborhoods T_D^{loc} and V_D^{loc} where the parametrization is well-posed in the sense of being injective (and thus identifiable) and the parameters are attached to transfer functions in a continuous way. In particular 'coordinate free' consistency of transfer function estimates in V_D^{loc} (see [2]) then implies consistency of the corresponding parameter estimates. However, we have no statements concerning the size of T_D^{loc} and V_D^{loc}, respectively.

(iii) For $n > 0$, the following holds: The closure of the parameter space T_D – note that $\bar{T}_D = \mathbb{R}^{2ns}$ – corresponds to transfer functions of equal *and* lower McMillan degrees. The equivalence classes in $\bar{T}_D \setminus T_D$ are generally given by nonlinear restrictions and are thus difficult to describe.

(iv) In general, T_D is not identifiable; as a 'second best' result, the equivalence classes for a generic subset V_D^{fin} are at least finite and thus consist of isolated points in T_D.

(v) deals with the structure of the set V_D; for a discussion of the relevance of (v) see [9].

(vi) The fact that $\bar{V}_D$ may contain more transfer functions than those described by the closure of the parameter space T_D can effect the actual estimation procedure. In that case the norm of the parameter vector may diverge to infinity whereas the corresponding sequence of transfer functions converges to a well defined transfer function estimate in $M(n)$. Problems of nonconvergence of algorithms due to this phenomenon have actually puzzled researchers in the past when using echelon canonical forms.

4 Separable least squares for ML-type estimation

One way to reduce the dimension of the parameter space over which a likelihood function has to be numerically optimized is to concentrate out parameters which enter linearly by an (ordinary or generalized) least squares step. For the concentrated likelihood again the $DDLC$-approach is used; see [5], [8] and [7].

Here, we commence from the inverse state space system

$$\begin{aligned} x_{t+1} &= \overbrace{(A - BC)}^{\bar{A}} x_t + \overbrace{B}^{\bar{B}} y_t \\ \varepsilon_t &= \underbrace{-C}_{\bar{C}} x_t + y_t \end{aligned} \tag{11}$$

and the corresponding parameters $(\bar{A}, \bar{B}, \bar{C})$ are in a one-to-one relation with

(A, B, C). The (Gaussian) conditional likelihood function is of the form

$$L_T(\bar{A}, \bar{B}, \bar{C}, \Sigma) = \log\det\Sigma + \frac{1}{T}\sum_{t=1}^{T} tr\left\{\varepsilon_t(\bar{A}, \bar{B}, \bar{C})\varepsilon_t(\bar{A}, \bar{B}, \bar{C})'\Sigma^{-1}\right\} \quad (12)$$

Substituting a consistent estimate $\hat{\Sigma}$ for Σ, we get an approximation of this criterion function, which we again denote by L_T. Because $\bar{B}$ enters linearly in L_T, we obtain

$$vec\hat{\bar{B}} = \left(\tilde{X}'\tilde{X}\right)^{-1}\tilde{X}'Y_1^T \quad (13)$$

by minimizing L_T with respect to $\bar{B}$ for fixed $\bar{A}$ and $\bar{C}$. Here, $Y_1^T = (y_1', \ldots, y_T')'$ is the stacked vector of observations and $\tilde{X}$ depends on Y_1^T, $\bar{A}$, $\bar{C}$ and $\hat{\Sigma}$ and we assume that $\tilde{X}$ has full column rank. This leads to the following new criterion function depending on $\bar{A}$ and $\bar{C}$ only:

$$L_T^{cc}(\bar{A}, \bar{C}) = tr\frac{1}{T}\sum_{t=1}^{T}\varepsilon_t(\bar{A}, \bar{C})\varepsilon_t(\bar{A}, \bar{C})'\hat{\Sigma}^{-1} \quad (14)$$

Given the (observable) pair $(\bar{A}, \bar{C})$, Y_1^T and $\hat{\Sigma}$, we obtain the original system by $\Delta_Y(\bar{A}, \bar{C}) = (A, B, C) = (\bar{A} - \hat{\bar{B}}\bar{C}, \hat{\bar{B}}, -\bar{C})$. The pairs $(\bar{A}_1, \bar{C}_1)$ and $(\bar{A}_2, \bar{C}_2)$ are called observationally equivalent if they correspond to the same transfer function, i.e. if $\pi(\Delta_Y(\bar{A}_1, \bar{C}_1)) = \pi(\Delta_Y(\bar{A}_2, \bar{C}_2))$. If $(\bar{A}, \bar{C})$ is observable, then, under certain additional assumptions, all observational equivalent pairs are given by $\mathcal{E}_{cc}(\bar{A}, \bar{C}) = (T\bar{A}T^{-1}, \bar{C}T^{-1})$, $T \in GL(n)$.

$\mathcal{E}_{cc}(\bar{A}, \bar{C})$ is a real analytic manifold of dimension n^2 and the *DDLC* construction is performed again by taking the orthocomplement in $\mathbb{R}^{n^2+ns}$ to the tangent space of $\mathcal{E}_{cc}(\bar{A}, \bar{C})$ at an initial point $(\bar{A}, \bar{C})$. Let us denote the new parameter space, where the non-minimal systems have been removed, again by $T_D \subseteq \mathbb{R}^{ns}$ and let us put $V_D = \pi(\Delta_Y(\varphi_D(\tau_D)))$. Here, φ_D is given by

$$\begin{array}{rcl} \varphi_D : T_D & \rightarrow & \mathbb{R}^{n^2+ns} \\ \tau_D & \mapsto & \begin{pmatrix} vec\bar{A}(\tau_D) \\ vec\bar{C}(\tau_D) \end{pmatrix} = \begin{pmatrix} vec\bar{A} \\ vec\bar{C} \end{pmatrix} + Q^{\perp} \cdot \tau_D \end{array} \quad (15)$$

where $Q^{\perp} \in \mathbb{R}^{n^2+ns\times ns}$ is now a matrix with orthonormal columns spanning the new orthocomplement to $\mathcal{E}_{cc}(\bar{A}, \bar{C})$ at the point $(\bar{A}, \bar{C})$; (15) is called the *slsDDLC* parametrization. For the following theorem see [7]:

Theorem 4.1. *Let Y_1^T and an initial (A, B, C) be given and let $(\bar{A}, \bar{B}, \bar{C})$ denote the corresponding inverse system in (11). The parametrization by slsDDLC as given in (15) has the following properties:*

(i) T_D *is an open and dense subset of* $\mathbb{R}^{ns}$.

(ii) *There exist open neighborhoods* $T_D^{loc} \subseteq T_D$ *of* $0 \in T_D$ *and* V_D^{loc} *of* $\pi(A,B,C)$ *in* V_D *such that* T_D^{loc} *is identifiable,* $V_D^{loc} = \pi(T_D^{loc})$ *and the mapping* $\psi_D^{loc} : V_D^{loc} \to T_D^{loc}$ *defined by* $\psi_D^{loc}(\pi(\tau_D)) = \tau_D$ *is a homeomorphism.*

(iii) $\pi(\bar{T}_D \cap T_X)$ *may (but need not necessarily) contain transfer functions of lower McMillan degree.*

(iv) *There exists an open and dense subset* V_D^{fin} *of* V_D *such that for every* $k \in V_D^{fin}$*, the corresponding equivalence class in* T_D *consists of a finite number of points.*

(v) $\pi(\bar{T}_D \cap T_X) \subseteq \bar{V}_D$*, where equality can hold, but the inclusion may also be strict.*

Here, T_X *denotes the (generic) set of* τ_D *such that* $\tilde{X}$ *has full column rank.*

Note that here, as opposed to ordinary $DDLC$, V_D^{loc} is not open in $M(n)$.

An alternative procedure is to concentrate out $\bar{C}$. In this case, ML estimation of Σ can also be incorporated; see [8].

5 A numerical comparison

Eight different minimal, stable and strictly minimum phase state space models (A,B,C) with two outputs are specified. The models are denoted by M_1, ..., M_8 and are of order 2, 4, ..., 16. The poles and zeros are quite close to each other and close to the unit circle, but they do not cancel.

Simulation data for models M_1, ..., M_8 comprising $T = 500$ output observations are created, where the white noise sequence (ε_t) is chosen to be Gaussian distributed with $\Sigma = I_2$.

In the next step, 50 random initial state space models are created by randomly perturbing the matrices (A,B,C) corresponding to the true systems. It is ensured that the perturbed models remain minimal, stable and minimum phase.

All computations are carried out using the system identification toolbox of the software package `MATLAB`, version `6.5.0.180913a (R13)`. The identification procedure itself is performed by using the built-in function `pem`. The option `'SearchDirection'` is set to `'Gn'` (a plain Gauss-Newton type algorithm is used for minimizing the criterion function). For a more detailed discussion of the simulation results presented below we refer to [6]. We confine ourselves to the following statements: $slsDDLC$ leads to

- better success rates. Note that an identification experiment is considered to have failed if the algorithm yields a final parameter estimate with a likelihood value larger than 1.2 times the value of the asymptotic likelihood at the true system; see Table 1 (A). Note e.g. that for *slsDDLC* only 1 out of 400 estimation runs failed, whereas usage of *DDLC* leads to 8 failed runs.

- fewer iterations until convergence due to the reduction of the dimension of the parameter space; see Table 1 (B).

- the lowest condition numbers of the Gauss-Newton approximation to the Hessian of the criterion function. Note that the echelon canonical form *Can* lead to the highest condition numbers; see Table 1 (D).

- better estimates, i.e. better or at least equally good values of the likelihood function at convergence; see Table 1 (F).

In total, the echelon canonical form performs worst, and *slsDDLC* is slightly better than *DDLC*. However, the actual computations turn out to be more time-consuming for *slsDDLC*, but still remain within a feasible range.

STATISTICAL ANALYSIS OF HANDWRITTEN ARABIC NUMERALS IN A CHINESE POPULATION

Wing K. Fung, C.T. Yang, C.K. Li and N.L. Poon

Key words: Writing habits, Arabic numerals, statistical study, classification system, test for independence, probability of occurrence.

COMPSTAT 2004 section: E-statistics.

Abstract: A sample of 187 subjects from the Chinese population in Hong Kong was selected to participate in a handwriting study of Arabic numerals. Characteristic features such as slant, direction of writing, angularity of turnings, directions of initial and/or ending strokes etc. were developed. A set of characteristic codes representing the profile of writing habits was assigned to each writer. Hierarchical cluster analysis was conducted on the characteristic features which were on nominal scale, and hence subjects who had similar writing habits for Arabic numerals were grouped. Pearson's χ^2 tests for independence for pairs of feature variables were constructed. The independence property allows us to estimate the probability of occurrence for certain characteristic features of a Arabic numeral. An alternative way for estimation is suggested when some of the features are not statistically independent.

1 Introduction

Writing habit, being a product of long-term adaptation to the needs and abilities of the writer, is believed to be unique. Various classification systems for handwriting have been suggested; see [3] for a review. A system for the classification of handwritten numerals have been developed by Ansell and Strach [1], and Strach [6]. Recently, computer algorithms for extracting features from scanned image of handwriting were used by Srihari et al. [5] for the analysis of individuality of handwriting.

It this paper, we analyse the characteristic features and codes of the Arabic numeral writings, i.e., $0, 1, \ldots, 9$, of 187 subjects. We give a detailed description on data collection and the methods of statistical analysis for the study. Hierarchical cluster analysis (Section 4.1) is conducted on the characteristic codes of the single numerals and the paired numerals. We define a cluster being the set of subjects having rescaled distance at the minimal level. From that, we can obtain the number of clusters in the dendrogram diagram, which is useful for measuring the variability of the numeral(s) in question.

We are also interested in investigating whether the characteristic features within each numeral are statistically independent. If the features are independent, it would provide a simple method to estimate the relative frequency or probability of occurrence of certain characteristic features, by simply multipling the marginal probabilities for individual features. χ^2 tests would be conducted for checking independence.

2 Data and methods

A sample of 187 subjects from the local Chinese population was selected to participate in the handwriting study. The subjects were asked to follow the instructions on the questionnaire provided to them. They had to write Arabic numerals, $0, 1, \ldots, 9$, as in their normal ways using their own pens. The specimens were collected together by the staff of the Hong Kong Government Laboratory for further examination. The collected numerals were then examined microscopically with the aid of a Nikon SMB-2B microscope by professional document examiners of the Hong Kong Government Laboratory. Characteristic features such as slant, direction of writing, angularity of turnings, directions of initial and/or ending strokes etc. were selected and a code was then assigned to each characteristic feature. Each feature normally has 2-5 possible assignments of characteristic codes.

Hierarchical cluster analysis is a set of statistical techniques that is particularly useful for separating a set of objects into constituent groups or clusters which minimize the variation between members of the same group [8] without making assumptions about the number of groups or the group structure. Grouping of objects into clusters is done on the basis of similarities or distances [8], [2]. The analysis is a powerful exploratory method commonly employed in many disciplines. The clustering method processes the values of the measure of similarities among pairs of objects, generating a tree or dendrogram that shows the hierarchy of similarities among all pairs of objects.

Since hierarchical cluster analysis is mainly designed for quantitative measurements, the code of the selected numeral was re-coded to a number of binary variables, with 1 referring to the presence of code status and 0 otherwise. Take for an example of numeral “0”, the original data size is 187 × 9 (number of subjects × number of characteristic features for “0”), and the recoded data has size 187 × 25 (25 codes for “0’). Proximity of dissimilarity is generated for binary data that ranges from 0 to 1 [4], [7], [2]. The dissimilarity measure is taken as the pattern difference of the fourfold table which is computed as $bc/(n^{**}2)$, where b and c refer to the diagonal cells corresponding to features present on a object but absent on the other and $n(= 187)$ is the total number of objects involving in the study [7]. Hierarchical cluster analysis measure for binary data was then employed using an algorithm that starts from all objects as apart and merge two clusters nearby until only one is left [4]. The default measure of pattern difference in SPSS was adopted for the binary codes to identify dissimilarity (notice that other similarity/dissimilarity measures have been attempted, and they give similar results to those reported in Section 4.1). Average linkage between objects was then taken to demonstrate the procedure of statistical classification. It defines the distance between two clusters as the average of the distances between all pairs of cases in which one member of the pair is from each of the clusters. This method uses information about all pairs of distances, not just the nearest or the farthest, and so it is usually preferred in cluster analysis [7]. Subjects having the similar (or the same) way of numeral writing were grouped/clustered together. A tree diagram or dendrogram was selected to present the results of cluster analysis, which is depicted horizontally with each row representing a case, and cases with high similarity are adjacent. The number of clusters and the cluster sizes were also measured.

Another question of interest is whether the quantified features are statistically independent of one another. Each feature is a nominal variable which can take different possible codes (normally 2-5). Pearson's χ^2 independence test for each pair of features is conducted. The evaluation on the probability of occurrence of certain characteristic features will be much simplified if the independence assumption is found to be valid.

3 Summary statistics

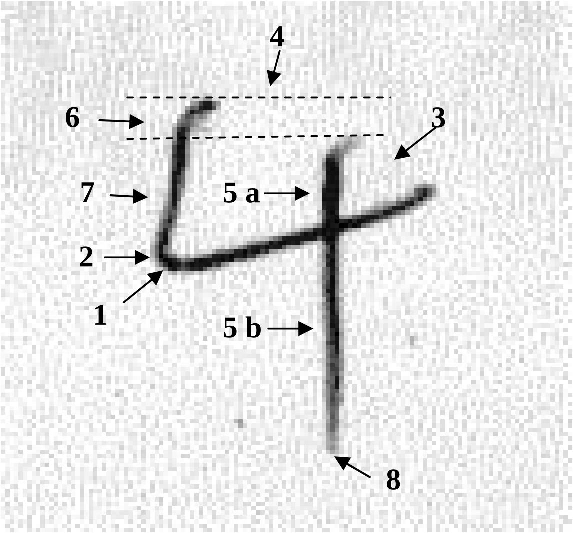
The majority of the participants were of young to middle age (20-49). Only 4% and 2% were of age < 20 and age ≥ 50 respectively. Nearly all (99%) of them were right-handed.

The assignment of characteristic features and codes is an important process in the project. Figure 1 shows an example of such an assignment for numeral 4. In this particular numeral, there are 8 characteristic features and each feature has 2-3 possible assignments of characteristic codes. Some of the features such as features 1, 2, 3, and 8 are relatively easy to distinguish, while others may need some comparisons on the length of the measurements. At the lower half of Figure 1, we have identified the code for each feature of that particular numeral. Moreover, one other code for each of the features is also provided for easy understanding. Numeral 4 has 8 characteristic features with 19 characteristic codes.

Table 1 gives an overall summary for the number of characteristic features and codes for the studied numerals; the detailed characteristic features and codes are omitted for brevity. We can see that numeral "1" is the simplest numeral as expected and it has 4 characteristic features (numeral "6" too), while numerals 5, 8 and 9 have the most features and codes.

Numeral	0	1	2	3	4	5	6	7	8	9
Feature	9	4	7	8	8	9	4	9	12	10
Code	25	11	19	20	19	30	10	23	33	31

Table 1: Numbers of characteristic features and codes for numerals 0-9.



Feature	Code of the above numeral	One other code
1. Turning to the left	Round (r)	 Angular
2. Loop on the left	No (n)	 Yes
3. Connection between horizontal and vertical strokes	Open (o)	 Closed
4. Relation between slanting and vertical strokes	Open (o)	 Closed
5. Ratio of vertical stroke above & below the horizontal stroke a/b	a - Shorter (sh)	 a - Longer
6. Top part of vertical stroke relative to left slanting stroke	Shorter (sh)	 Taller
7. Left slanting stroke (a)/ portion of vertical stroke below horizontal stroke (b)	Shorter (sh)	 a - Longer
8. Ending of vertical stroke	Tapered (t)	 Blunted

Figure 1: Assignment of characteristic features and codes for numeral 4.

4 Statistical analysis

4.1 Hierarchical cluster analysis

We employ hierarchical cluster analysis for subjects grouping in the writing of numeral “4”. Figure 2 gives the dendrogram for the clustering of the subjects; for clarity, only the last 20 subjects were selected for classification. As noted from Figure 2, we have identified four tightly linked clusters namely, cluster a: subjects $(14, 20, 1, 8)$; cluster b: $(4, 7)$; cluster c: $(10, 11)$; and cluster d: $(3, 18, 9)$. The subjects within each cluster are very similar to each other and so they are grouped together. For example, we can see from the figure that subjects 14, 20, 1 and 8 are grouped together and after checking the original data we found that they in fact wrote in (exactly) the same pattern during the writing of numeral “4”. The same situation also happens to subjects 4 and 7, 10 and 11, and 3, 18 and 9. The dendrogram of the cluster analysis can give us information on the similarity/dissimilarity in the writing of “4” amongst the subjects.

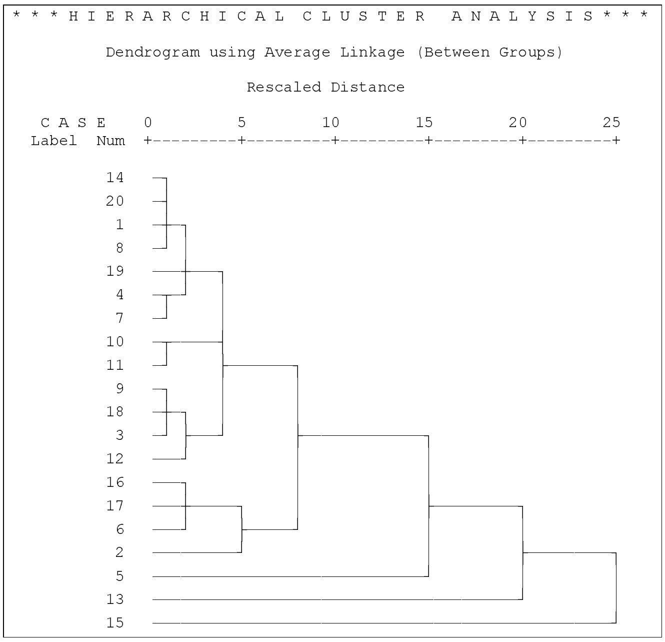


Figure 2: Clustering of the last 20 subjects for numeral 4.

We can also count the number of clusters formed in Figure 2. A cluster is defined as follows: a cluster is of size two or more subjects if its rescaled distance is at the minimal level or at the lowest part of the dendrogram and a cluster is of size 1 if otherwise. The clusters in Figure 2 are identified as, C1: (14, 20, 1, 8), C2: (19), C3: (4, 7), C4: (10, 11), C5: (9, 18, 3), and subjects

12, 16, 17, 6, 2, 5, 13 and 15 each form the remaining clusters C6, C7, ..., C13, respectively. Using the same procedure, 16 clusters are identified for the paired numerals 4 and 7 in the dendrogram of Figure 3 which is to be discussed in more details below.

Hierarchical cluster analysis is again conducted for two numerals "4" and "7" and the results are shown in Figure 3. As we can see that there are only two tightly linked clusters, less than that formed in Figure 2 for a single numeral "4". The clusters are, cluster i: subjects $(3, 18, 8, 12)$ and cluster ii: subjects $(1, 20)$. In fact, after checking the original data, we found that there were some differences in the way of writing of numerals "4" and "7" for subjects 3, 18, 8 and 12 of cluster i. The two subjects 1 and 20 of the other cluster also did not write exactly the same numerals "4" and "7".

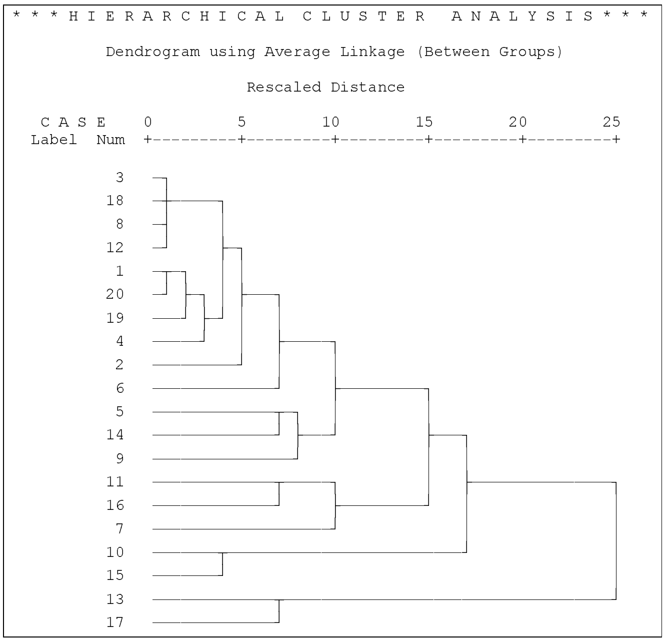

Figure 3: Clustering of the last 20 subjects for numerals 4 and 7.

Table 2 summarizes the findings obtained from hierarchical cluster analysis of Arabic numerals. The number of clusters formed and the maximum and the second maximum sizes of clusters are listed for reference. According to cluster analysis numeral "1" is the simplest handwriting character amongst all. Totally, there are only 36 clusters formed via the classification procedure with merely 8 clusters containing 5 or more subjects and the largest cluster involving 63 homogenous subjects. On the contrary, numeral "5", arming with 9 features and 30 codes, is the most informative character that help distinguish subjects' distinctiveness on handwriting.

Numerals	No. of features	No. of clusters	No. of clusters with size ≥ 5	Max. size of cluster	Second size
0	9	85	7	13	13
1	4	36	8	63	27
2	7	82	8	20	18
3	8	123	3	19	7
4	8	81	8	23	14
5	9	139	0	4	4
6	4	69	10	23	19
7	9	97	8	17	10
8	12	108	4	20	7
9	10	115	6	10	10

Table 2: Summary findings for cluster analysis of single Arabic numeral.

The combined numerals increase the number of characteristic features and codes on handwriting discrimination and enhance the heterogeneity among subjects. Table 3 summarizes the findings of cluster analysis of two Arabic numerals, 4 and others, demonstrating the dissimilarity reinforcement between subjects in handwriting. Comparing with the findings in Table 2, the combined Arabic numerals overall increases the number of clusters formed; that is, the subjects are more heterogeneous from one another than that in the writing of a single numeral. It is to be noted that for the combined numerals 4 and 5, 175 clusters (out of 187 subjects) are identified, which indicates that the handwritings of the 187 subjects for numerals 4 and 5 together are nearly all different (in one or more characteristic features).

Numerals	No. of features	No. of clusters	No. of clusters with size ≥ 5	Max. size of cluster	Second size of cluster
0, 4	17	133	2	7	5
1, 4	12	98	6	11	11
2, 4	15	147	0	4	4
3, 4	16	147	2	6	5
4, 5	17	175	1	5	2
4, 6	12	135	3	6	6
4, 7	17	140	3	7	6
4, 8	20	166	1	6	4
4, 9	18	149	1	8	4

Table 3: Summary findings for cluster analysis of two Arabic numerals.

4.2 Tests for independence and probability assessment

Next we would like to investigate whether the features within each numeral are statistically independent. Let us consider the simplest numeral "1" first. The common χ^2 test for independence is employed. There are four characteristic features measured for numeral 1, including slant, initial hook, serif and ending position. Since a large majority of the subjects (99%) wrote numeral 1 without the serif feature, this feature is excluded from the χ^2 test based on the common rule-of-five in applying the test. The other three features can form 3 sets of paired features, and the features of each pair are found to be statistically independent (each at $\alpha = 5\%$ significance level; details omitted). This sort of independence can be very important for evaluating the relative frequency or probability of occurrence of certain characteristic features. For example, we may evaluate the probability, because of independence, as

$$\begin{aligned} & P_{123}\ [(\text{Slant (S)} = \text{forward (f)}, \text{Initial Hook (IH)} = \text{right (r)}, \\ & \qquad \text{Ending Position (EP)} = \text{hook (h)}] \\ = \ & P_1(S = f) \quad P_2(IH = r) \quad P_3(EP = h) \\ = \ & 0.69 \times 0.14 \times 0.25 \\ = \ & 0.02415, \end{aligned}$$

where the marginal probabilities 0.69, 0.14 and 0.25 are obtained from the direct counting method. Of course there are many assumptions behind this estimate which might be rather crude. It is to be awared that the pairwise independence does not imply the features being all mutually independent. The estimate may also be adjusted upward if we want to make it conservative (forensic document examiners like to take the conservative approach in practice).

2			ind	ind	ind	ind	ind	ind
3				D	D	D	ind	ind
4					D	ind	ind	D
5						D	D	ind
6							D	ind
7								ind

Table 4: Results of χ^2 independence tests for features $1, \ldots, 8$ (meanings refer to text) of numeral "0", each at 5% significance level. D and ind stand for features being statistically dependent and independent respectively.

Next we investigate the numeral 0 which has nine features on (1) slant, (2) initial and ending strokes, (3) starting position, (4) ending position at right, middle or left, (5) stroke crossing position, (6) ending position being tapering or blunt, (7) shape, (8) ending position at upper half, middle or lower, and (9) the writing direction which is however omitted in our analysis because of the rule-of-five. The independence test results for feature pairs are summarized in Table 4. It is interesting to note that only feature 2, initial and ending strokes (being open or close), is statistically independent from other features considered. Feature 8 is (pairwise) independent of all other features except 4. Thus, it seems difficult to use a kind of (simple) product rule, as presented in numeral 1 where the assumption of feature independence is taken, to estimate the relative frequency or probability of occurrence of the particular characteristic features for numeral 0.

We suggest below an alternative way to (conservatively) estimate the probability of occurrence of the following feature codes for numeral 0,

$$\begin{aligned} & P_{1\,2\,3\,4\,5\,6\,7\,8}(f,c,l,m,l,t,e,u) \\ = \;& P_2(c)P_{1\,3\,4\,5\,6\,7\,8}(f,l,m,l,t,e,u) \\ < \;& P_2(c)P_{1\,3\,5\,6\,7\,8}(f,l,l,t,e,u) \\ = \;& P_2(c)P_{1\,3\,5\,6\,7}(f,l,l,t,e)P_8(u), \end{aligned}$$

where $P_2(c)$ and $P_8(u)$ can be evaluated easily, and $P_{1\,3\,5\,6\,7}(f,l,l,t,e)$ can also be estimated based on some direct counting from the sample. It is noted that similar assumptions as for numeral 1 may have to be made as well. Furthermore, we need to aware that the overall level of significance is not equal to 5%, though the individual level is set to be 5% for each paired comparison, because of multiple comparisons. Moreover, it may also not be reasonable to regard the features being statistically all independent, or all dependent.

Another question of interest is on the estimation of the probability of occurrence for characteristic feature codes of two or more numerals. We shall not attempt to answer this question due to the possible very complex dependence structure in the data.

5 Concluding remarks

We have investigated characteristic features of numerals $0,\ldots,9$. The Arabic numerals are chosen because they are commonly found in daily life. Hierarchical cluster analysis is used to classify subjects of similar handwriting features into groups. As expected, a subject is more difficult to cluster/group with others when more numerals are considered. In fact, the individuality of handwriting features may be identified in our sample when we consider 2 or 3 numerals together such as 5, 8, and 9 which have more characteristic features. This phenomenon may also be of interest to document examiners.

The χ^2 tests are constructed to see if the features are statistically pairwise independent. The features (except the serif feature) in numeral 1 are independent, while some features in numeral 0 are dependent of one another.

This dependence structure would also be found in other numerals. However, it is still possible to find some independence structure in the features such that the probability of occurrence of some characteristic features can be estimated, of which the possible limitations have to be awared. Furthermore, it is suggested that the probability should be estimated for a single numeral, and not for two or more combined numerals.

METHODS AND ALGORITHMS FOR ROBUST FILTERING

Ursula Gather and Roland Fried

Key words: Signal extraction, drift, edge, outlier, update algorithm.

COMPSTAT 2004 section: Robustness.

Abstract: We discuss filtering procedures for robust extraction of a signal from noisy time series. Moving averages and running medians are standard methods for this, but they have shortcomings when large spikes (outliers) respectively trends occur. Modified trimmed means and linear median hybrid filters combine advantages of both approaches, but they do not completely overcome the difficulties. Improvements can be achieved by using robust regression methods, which work even in real time because of increased computational power and faster algorithms. Extending recent work we present filters for robust online signal extraction and discuss their merits for preserving trends, abrupt shifts and extremes and for the removal of spikes.

1 Introduction

In speech recognition, video transmission and intensive care monitoring the basic task is to extract a signal from the observed noisy time series. The signal is assumed to vary smoothly most of the time with a few abrupt shifts. Besides the attenuation of normal observational noise and the removal of outlying spikes for recovering smooth sequences, the preservation of the locations and heights of shifts and local extremes is important. All this needs to be done automatically and in real time with short delays. This increases the risk of confusing outlier sequences and shifts or local extremes. For distinguishing extremes and outliers we rely on the smoothness of the underlying signal, i.e. observations which are far away from an estimated signal value are treated as outliers and not as being due to a signal peak. We can identify shifts by their duration setting a lower limit for the length of a relevant shift.

Moving averages and other linear filters are popular for signal extraction as they recover trends and are very efficient in Gaussian samples, but they are highly vulnerable to outliers and they blur level shifts. Tukey [16] suggests running medians for removing outliers and preserving level shifts, but standard medians have deficiencies in trend periods [8]. Linear median hybrid filters [10], [11] have been suggested as they are computationally more efficient than running medians, and preserve shifts similarly good or even better than these. These filters track polynomial trends, but they can only remove single isolated outliers. Modified trimmed mean filters are another compromise between running means and running medians. They choose an adaptive amount of trimming, but like running medians they also deteriorate in trend periods.

A better solution for tracking trends is to replace the median, a robust location estimator, by the estimated intercept obtained by robust regression of the data in a moving window against time. Based on a comparison of functionals with high breakdown point Davies, Fried and Gather [8] recommend Siegel's [15] repeated median because of its robustness against outliers and its stability. Since larger outliers have stronger effects on the repeated median we can add automatic rules for online trimming of outliers and construct procedures which are almost as bias-robust as filters based on least median of squares regression [13], but considerably faster and more efficient for Gaussian samples [5]. The Q_α-method [3], [14] has very nice properties for scale estimation even when a level shift occurs [9].

Robust regression also allows to construct hybrid filters which have similar benefits as linear median hybrid filters, while being considerably more robust [6]. Procedures applying adaptive trimming which do not deteriorate in trend periods can also be derived [7].

In Section 2 we introduce the filtering procedures. In Section 3 we discuss computational and other aspects. In Section 4 we propose a robust rule for the adaptive choice of the window widths. In Section 5 we analyze real and simulated data for further comparison before we give some conclusions.

2 Methods for robust filtering

We assume a component model for the sequence (x_t) of observed data

$$x_t = \mu_t + u_t + v_t,\ t \in \mathbb{Z}. \tag{1}$$

The underlying signal μ_t is the level of the time series, which is assumed to vary smoothly with a few sudden changes, while u_t is additive noise from a symmetric distribution with mean zero and variance σ^2, and v_t is impulsive (spiky) noise from an outlier generating mechanism. For online signal extraction we move a time window of width $n = 2k + 1$ through the series and use $x_{t-k}, \ldots, x_{t+k}$ to approximate μ_t. This causes a time delay of k observations. Firstly we fix k to a given value for all filters.

2.1 Filters based on robust regression

A standard median filter (running median) approximates the signal μ_t by the median of the observations $\{x_{t-k}, \ldots, x_{t+k}\}$ within a moving time window,

$$SM(x_t) = \tilde{\mu}_t = med\{x_{t-k}, \ldots, x_{t+k}\},\ t \in \mathbb{Z},$$

where μ_t is regarded as the level of the series at time point t, which is assumed to be locally constant. For tracking trends, Davies et al. [4] suggest fitting a local linear trend $\mu_{t+i} = \mu_t + i\beta_t,\ i = -k, \ldots, k$, to $\{x_{t-k}, \ldots, x_{t+k}\}$ by robust regression and recommend Siegel's [15] repeated median (RM). When applied to the data (i, x_{t+i}), $i = -k, \ldots, k$, the RM reads

$$\begin{aligned} RM(x_t) = \tilde{\mu}_t^{RM} &= med\{x_{t-k} + k\tilde{\beta}_t, \ldots, x_{t+k} - k\tilde{\beta}_t\} \\ \tilde{\beta}_t^{RM} &= med_{i=-k,\ldots,k}\left\{med_{j\neq i}\frac{x_{t+i} - x_{t+j}}{i-j}\right\}. \end{aligned}$$

2.2 Filters based on trimming

Lee and Kassam [12] suggest modified trimmed mean (MTM) filtering as a compromise between running means and running medians. MTM filters regulate the amount of trimming depending on the data. Firstly the local median $\tilde{\mu}_t$ and the local median absolute deviation about the median (MAD) $\tilde{\sigma}_t$ are calculated, then all observations farther away from the median than a multiple $q_t = d\tilde{\sigma}_t$ of the MAD are trimmed. Finally, the average of the remaining observations is taken as filter output:

$$\begin{aligned} MTM(x_t) &= \frac{1}{n_t}\sum_{i=-k}^{k} x_{t+i} \cdot 1_{[\tilde{\mu}_t - q_t, \tilde{\mu}_t + q_t]}(x_{t+i}), \\ n_t &= \#\{x_{t+i} \in [\tilde{\mu}_t - q_t, \tilde{\mu}_t + q_t], i = -k, \ldots, k\}, \\ q_t &= d \cdot c_n \cdot med\{|x_{t-k} - \tilde{\mu}_t|, \ldots, |x_{t+k} - \tilde{\mu}_t|\}. \end{aligned}$$

Here, c_n is a correction factor, which is chosen to achieve unbiasedness for Gaussian noise. For a very large window width we get $c_n = 1.483$, while e.g. for $n = 21$ we have $c_n = 1.625$. For $d = 0$, $MTM(x_t)$ is a running median, while for $d = \infty$ we get a moving average.

MTM filters implicitly assume a location model as standard median filters do. A straightforward modification is to fit a local linear trend by the repeated median and trim those observations having large residuals in this regression setting. The local variability can be estimated by applying the MAD to the regression residuals [7]. The filter output can then be derived either by least squares regression or by the repeated median of the observations with moderately large residuals. We denote the resulting filters by TRM and MRM, respectively:

$$\begin{aligned} TRM(x_t) &= \overline{x}_{J_t} - \tilde{\beta}_t^{TRM}\overline{j}_{J_t} \\ \overline{x}_{J_t} &= \frac{1}{|J_t|}\sum_{j\in J_t} x_{t+j} \\ \overline{j}_{J_t} &= \frac{1}{|J_t|}\sum_{j\in J_t} j \end{aligned}$$

$$\begin{aligned}
\tilde{\beta}_t^{TRM} &= \frac{\sum\limits_{j\in J_t}(j-\overline{j}_{J_t})(x_{t+j}-\overline{x}_{J_t})}{\sum\limits_{j\in J_t}(j-\overline{j}_{J_t})^2} \\
J_t &= \{j=-k,\ldots,k : |x_{t+j}-\tilde{\mu}_t^{RM}-j\tilde{\beta}_t^{RM}| \le q_t\} \\
MRM(x_t) &= med\{x_{t+j}-j\tilde{\beta}_t^{MRM},\ j\in J_t\} \\
\tilde{\beta}_t^{MRM} &= med_{i\in J_t}\left\{med_{j\in J_t, j\neq i}\frac{x_{t+i}-x_{t+j}}{i-j}\right\},
\end{aligned}$$

with $(\tilde{\mu}_t^{RM}, \tilde{\beta}_t^{RM})$ being the repeated median level and slope estimate for the current time window $\{x_{t-k},\ldots,x_{t+k}\}$.

2.3 Hybrid filters

Linear median hybrid filters are combinations of linear and median filters [10], [11]. Linear subfilters are applied to the input data before taking the median of their outcomes as final filter output. This reduces computation time and increases the flexibility compared to standard median filters due to the variety of linear subfilters. Linear median hybrid filters with finite impulse response, briefly FMH filters, are characterized by subfilters which respond to a finite number of impulses only.

A simple FMH filter corresponds to a location model and applies two one-sided moving averages and the current observation x_t as central subfilter for edge preservation:

$$SFMH(x_t) = med\{\Phi_1(x_t),\ x_t,\ \Phi_2(x_t)\}$$

$$\Phi_1(x_t) = \frac{1}{k}\sum_{i=1}^{k} x_{t-i}, \qquad \Phi_2(x_t) = \frac{1}{k}\sum_{i=1}^{k} x_{t+i}.$$

Predictive FMH filters correspond to a linear trend model and apply predictive FIR subfilters for one-sided extrapolation of a trend:

$$PFMH(x_t) = med\{\Phi_F(x_t), x_t, \Phi_B(x_t)\},$$

$$\Phi_F(x_t) = \sum_{i=1}^{k} h_i x_{t-i}, \qquad \Phi_B(x_t) = \sum_{i=1}^{k} h_i x_{t+i}.$$

Choosing the weights $h_i = \frac{4k-6i+2}{k(k-1)}$, $i=1,\ldots,k$ results in the minimal mean square error (MSE) predictions for a linear trend which is disturbed by white noise [11].

Combined FMH filters use predictions of different degrees,

$$CFMH(x_t) = med\{\Phi_F(x_t), \Phi_1(x_t), x_t, \Phi_2(x_t), \Phi_B(x_t)\},$$

with $\Phi_1(x_t)$, $\Phi_2(x_t)$, $\Phi_F(x_t)$ and $\Phi_B(x_t)$ being the subfilters for forward and backward extrapolation of a constant signal and a linear trend as given above.

In view of increased computational power and because of improved algorithms, computation time is nowadays not a great problem. Fried, Bernholt and Gather [6] use half-window medians and repeated medians to construct robust hybrid filters:

$$\begin{aligned} PRMH(x_t) &= med\{RM^F(x_t), x_t, RM^B(x_t)\} \\ CRMH(x_t) &= med\{RM^F(x_t), \tilde{\mu}_t^F, x_t, \tilde{\mu}_t^B, RM^B(x_t)\} \end{aligned}$$

Here, $\tilde{\mu}_t^F = med\{x_{t-k}, \ldots, x_{t-1}\}$ and $\tilde{\mu}_t^B = med\{x_{t+1}, \ldots, x_{t+k}\}$ are half-window medians, while $RM^F(x_t)$ and $RM^B(x_t)$ estimate the level at time t using the repeated median of $x_{t-k}, \ldots, x_{t-1}$ and $x_{t+1}, \ldots, x_{t+k}$, respectively:

$$\begin{aligned} RM^F(x_t) &= med\{x_{t-k} + k\tilde{\beta}_t^F, \ldots, x_{t-1} + \tilde{\beta}_t^F\} \\ \tilde{\beta}_t^F &= med_{i=-k,\ldots,-1}\left\{ med_{j=-k,\ldots,-1, j\neq i} \frac{x_{t+i} - x_{t+j}}{i-j} \right\} \\ RM^B(x_t) &= med\{x_{t+1} - \tilde{\beta}_t^B, \ldots, x_{t+k} - k\tilde{\beta}_t^B\} \\ \tilde{\beta}_t^B &= med_{i=1,\ldots,k}\left\{ med_{j=1,\ldots,k, j\neq i} \frac{x_{t+i} - x_{t+j}}{i-j} \right\}. \end{aligned}$$

3 Comparison of different filtering procedures

In the following we compare the previous filtering procedures w.r.t. computation time and their analytical properties.

3.1 Computation

The time needed for the filtering is crucial in real time applications. Fast algorithms for the update of the filter output are needed for online signal extraction. Denoting the length of the time window by n, the median of the proceeding window can be updated in logarithmic time ($O(\log n)$) using linear space if the data in the window are stored in sorted order using a red-black tree [2, Section 15.1]. This improves on the linear time needed for calculating the median from scratch.

An algorithm for the update of the repeated median in linear time using quadratic space based on a hammock graph is proposed by Bernholt and Fried [1], and another update algorithm needing only linear space running in $O(n \log n)$ average time is presented by Fried, Bernholt and Gather [6].

Updating the residuals and calculating the MAD can be done in linear time. Hence, the MTM and the TRM can both be calculated in linear time. For the MRM, however, $O(n^2)$ time is needed at least for the second repeated median. Detailed descriptions of the update algorithms can be found in Fried, Bernholt and Gather [6], [7].

The Table given below summarizes the time and the space needed for the updates of the filtering procedures. Note that the space for the repeated median and both repeated median hybrid filters can be reduced to $O(n)$, but at the expense of larger computation times.

	SM	RM	MTM	MRM	TRM	FMH	RMH
time	$O(\log n)$	$O(n)$	$O(n)$	$O(n^2)$	$O(n)$	$O(1)$	$O(n)$
space	$O(n)$	$O(n^2)$	$O(n)$	$O(n)$	$O(n^2)$	$O(n)$	$O(n)$

Table 1: Time and space needed for the update of the filters.

3.2 Analytical properties

For a discussion of the filtering procedures we concentrate on the analytical properties within a single time window when being applied to data generated from the component model (1).

Equivariance and invariance are important properties of statistical procedures. Location equivariance means that adding a constant to all observations in a window changes the filter output accordingly. Scale equivariance means that multiplication of all observations with a constant changes the estimate in the same way. All the above procedures possess these two properties.

Only some of the procedures are trend invariant, however [6], [7]. This property means that the extracted level does not change when adding a linear trend as long as the central level is fixed. The RM, the PFMH, the PRMH, the TRM and the MRM are trend invariant, while the median, the MTM, the CFMH and the CRMH are not. Therefore, for the latter methods the efficiency, the removal of spikes and the preservation of shifts are influenced by underlying trends.

Filters which are not trend invariant blur e.g. upward shifts within downward trends. Although the median and the MTM can remove k spikes completely in a single time window from a constant signal if there is no observational noise ($\sigma^2 = 0$), even a single positive outlier within a downward trend causes smearing. The predictive FMH can remove a single spike and preserve a shift exactly within a linear trend irrespectively of the directions as it is trend invariant, while the combined FMH does so only if the outlier (shift) has the same direction as the trend. The RMH filters improve on the FMH filters as they can remove up to $\lfloor k/2 \rfloor$ subsequent spikes without any effect. Furthermore, the predictive RMH preserves shifts exactly, while for the combined RMH this is true only if the shift is in the same direction as the trend, just like for the combined FMH. The RM, the TRM and the MRM can even remove $k-1$ spikes completely within a single time window irrespectively of a linear trend if $\sigma^2 = 0$.

The previous results hold when there is no observational noise. Lipschitz continuity restricts the influence of minor changes in the data due to small noise or rounding. The standard median, the FMH, the RM and the RMH filters are Lipschitz-continuous. The median is Lipschitz-continuous with constant 1 like all order statistics, while the repeated median and the repeated median hybrid filters are Lipschitz-continuous with constant $2k+1$. An FMH filter is Lipschitz-continuous with constant $\max|h_i^j|$, the maximal absolute weight given by a subfilter. MTM, MRM and TRM filters, however, are not Lipschitz-continuous, which can cause instabilities when there are small changes in the data. The discontinuity is caused by the trimming of observations. Application of continuous M-estimators is preferable for this reason, but computationally more expensive. Nevertheless, we investigate simpler trimming based methods in order to obtain information about the possible gain by further iterations.

The finite-sample breakdown point (FSBP) is the fraction of observations which have to be put into worst case positions in order to make the estimate take arbitrarily wrong values. For the median the breakdown point becomes $(k+1)/n$ when applied to $n = 2k+1$ data points, meaning that at least half of the window needs to be outlying in order to cause an arbitrarily large spike in the extracted signal. Since for the explosion of the local MAD also at least $k+1$ observations need to be modified, the MTM has the same breakdown point, while for the FMH filters two outliers are sufficient to make it break down. From the following Table we see that the RMH filters are considerably more robust than the FMH filters, and that the RM, TRM and MRM are almost as robust as the median in the sense of breakdown.

SM	MTM	RM	TRM	MRM	FMH	PRMH	CRMH
$\frac{k+1}{n}$	$\frac{k+1}{n}$	$\frac{k}{n}$	$\frac{k}{n}$	$\frac{k}{n}$	$\frac{2}{n}$	$\frac{\lfloor k/2\rfloor+1}{n}$	$\frac{\lfloor k/2\rfloor+2}{n}$

Table 2: Fraction of outliers in a window causing breakdown.

Simulations show the effect of the second step in the derivation of the TRM and the MRM on their MSE as compared to that of the RM filter. Application of least squares to the trimmed observations (TRM) increases the efficiency for Gaussian noise, but almost preserves the robustness of the repeated median, while application of the repeated median (MRM) further reduces the bias caused by outliers [7].

4 Adaptive choice of the window width

From the previous discussion we see that only the repeated median and the predictive hybrid filters PFMH and PRMH are both trend invariant and continuous, i.e. stable w.r.t. the occurrence of both trends and small changes in the data. The hybrid filters tend to preserve shifts and extremes, while the repeated median smoothes them considerably when being applied with a large window width [6], [7]. This means that on the one hand we should choose a short window width, but on the other hand a large window width is better for removing outlier patches and for the attenuation of the observational noise. This is a robust variant of the common problem of bandwidth selection in nonparametric smoothing.

Fried [5] investigates rules for online shift detection based on the most recent residuals in the time window. Similarly, we can formulate rules for the automatic choice of the window width using the regression residuals. Often least squares criteria are used to assess the local model fit and to find the bandwidth, but this is not suitable when outliers are present. Instead, a robust criterion is needed. Remembering that the median is the value which balances the signs of the residuals and that the repeated median is a regression analogue, it is natural to use the sign of the residuals. In this way we give the same weight to all observations irrespectively of their magnitude. However, note that there are always as many positive as negative residuals in the window for the repeated median fit. Therefore, we have to apply this idea to a suitable subset.

The Figure below visualizes the smoothing of a maximum by fitting a line with a too large window width. The residuals in the center will typically be positive, while most of the residuals at the start and the end of the window will be negative. These signs are simply al reverse for a minimum. Therefore it is natural to use the total number of positive residuals at the start and the end of the window for assessing the model fit. We divide the window into three sections as follows, namely the first $\lfloor (k+1)/2 \rfloor$ observations, the central $n - 2\lfloor (k+1)/2 \rfloor$ observations and the last $\lfloor (k+1)/2 \rfloor$ observations. If the total number T of positive residuals in the first and the last section is much larger than the average $\lfloor (k+1)/2 \rfloor$, we should shorten the window width since the signal slope might be decreasing substantially within the window. If T is much smaller than $\lfloor (k+1)/2 \rfloor$, the window width should also be shortened since the signal slope might be increasing.

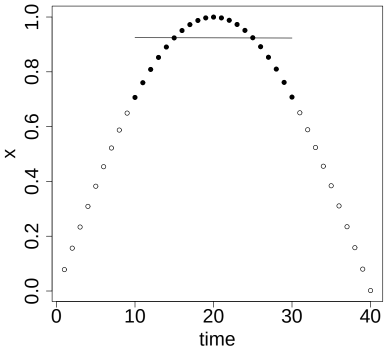

Figure 1: Smoothing of a maximum by fitting a line to the filled points.

However, this reduction should not result in a window width which is too small to resist outlying patterns. Results of previous studies [6], [7] show that the repeated median resists up to between 25% and 30% outliers without being substantially affected. Therefore, the minimal window width should be about four times the maximal length of outlier patches to be removed. For patches of length three e.g. we use the constraint $n \geq 11$. Since longer time windows allow better attenuation of observational noise and also robustness against many outliers we increase the window width after each step whenever possible.

The proposed repeated median algorithm with robust adaptive selection of the window width is as follows: Let $k_l < k_u$ be lower and upper bounds for k, and $0 \leq d_l < 1 < d_u \leq 2$ be constants. Set $k = k_l$ and $t = k + 1$.

1. Calculate the repeated median fit $(\tilde{\mu}_t, \tilde{\beta}_t)$ for $x_{t-k}, \ldots, x_{t+k}$ to obtain $RM(x_t) = \tilde{\mu}_t$.
2. Get the residuals $r_i = x_{t+i} - \tilde{\mu}_t - i\tilde{\beta}_t$, $i = -k \ldots, k$, and set $T = \#\{i = -k, \ldots, -k - 1 + \lfloor (k+1)/2 \rfloor, k + 1 - \lfloor (k+1)/2 \rfloor, \ldots, k : r_i > 0\}$.
3. If $k > k_l$ and $T < d_l \cdot \lfloor (k+1)/2 \rfloor$ or $T > d_u \cdot \lfloor (k+1)/2 \rfloor$ set $k = k - 1$ and go to 1.
4. If $k < k_u$ set $k = k + 1$.
5. Set $t = t + 1$ and go to 1.

The same or similar approaches can be used for the other robust filters. We just need to modify the window sections for the hybrid filters possibly obtaining asymmetric filters.

5 Application

We now apply the filtering procedures to two data sets. The first example is a time series simulated from an underlying sawtooth signal, which is overlaid by Gaussian white noise with zero mean and unit variance, and there are three isolated, three pairs and two triples of outliers of size -5. The Figure below shows the outputs of the CRMH and the adaptive RM filter with $k_l = 5$, $k_u = 15$, $d_l = 0.7$ and $d_u = 1.3$. The CRMH with $n = 21$ preserves the local extremes very well, but it is rather variable. The adaptive RM is almost as good at the extremes while being much smoother. Most of the time a width close to the maximal $n = 31$ is chosen, but close to the three local extremes and at about t=280 the width decreases even to the minimal $n = 11$. The PRMH not shown here is similar to the CRMH, but it is more affected by the outliers, while the ordinary RM and the median cut the extremes.

As a second example we analyze five hours of measurement of the arterial blood pressure of an intensive care patient. Figure 3 visualizes these data along with the outcomes of the MRM with a window width of $n = 21$ and of the adaptive RM filter with the same constants as before. The MRM resists some aberrant patterns very well, but it oversmoothes the local extremes at $t = 70$ and at $t = 290$. The adaptive RM again chooses the largest width $n = 31$ most of the time, but the width drops down to $n = 17$ about t=175 and t=225, and even to the minimal $n = 11$ about t=60 and t=130.

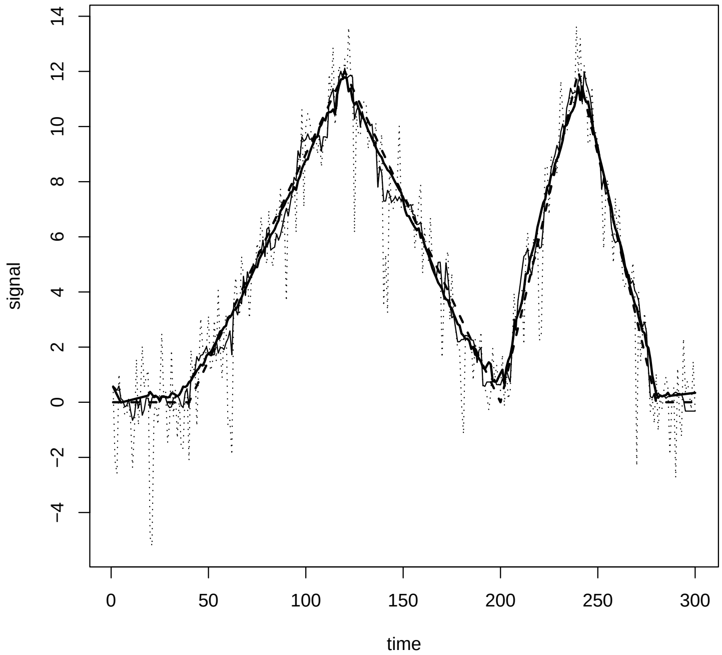

Figure 2: Simulated time series (dotted), underlying signal (dashed) and outputs of the CRMH (thin solid) and the RM with adaptive window width (bold solid).

It performs better at the extremes than the MRM, but it is affected by two subsequent outlying patterns about t=180. The RM with fixed window width also shows a spike there and performs in between the adaptive RM and the MRM at the extremes.

6 Conclusion

Improved numerical algorithms render the real time application of robust procedures for time series filtering possible. Methods for robust regression like the repeated median allow to construct filters which have similar benefits like classical linear or location based approaches when these perform well, but overcome deficiencies w.r.t. the removal of spiky noise (outliers) or the tracking of trends. We find the repeated median procedure with robust adaptive choice of the window width particularly promising. First applications show that this algorithm can be modified even for online filtering without any time delay by estimating the intercept at the right hand side of the time window, but more experience is needed to optimize the automatic choice of the window width then.

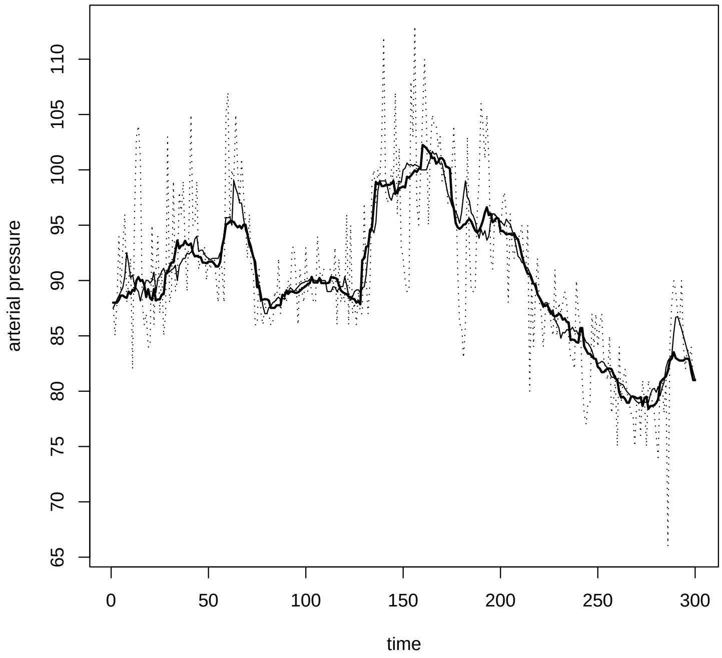

Figure 3: Arterial blood pressure (dotted) and outputs of the MRM (bold solid) and the RM with adaptive window width (thin solid).

USING GO FOR STATISTICAL ANALYSES

Robert Gentleman

Key words: Ontology, bioinformatics, graphs.

COMPSTAT 2004 section: Biostatistics.

Abstract: In this paper we use meta-data packages from the Bioconductor Project to carry out statistical analyses of gene expression data. But would like to note that the potential scope of these applications is much broader and many of the methods described here could be applied to other types of high-throughput data. To provide context we make use of data from an investigation into acute lymphoblastic leukemia.

1 Introduction

While there are a number of different definitions of an ontology we will use the notion of a restricted vocabulary as the basis for the discussions here. Ontologies and related concepts are becoming increasingly important tools for organizing and navigating information. Initiatives in biology (our main focus) as well as the semantic web are providing a variety of resources and interesting problems related to ontologies.

For genes and gene products the Gene Ontology Consortium, or GO, (`www.geneontology.org`) is an initiative that is designed to address this problem. GO provides a restricted vocabulary as well as clear indications of the relationships between terms. GO is clearly a valuable tool for data analysis, however its structure (as a DAG) and the complex nature of the relationships that it represents make appropriate use of this tool challenging.

1.1 The graph structure of GO

The GO ontologies are structured as directed acyclic graphs (DAGs) that represent a network in which each term may be a *child* of one or more *parents*. We use the expressions *GO node* and *GO term* interchangeably. Child terms are more specific than their parents. The relationship between a child and a parent can be and be either a *is a* relation or a *has a* (*part of*) relation.

Each term in the ontology is associated with a unique identifier and the relationships between the GO terms (parent/child) as well as other relevant data are provided by *GO*. The *GO* package provides six sets of mappings, two for each ontology.

In general, given a set of most specific terms of interest we can find the graph that consists of those terms and any less specific terms (parents). We will refer to this graph as the *induced GO graph* for the specific set of child nodes.

GO itself is strictly the ontology. The mapping of genes to GO terms is carried out separately. The actual mappings are provided by GOA [1] and are mappings between GO terms and LocusLink IDs which are modified to account for the multiplicity of mappings between the manufacturer IDs and LocusLink IDs.

2 An example

To demonstrate some of the tools that are included in the *GOstats* package we consider expression data from 79 samples from patients with acute lymphoblastic leukemia (ALL) that were investigated using Affymetrix GeneChip arrays [2]. The data were normalized using quantile normalization and expression estimates were computed using RMA [4]. Of particular interest is the comparison of 37 samples from patients with the BCR/ABL fusion gene resulting from a chromosomal translocation (9;22) with the 42 samples from the NEG group.

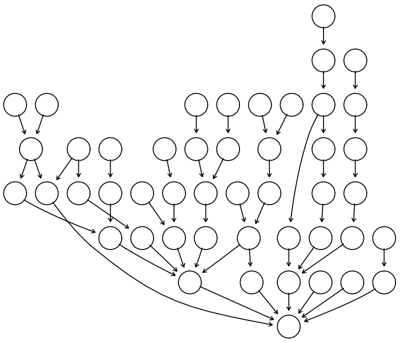

Figure 1: The induced GO graph for the selected genes.

To reduce the set of genes for consideration we applied two different sets of filters (gene filtering is considered in more detail in [5] and the interested reader is referred there). A non-specific filter was used to remove genes that showed little or no change in expression level across experiments. The resulting data set had 2391 probes remaining. To select genes whose expression values were associated with the phenotypes of interest (BCR/ABL and NEG) we used the `mt.maxT` function from the *multtest* package which computes a permutation based t-test for comparing two groups.

After adjustment for multiple testing there were only 19 probes (which correspond to 16 genes) with an adjusted p-value below 0.05. Using those genes we obtain the set of most-specific GO terms in the MF ontology that they are annotated at and compute the induced GO graph which is rendered in Figure 1. No labels have been added to the nodes in this plot since there is not sufficient room to provide informative ones. Notice that the most specific terms are at the top of the graph and that arrows go from more specific nodes to less specific ones. The node in the bottom center is the MF node. Clearly some sort of interactivity (e.g. tooltips) would be beneficial. We will return to this plot in the next section and use it to provide a more detailed view of the data.

3 Statistical analyses

3.1 Finding interesting GO terms

If genes have been partitioned into distinct sets, say by finding those with small p-values (as was done above) or by some form of clustering, then one of the questions that arises is whether genes that comprise a cluster have a common function, process or location in the cell. A second, related application of this idea is to provide meaning to a list or set of genes that were selected according to some criteria. For example, in our microarray experiment we selected genes that were differentially expressed between the BCR/ABL group and the NEG group. We might then wonder whether these genes have a common function, are involved in common processes, or perhaps are co-located in some region of the cell.

We can ask if there are more interesting genes at the node than one might expect by chance. If that is true, then that term can be thought of as being overrepresented in the data. This question can be answered using a Hypergeometric distribution. Suppose that there are N total genes annotated for the ontology of interest and that our list of interesting genes contains m distinct genes. Then we can imagine an urn with N balls in it and $N-m$ are black while m are white. If we draw k balls from the urn, where k is the number of genes annotated at a node, we are asking whether the number of white balls in that drawn sample is unusually large. Suppose that there are q white balls (interesting genes) in the drawn sample, we then ask what is the probability that $X \geq q$ where X is a Hypergeometric random variable with parameters as we have described. This probability constitutes a p-value since it is the probability of seeing something as extreme or more extreme than what was observed. This functionality is provided in the function `GOHyperG` available in the *GOstats* package.

In Figure 2, we reproduce the plot from Figure 1 except that we have now colored the nodes according to the p-value obtained from the Hypergeometric test described above. The nodes in Figure 2 are colored either red or blue depending on whether the unadjusted Hypergeometric p-value was less than 0.10 or not (for those viewing this document in black and white the nodes should be dark and light grey, respectively). The GO terms for the terms colored red are printed below. The relevant biology suggests that these are quite reasonable. We note that while the smallest p-values are associated with nodes that have few genes annotated at them there are some nodes with a reasonable number of genes annotated at them (counts) and small p-values.

Table 1: GO terms, p-values and counts.

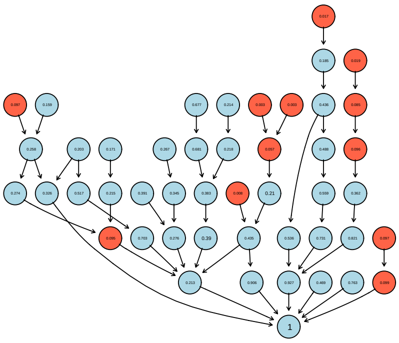

Figure 2: The induced GO graph colored according to unadjusted Hypergeometric p-values.

3.2 Selecting genes according to GO term

GO can also be used as a method of data reduction. Here one might carry out an analysis focusing on a particular subset of genes, say those associated with the GO term `transcription factor`.

Many of the effects due the BCR/ABL translocation are mediated by tyrosine kinase activity. It will therefore be of interest to examine genes that are known to have tyrosine kinase activity. We examine the set of GO terms and identify the term, `GO:0004713` from the *molecular function* portion of the GO hierarchy as referring to `protein-tyrosine kinase activity`. We see that for the Affymetrix HGU95av2 chip 230 probe sets are annotated at this particular term. Of these only 32 were selected by the non-specific filtering step. We focus our attention on these probes and carry out a permutation t-test analysis.

In this analysis of the GO–filtered data, 4 probe sets have FWER–adjusted p–values less than 0.1. They are printed below, together with the adjusted p-values from an analysis that used all probes that passed our non-specific filter and hence involved 2391 genes.

```
GO analysis

40480_s_at  2039_s_at   36643_at  2057_g_at
   0.00002    0.00025    0.02146    0.07481

All Genes"

40480_s_at  2039_s_at   36643_at  2057_g_at
     0.001      0.018      0.473      0.823
```

Due to the reduced number of tests in the analysis focused on tyrosine kinases, we are left with more significant genes after correcting for multiple testing. For instance, the probe set `36643_at`, which corresponds to the gene DDR1, was not significant in the unfocused analysis, but would be if instead the investigation was oriented towards studying tyrosine kinases *a priori*.

3.3 Using shortest paths

[6] consider some interesting applications of GO in conjunction with microarray expression data. In this section we consider a related idea and apply it to the ALL data. At their most basic level the ideas of [6] consist of forming a graph between genes (which are the nodes) based on some relevant distance. This distance might be correlation distance or it could be any other relevant distance. Then all edges in the graph that correspond to distances that are larger than some threshold are removed. Next, genes are grouped according to some specific categorization (they used GO biological process terms) and the shortest paths (using Dijkstra's algorithm) between all pairs of nodes are computed. Those shortest paths can then be examined to see whether they provide information of relevance.

In the ALL experiment we are most interested in comparing patients that have the BCR/ABL defect to those that have no measured cytogenetic abnormalities. Our adaptation of the shortest path technology is as follows. We use the output of the first filtering step described previously – that is we select genes that show some level of expression and some variation in expression across samples. We then separate the data into two sets (BCR/ABL and NEG) and within each group we define the distance between two genes as one minus the Pearson correlation (other approaches such as that use by [6] or some other robust correlation estimates). We then used an edge weight of

$d(u,v) = (1 - C_{u,v})^k$ with $k = 1$ and $\tau = 0.6$ as the cutoff for correlations, if $C_{u,v} < \tau$ then no edge exists (Zhou et. al used $k = 6$ in their analysis and some experimentation may be warranted).

Our interest in this particular example is on transcription factors. Hence we use the GO term `GO:0003700` which maps to the molecular function `transcription factor activity` to identify all genes with transcription factor activity. We used only genes for which this was a most specific annotation and obtained 814 mappings and 531 unique LocusLink ids. Of these 152 were among those probes selected for our analysis. Of these we found that there were 6 with duplicate entries. A visual inspection (not reported) suggested that the correlation between these duplicate probes was quite high and so only one of each was used in the subsequent analysis. This left us with 146 distinct transcription factors for our study.

For every pair of transcription factors we compute two quantities. The shortest path between each pair for each of the different conditions. For example in our ALL example we compute the shortest paths between all transcription factors using a graph based only on data from those with BCR/ABL and secondly the same set of values based only on data from those without any noticeable genomic defects. Then for each pair the distances are compared (plotted) and those pairs for which the distance has changed the most identified and further explored.

We first consider those transcription factors that are not connected to the others in their respective graphs. There are three sets, those that are not connected in either graph, those that are not connected in one of the two graphs but not in the other. They are reported in Table 2.

	Affymetrix ID	Symbol	Which graph
1	`34730_g_at`	TRO	Both
2	`1106_s_at`	TRA@	NEG only
3	`34850_at`	UBE2E3	NEG only
4	`1185_at`	IL3RA	BCR/ABL only
5	`32186_at`	SLC7A5	BCR/ABL only
6	`33641_g_at`	AIF1	BCR/ABL only

Table 2: Genes not connected in the different graphs.

We now consider the finite pairwise distances. First a simple t-test can be carried out to see if there is any difference between the distances in one graph versus the other. We took each pairwise distance in the NEG graph and subtracted from it the same pairwise distance computed on the BCR/ABL graph. The t-test is for whether the mean is zero and the test statistic was 0.179 with an extremely small p-value. So we see that distances in the NEG graph seem to be longer than those in the BCR/ABL. Further evidence of this difference comes from the observation that proportion of values that were larger in the NEG graph was 0.589.

We will focus our attention on those differences that are large in absolute value. We chose a value of 2.5 as our cut-off and found that there were 66 differences that were larger than 2.5. These corresponded to 26 distinct genes.

While all may be interesting and a particular investigator may want to expend considerable effort in study transcription factors that are of particular interest we will center our analysis on the set of genes that appear most frequently in this list.

There are three genes that have high counts, namely, MYC, MPO and GADD45A. This fact suggests that perhaps the expression patterns of these three different transcription factors are substantially different in the two phenotypes we are studying.

For each of the three transcription factors we can compute the average distance, separately within each graph, to all the other selected genes. We find that the results are quite consistent and that in all cases the path length is much shorter in the BCR/ABL group than it is in the NEG group. For MYC the means were 5 for NEG and 2 for BCR/ABL, and for MPO they were 4 for NEG and 2 for BCR/ABL and for GADD45A the means were 5 for NEG and 2 for BCR/ABL. It is rather interesting to observe that amongst the pairwise distances that have changed the most are those between these three specific genes.

Specific paths between transcription factors can also be examined. Recall that we compute out distance between two transcription factors based on the shortest path length between them in each of the two graphs. In our examples we focus on MYC and the distances between it and MPO and GADD45A.

We print out the different shortest paths for genes connecting MYC to both MPO and GADD45A for each of the two phenotypes, respectively (first the paths for BCR/ABL, then for the NEG samples). The MYC to MPO results are:

```
BCR/ABLE
MYC->EIF4G1->HMG20B->MPO
NEG
MYC->CDC25B->TRAP1->FLJ10326->LANCL1->EMP3->S100A4
          ->LGALS1->MPO
```

If we then make use of the results in Figure 3 we see that there are positive correlations between MYC and EIF4G1 and as well between EIF4G1 and HMG20B, but that for HMG20B and MPO the correlation is negative. Positive correlations are suggestive of shared transcriptional activity while negative correlations are suggestive of transcriptional inhibition.

The results comparing MYC to GADD45A are:

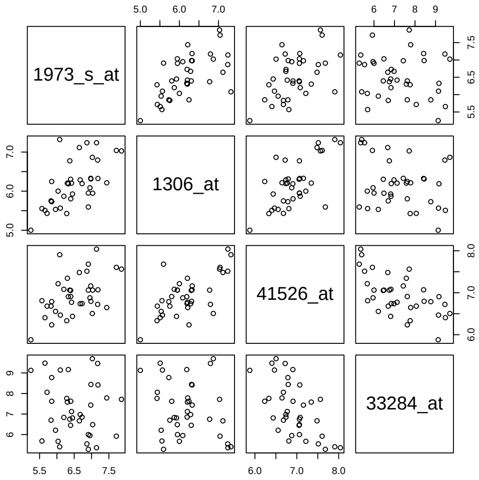

Figure 3: Pairwise scatterplots of gene expression for those genes on the shortest path between MYC and MPO from patients with the BCR/ABL translocation.

```
BCR/ABLE
MYC->UBE2A->BAZ1A->CD53->GADD45A
NEG
MYC->CDC25B->TRAP1->SSBP1->SMC1L1->TK1->HCK->
           SH3PB1->PVRL2->GADD45A
```

We do not have space to present the other pairwise scatterplots here but readers that are making use of the compendium version of this paper can easily explore those different plots on their own.

We notice that the path lengths for the NEG samples are longer (involve more genes) than those for the BCR/ABL samples. We might also want to ask whether the distances are also larger (that is that the correlations are smaller). To do this we need to obtain the edge weights from the respective graphs and compare them. We found that there appeared to be no difference (all averaged around a distance of about 0.65) but the number of edges is quite small and one might expect to see systematic differences if a larger study were undertaken.

We can check our results, at least to some extent, by examining pairwise scatterplots of the gene expressions. In Figure 3 the genes on the path from MYC to MPO are plotted. We see quite strong correlations along the diagonal and note that HMG20B and MPO have a negative correlation.

Finally, we finish our examination of these data by considering some of the specific paths between the different transcription factors. We see, in

Figures 4 the actual shortest path between the genes MYC and MPO. The two end points have been colored red, genes along the path are colored blue.

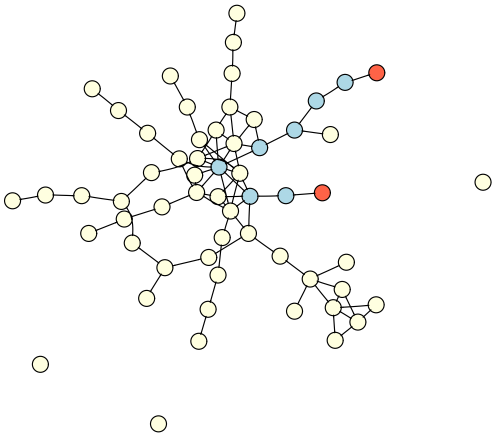

Figure 4: Shortest path between MYC and MPO in the NEG samples.

4 Discussion

GO and the mappings from genes to specific terms in each of the three ontologies provide a number of important and unique data analytic opportunities. In this paper we have considered three separate applications of these resources to the problem of analysing gene expression data and in all cases the GO related data have provided new and important insights into the data.

Using GO mappings to select certain terms for further study and reference has the possibility of providing meaning to sets of genes that have been selected according to different criteria. An equally important application is to use GOA mappings to reduce the set of genes under consideration. As the capacity of microarrays increases it is important that we begin developing tools and strategies that directly address specific questions of interest. P-value correction methods are at best a band-aid and do not represent an approach that has long term viability [5].

In our final example we adapted the method proposed by [6] to a different problem, one where we consider only transcription factors and where we are interested in understanding their interrelationships. The results are promising and in our example reflect a fundamental difference between those with the BCR/ABL translocation and those patients with no observed genetic abnormalities. Ideally these, and other observations will lead to better understanding of transcriptional regulation and from that to better understanding modalities of efficacy for drug treatments.

Perhaps more important than the statistical presentation is the fact that we have also provided software implementations for all tools described and discussed in this paper. They are available from the Bioconductor Project in the form of the *GOstats* package. *GOstats* makes substantial use of software infrastructure from the Bioconductor Project in carrying out this analysis. In particular the *graph*, *Rgraphviz* and *RBGL*, together with the different meta-data packages.

Finally, this document itself represents an approach to reproducible research in the sense discussed by [3] and it can be reproduced on any users machine equipped with R and the appropriate set of R packages. We encourage the interested reader to avail themselves of the opportunity to explore the data and the methods in more detail on their own computer.

COMPSTAT'2004 Symposium

COMPUTATIONAL CHALLENGES IN DETERMINING AN OPTIMAL DESIGN FOR AN EXPERIMENT

Subir Ghosh

Key words: Balanced arrays, computational challenges, factorial designs, interactions, orthogonal arrays, robust designs, search designs, search linear models, search probabilities, unavailability of data.

COMPSTAT 2004 section: Design of experiments.

Abstract: In this paper we present some computationally challenging problems for finding an optimum design in an experiment. We consider the problem of finding an optimum design when one model from a set of possible models would describe the data better than other models in the set but we do not know this model a priori. We also consider the robustness of optimum designs under a model when some observations are unavailable.

1 Introduction

In the early development of designing a statistically efficient experiment, considerable attention was given to the computational simplicity of the analysis and to some desirable properties of the inferences drawn on the comparisons (parameters) of interest [2]. The concepts of orthogonality and balance in experimental designs were developed. With the progress in methodological research and the development in computing technology, the concepts of optimum designs and various optimality criteria were proposed [10]. The experiment could be performed at a single stage or at many stages over time. The data could be continuous, discrete, univariate, multivariate, time series, spatial, and other kinds or some combinations of them. Inference procedures could be parametric, nonparametric, semiparametric, frequentist, Bayesian, and others. The most amazing aspect in the design research is the enormous contributions of all kinds of researchers from extreme theorists to extreme practioners [8]. We do not attempt to make any futile effort to list all the contributors and their research. In this paper we examine some aspects of determining optimal designs and discuss some challenging problems.

2 Optimum designs

An optimum design is normally obtained by satisfying one or more optimality properties (minimizing variance, maximizing power and many others) for the comparisons (parameters) of interest under an assumed model. The choice between a best design with respect to (w.r.t.) one criterion and a best design w.r.t. another criterion is always an issue at the time of the selection of an optimum design. With the change in the computing environment, this issue has become much more complex. For example, the orthogonal fractional factorial plans may be best w.r.t. many optimality criteria but they require more runs in most situations than nonorthogonal plans and furthermore may not perform well compared to nonorthogonal plans when the assumed model is really inadequate. If we decide to give up orthogonality and opt for optimal balanced fractional factorial plans as our nonorthogonal plans, then we may cut down the cost of running the experiment as well as improve the performance when the assumed model is inadequate. Finding optimal balanced fractional factorial plans as nonorthogonal plans is always computationally challenging but it is possible to find such plans in the modern computing environment. Many such plans are already available in the design literature. The list of references is available in Ghosh and Rao [7], [8].

3 Robust designs

The unavailability of data that we often encounter in conducting an experiment should be a concern at the design stage. Ghosh [3] introduced the concept of robustness of design against the unavailability of any t (a positive integer) observations in the sense that the unbiased estimation of all the parameters of interest is still possible when any t observations are unavailable. For n observations, there are $\binom{n}{t}$ possible sets of t observations. Ghosh and Namini [5] gave several criteria and methods for determining the influential set of t observations for robust designs. There are numerous such practical issues including the presence of outliers, time trend in observations, and others in real life experiments. Such practical issues give rise to challenging computational problems in the selection of designs.

4 Model identification using search designs

The problem of finding a best design or a class of best designs satisfying one or more optimality criteria under an assumed model is a challenging task. Analytical methods are not often sufficient for resolving this task. Computational methods are very powerful in addition to the applicable analytical methods in resolving this problem. When we are not absolutely sure about the assumed model that will fit the experimental data adequately, the problem becomes daunting. In reality we are rarely sure about a particular model in terms of its effectiveness in describing the data adequately. However, we are normally sure about a set of possible models that would describe the data better than other models in the class. The pioneering work of Srivastava [13] introduced the search linear model with the purpose of searching for and identifying the best model from a set of possible models that includes the best model. We now focus on finding a best design or a class of best designs for model identification through the use of the search linear models. Computational methods are indispensable for this purpose.

In factorial experiments, the lower order effects are normally important and the higher order effects are all assumed to be negligible. In main effect plans, the main effects are important and the interaction effects are assumed to be zero. Such an assumption may or may not hold true in reality because of the possible presence of a few significant non-negligible interactions. The standard linear models cannot identify these non-negligible effects using a small number of runs or treatments considerably smaller than the total number of possible runs for an experiment. This motivates the use of search designs under the search linear model in searching for and identifying non-negligible interaction effects. We consider the problem of comparing search designs with the ability of searching for and identifying k (a positive integer) non-negligible interaction effects.

5 Search linear model

Consider the search linear model [13]

$$E(\boldsymbol{y}) = \boldsymbol{A_1}\boldsymbol{\xi_1} + \boldsymbol{A_2}\boldsymbol{\xi_2},\ V(\boldsymbol{y}) = \sigma^2\boldsymbol{I}\ , \tag{1}$$

where $\boldsymbol{y}(n \times 1)$ is the vector of observations, $\boldsymbol{A_1}(n \times \nu_1)$ and $\boldsymbol{A_2}(n \times \nu_2)$ are matrices known from the underlying design. The elements of the vector $\boldsymbol{\xi_1}(\nu_1 \times 1)$ are unknown parameters. About the elements of $\boldsymbol{\xi_2}(\nu_2 \times 1)$ we know that at most k elements are nonzero but we do not know which elements are nonzero. The k is small compared to ν_2. The goal is to search for and identify the nonzero elements of $\boldsymbol{\xi_2}$ and then estimate them along with the elements of $\boldsymbol{\xi_1}$. Such a model is called a search linear model. When $\boldsymbol{\xi_2} = \boldsymbol{0}$, the search linear model becomes the ordinary linear model. For the search linear model, we have $\boldsymbol{\xi_2} \neq \boldsymbol{0}$.

Let $\boldsymbol{A_{22}}$ be any $(n \times 2k)$ submatrix obtained by choosing $2k$ columns of $\boldsymbol{A_2}$. A design is called a search design [13] if, for every submatrix $\boldsymbol{A_{22}}$,

$$\text{Rank}[\boldsymbol{A_1}, \boldsymbol{A_{22}}] = \nu_1 + 2k. \tag{2}$$

The rank condition (2) allows us to fit and discriminate between any two models in the class of possible models described earlier. Any two models in the class have ν_1 common parameters which are the elements of $\boldsymbol{\xi_1}$ and at most $2k$ uncommon parameters which are the elements of $\boldsymbol{\xi_2}$. Note that $n \geq \nu_1 + 2k$. A search design allows us to search for and identify the nonzero elements of $\boldsymbol{\xi_2}$ and then estimate them along with the elements of $\boldsymbol{\xi_1}$.

6 Computationally challenging problems

Consider a class of $\binom{\nu_2}{k}$ linear models from (1) with the parameters as $\boldsymbol{\xi_1}$ and k elements of $\boldsymbol{\xi_2}$. The $\binom{\nu_2}{k}$ possible sets of k elements of $\boldsymbol{\xi_2}$ give rise to $\binom{\nu_2}{k}$ such models. For any two models in this class, the elements $\boldsymbol{\xi_1}$ are common parameters but in the two sets of k elements in $\boldsymbol{\xi_2}$ some common parameters may or may not be present. A search procedure identifies the model which best fits the data generated from the search design. To identify this model, the sum of squares of errors (SSE) of each model is used [13]. If SSE for the first model ($M1$) is smaller than the SSE for the second model ($M2$), then $M1$ provides a better fit and is selected over $M2$. For a fixed value of k, all $\binom{\nu_2}{k}$ models are fitted to the data and the search procedure selects the model with the smallest SSE as the best model for describing the data.

6.1 Optimal search designs

For each model in the class of $\binom{\nu_2}{k}$ linear models from (1), we consider the variance-covariance matrix of the least squares estimators of the parameters. We calculate the values of the Determinant(D), Trace(T), and Maximum Characteristic Root(MCR). So we obtain $\binom{\nu_2}{k}$ sets of values of D, T, and MCR. We calculate the arithmetic means and the geometric means of D, T, and MCR and denote them by AD, AT, AMCR, GD, GT, and GMCR. The smaller are the values of AD, AT, AMCR, GD, GT, and GMCR, the better is the search design. Note that the minimization of only D, T, and MCR represent the A- , D- , and E- optimality criteria [10]. The arithmetic mean is more meaningful than the geometric mean in some areas of application and vice versa. We use these six criteria for comparing search designs with the same number of runs. This is computationally a huge task.

For a factorial experiment with four factors each at two levels (+) and (−), suppose that $\boldsymbol{\xi_1}$ consists of the general mean and main effects and $\boldsymbol{\xi_2}$ consists of only two factor interactions. Consider two designs, d1 and d2 with 8 runs. Design d1 has the ability of searching for one nonnegligible two-factor interaction and furthermore, this plan is optimal w.r.t. the AD, GD, AT, and GT criteria. Design d2 has also the ability of searching for one nonnegligible two-factor interaction and furthermore, this plan is optimal w.r.t. the AMCR and GMCR criteria. These new plans are obtained by first finding all the search designs with 8 runs and 4 factors and then calculating their AD, AT, AMCR, GD, GT, and GMCR values. Finding of d1 and d2 is indeed a computer intensive task. Table 1 presents d1 and d2.

6.2 Search probabilities

The probability of selecting one model over another model depends on σ^2, the noise variance which we refer to as the noise. To see this dependence, we consider three cases $\sigma^2 = 0$, $\sigma^2 = \infty$, and $0 < \sigma^2 < \infty$. Let $M0$ be the true model in the class of models described above. Furthermore, let $M1$ be a competing model where $M1 \neq M0$. In the noiseless case, $\sigma^2 = 0$, the SSE for $M0$, SSE($M0$), is zero, which is always smaller than the SSE($M1$). Hence, $M0$ will definitely be selected over $M1$. Therefore, the correct nonzero interaction will always be identified with probability one. Thus, $P[SSE(M0) < SSE(M1)|M0, M1, \sigma^2 = 0] = 1$. In reality $\sigma^2 > 0$ and the SSE($M0$) may

+	+	-	-	+	+	-	-

Table 1: d1 and d2 with 8 runs and 4 factors.

not be less than SSE($M1$). Therefore, $M0$ may not necessarily be selected over $M1$. Hence, the probability of correctly identifying the nonzero interaction is less than one and we write $P[SSE(M0) < SSE(M1)|M0, M1, \sigma^2 > 0] < 1$. In the case of infinite noise, $M0$ and $M1$ are equally likely to be selected and so the probability of selecting $M0$ over $M1$ is 1/2, and we write $P[SSE(M0 < SSE(M1)|M0, M1, \sigma^2 = \infty] = 1/2$. For $0 < \sigma^2 < \infty$, $P[SSE(M0) < SSE(M1)|M0, M1, \sigma^2]$ is called the *search probability* for a given $M0, M1$, and σ^2. Note that the search probability is between 1/2 and 1. Shirakura et al. [12] presented the search probability for searching one nonnegligible effect ($k = 1$) based on the normality assumption for observations under the search linear model (1).

There are many of these search probabilities to consider. We note that for a given true model $M0$, there are $(\nu_2 - 1)$ competing models of $M1$ for $k = 1$. Since the true model $M0$ is unknown, we consider all $\nu_2(\nu_2 - 1)$ possible pairs of $(M0, M1)$ and calculate all the search probabilities for a given σ^2. From these search probabilities, Ghosh and Teschmacher [9] presented a $\nu_2 \times \nu_2$ search probability matrix (SPM) where the columns correspond to the possible true models and the rows correspond to the possible competing models. The off-diagonal elements of the SPM represent the search probabilities corresponding to all possible pairs of $M0$ and $M1$ for a given σ^2. Since the true model $M0$ is different from the competing model $M1$, the diagonal elements of the SPM are not meaningful and therefore left blank.

When comparing two designs, we would like to determine which design has a greater chance of identifying the true nonzero interaction term. A method for doing this is by comparing the SPMs of the two designs for a given σ^2. The SPM for a design is dependent on a parameter, ρ, which is the ratio of the magnitude of the true unknown interaction term (signal) and σ (noise). In other words, the SPM depends on σ^2 through ρ. Let $SPM_i(\rho)$ be the SPM of the ith design for a given ρ, where the columns and rows correspond to the possible true and competing models, respectively.

Shirakura, et al. [12] proposed a criterion for comparing search designs for a specific value of ρ. This criterion is based on the minimum value of all the elements of the SPM. The higher is this minimum value, the better is the design. Ghosh and Teschmacher [9] defined the SPM, proposed two other criteria, and presented methods of comparing search designs for all values of ρ using all three criteria. One of the two proposed criteria in Ghosh and Teschmacher [9] is based on the element-by-element comparison of two $SPMs$ and the other one is based on comparing two minimum search probability vectors ($MSPVs$) whose elements are the minimum values of the columns of two $SPMs$. The comparisons are then made by using a majority rule in the sense of having the fifty percent or more elements of an SPM are greater the corresponding elements of another SPM. Similar comparisons are also made for two MSPVs. The methods proposed in Ghosh and Teschmacher [9] have opened up a new direction of computationally challenging problems for finding optimum designs.

Orthogonal designs have many well-known optimality properties under the ordinary linear model. However, balanced designs can perform better than orthogonal designs under the search linear model. Consider two search designs, $D1$ and $D2$, each with 12 runs, and 4 factors each at two levels $(-)$ and $(+)$. Design $D1$ is a balanced array of full strength and design $D2$ is an orthogonal array of strength 2 obtained from the 12-run Plackett-Burman design [11] by choosing the first four columns. Table 2 presents $D1$ and $D2$. Design $D1$ performs better than Design $D2$ under the ordinary linear model with $\boldsymbol{\xi_2} = \mathbf{0}$. However, $D2$ performs better than $D1$ under the search linear model when the vector $\boldsymbol{\xi_2}$ consists of two and three factor interactions only one of which is nonzero, so that $k = 1$. This is a really striking example illustrating the fact that an orthogonal design is not necessarily the best in all situations.

6.3 Robust designs

The optimal designs may no longer be optimal when some observations become unavailable during the experiment. Determining the robustness of optimal designs against the unavailability of data is a computationally difficult problem [3], [5]. Ghosh and Al-Sabah [6] presented some efficient composite plans for response surface experiments with surprisingly higher efficiency than existing comparable plans in the literature w.r.t. all three criteria, D, T, and MCR. For example, under the second order response surface model with ten factors, the MCR, T, and D x 10^{70} values are 7.1, 31.2, and .033 for Ghosh-Al-Sabah plan and 6791.4, 6850.0, and 1.6 for the existing Draper-Lin plan [1]. Ghosh-Al-Sabah plans were obtained while studying the robustness properties of some existing designs.

7 Conclusions

In this paper we have described some challenging computational problems in finding a best design for an experiment. Modern computing environment has

VISUALIZATION OF PARAMETRIC CARCINOGENESIS MODELS

Jutta Groos and Annette Kopp-Schneider

Key words: Hepatocarcinogenesis, color-shift model, maximum likelihood estimate.

COMPSTAT 2004 section: Biostatistics.

Abstract: This paper concentrate on the effective tools to compare different carcinogenesis models with respect to their ability to predict numbers and radii of foci in hepatocarcinogenesis experiments. Especially the CSM-GUI (Color-Shift graphical user interface) shows to be a powerful instrument to test a new model before starting the very time-intensive procedure of finding the maximum likelihood parameters.

1 Introduction

Hepatocarcinogenesis experiments identify focal lesions consisting of intermediate cells at different preneoplastic stages. Several hypotheses are established to describe the formation and progression of preneoplastic liver foci. A common model of hepatocarcinogenesis is the multi-stage model, which is based on the assumption that cells have to undergo multiple successive changes on their way from the normal to the malignant stage. In this model single cells change their phenotype through mutation into the next stage and proliferate according to a linear stochastic birth-death process [4] [5].

In contrast, the Color-Shift-Model (CSM) was introduced by Kopp-Schneider and colleagues [4] to describe that whole colonies of altered cells simultaneously alter their phenotype. In this model, preneoplastic foci are assumed to grow exponentially with deterministic rate and to change their phenotype ('color') after an exponentially distributed waiting time [1] [3].

To take into account that the assumption of deterministic growth rates for foci in the CSM seems to oversimplify the real process, a CSM with stochastic growth rates is introduced.

In order to compare different models with respect to their ability to predict numbers and radii of foci in a rat hepatocarcinogenesis experiment maximum likelihood estimates for the model parameters are used and the predicted and empirical distributions are vizualized.

2 Color-shift-model with stochastic growth rates in case of 2 colors

The assumption of deterministic growth rates for the foci in the CSM seems to oversimplify the real process. Therefore, a CSM with stochastic color dependent growth rates is introduced, which assumes that foci change their color when reaching a deterministic radius r_{switch} . As in the CSM, the formation of spherical foci with initial radius r_0 is described by a homogeneous Poisson process with rate μ. Let B_1 and B_2 be independent positive random variables with densities f_{B_1} and f_{B_2} . The random variables B_1 and B_2 describe the exponential growth of foci of color 1 and color 2.

Given that a focus is present at time t, the timepoint of its formation, τ_0, is a realisation of a random variable T uniformly distributed on $[0, t]$, where T , B_1 and B_2 are independent.

Consider exemplarily a focus generated at time $T = \tau_0$ which grows in color $C = 1$ with rate $B_1 = b_1$ until it reaches the radius r_{switch} , where it changes its color and grows in color $C = 2$ with rate $B_2 = b_2$.

Color 1: $R(t) < r_{switch}$:
The radius at time $t > \tau_0$, $R(t)$, is described by:

$$\boxed{R(t) = r_0 \exp(b_1(t - \tau_0))}$$

Color 2: $R(t) \geq r_{switch} \Leftrightarrow t > \frac{\ln(\frac{r_{switch}}{r_0})}{b_1} + \tau_0$.
Define

$$\tau_1 := \frac{\ln(\frac{r_{switch}}{r_0})}{b_1}$$

as the time spent in color 1 until change to color 2.
The radius of a focus of color $C = 2$ at timepoint $t > \tau_0 + \tau_1$, $R(t)$, is described by:

$$\boxed{R(t) = r_{switch} \exp(b_2(t - \tau_1 - \tau_0))}$$

So that an expression for the joint distribution of radius $R(t)$ and color $C(t) = 1$ at time t can be derived:

$$\begin{aligned}
&P(R(t) \leq r, C(t) = 1) \\
&\quad = \quad P(R(t) \leq r, R(t) \leq r_{switch}) \\
&\quad = \quad \begin{cases} 0 & r \leq r_0 \\ P(R(t) \leq r) & r \in (r_0, r_{switch}] \\ P(R(t) \leq r_{switch}) & r > r_{switch} \end{cases} \\
&\quad = \quad \begin{cases} 0 & r \leq r_0 \\ \frac{\ln(\frac{r}{r_0})}{t} \int\limits_{\frac{\ln(\frac{r}{r_0})}{t}}^{\infty} \frac{f_{B_1}(b_1)}{b_1} \, db_1 + F_{B_1}\left(\frac{\ln(\frac{r}{r_0})}{t}\right) & r \in (r_0, r_{switch}] \\ \frac{\ln(\frac{r_{switch}}{r_0})}{t} \int\limits_{\frac{\ln(\frac{r_{switch}}{r_0})}{t}}^{\infty} \frac{f_{B_1}(b_1)}{b_1} \, db_1 + F_{B_1}\left(\frac{\ln(\frac{r_{switch}}{r_0})}{t}\right) & r > r_{switch} \, , \end{cases}
\end{aligned}$$

where F_{B_1} and f_{B_1} are distribution and density of the random variable B_1 .

Therefore the joint density of radius $R(t)$ and color $C(t) = 1$ at time t is:

$$\begin{aligned}
&f_{R(t),\,C(t)}(x,1) \\
&= \left[\frac{1}{xt}\int\limits_{\frac{\ln(\frac{x}{r_0})}{t}}^{\infty} \frac{f_{B_1}(b_1)}{b_1}\,db_1 - \frac{\ln(\frac{x}{r_0})}{t}\,\frac{f_{B_1}(\frac{\ln(\frac{x}{r_0})}{t})}{\frac{\ln(\frac{x}{r_0})}{t}}\,\frac{1}{xt} + f_{B_1}\left(\frac{\ln(\frac{x}{r_0})}{t}\right)\frac{1}{xt}\right] \\
&\quad \cdot 1_{(r_0,r_{switch}]}(x) \\
&= \frac{1}{xt}\int\limits_{\frac{\ln(\frac{x}{r_0})}{t}}^{\infty} \frac{f_{B_1}(b_1)}{b_1}\,db_1 \cdot 1_{(r_0,r_{switch}]}(x)\,.
\end{aligned}$$

with the indicator function:

$$1_{(a,b]}(x) := \begin{cases} 1 & x \in (a,b] \\ 0 & x \notin (a,b]\,. \end{cases}$$

The joint distribution of radius $R(t)$ and color $C(t) = 2$ at time t is:

$$\begin{aligned}
&P(R(t) \le r, C(t) = 2) \\
&= P(R(t) \le r, R(t) > r_{switch}) \\
&= \begin{cases} 0 & r \le r_{switch} \\ P(R(t) \le r | R(t) > r_{switch})P(R(t) > r_{switch}) & r > r_{switch}\,. \end{cases}
\end{aligned}$$

Therefore if $r > r_{switch}$:

$$\begin{aligned}
&P(R(t) \le r, C(t) = 2) \\
&= \int\limits_{\frac{\ln(\frac{r_{switch}}{r_0})}{t}}^{\infty}\ \int\limits_{\frac{\ln(\frac{r}{r_{switch}})}{t-\tau_1}}^{\infty} \frac{\ln(\frac{r}{r_{switch}})}{b_2 t} f_{B_2}(b_2) f_{B_1}(b_1)\,db_2 db_1 \\
&+ \int\limits_{\frac{\ln(\frac{r_{switch}}{r_0})}{t}}^{\infty}\ \int\limits_{-\infty}^{\frac{\ln(\frac{r}{r_{switch}})}{t-\tau_1}} \frac{t-\tau_1}{t} f_{B_2}(b_2) f_{B_1}(b_1)\,db_2 db_1 \\
&= \frac{\ln(\frac{r}{r_{switch}})}{t}\int\limits_{\frac{\ln(\frac{r_{switch}}{r_0})}{t}}^{\infty}\ \int\limits_{\frac{\ln(\frac{r}{r_{switch}})}{t-\tau_1}}^{\infty} \frac{f_{B_2}(b_2) f_{B_1}(b_1)}{b_2}\,db_2 db_1 \\
&+ \frac{1}{t}\int\limits_{\frac{\ln(\frac{r_{switch}}{r_0})}{t}}^{\infty} F_{B_2}\left(\frac{\ln(\frac{r}{r_{switch}})}{t-\tau_1}\right)(t-\tau_1) f_{B_1}(b_1)\,db_1,
\end{aligned}$$

where F_{B_1} and F_{B_2} , f_{B_1} and f_{B_2} are distributions and densities of the random variables B_1 and B_2 .

Hence the following expression for the joint density of radius $R(t)$ and color $C(t) = 2$ at time t is obtained:
Let $x > r_{switch}$:

$$
\begin{aligned}
f_{R(t),\,C(t)}(x,2) = {} & \frac{1}{xt} \int\limits_{\frac{\ln(\frac{r_{switch}}{r_0})}{t}}^{\infty} \int\limits_{\frac{\ln(\frac{x}{r_{switch}})}{t-\tau_1}}^{\infty} \frac{f_{B_1}(b_1) f_{B_2}(b_2)}{b_2}\, db_2 db_1 \\
& - \frac{\ln(\frac{x}{r_{switch}})}{t} \int\limits_{\frac{\ln(\frac{r_{switch}}{r_0})}{t}}^{\infty} f_{B_1}(b_1) \frac{f_{B_2}\left(\frac{\ln(\frac{x}{r_{switch}})}{t-\tau_1}\right)}{\frac{\ln(\frac{x}{r_{switch}})}{t-\tau_1}} \frac{1}{x\,(t-\tau_1)}\, db_1 \\
& + \frac{1}{t} \int\limits_{\frac{\ln(\frac{r_{switch}}{r_0})}{t}}^{\infty} f_{B_2}\left(\frac{\ln(\frac{x}{r_{switch}})}{t-\tau_1}\right) \frac{1}{x\,(t-\tau_1)}\,(t-\tau_1)\, f_{B_1}(b_1)\, db_1 \\
= {} & \frac{1}{xt} \int\limits_{\frac{\ln(\frac{r_{switch}}{r_0})}{t}}^{\infty} \int\limits_{\frac{\ln(\frac{x}{r_{switch}})}{t-\tau_1}}^{\infty} \frac{f_{B_1}(b_1) f_{B_2}(b_2)}{b_2}\, db_2 db_1 .
\end{aligned}
$$

For $x \leq r_{switch}$ is $f_{R(t),\,C(t)}(x,2) = 0$.

Therefore the joint densitity of radius $R(t)$ and color $C(t)$ at time t is:

Color 1

$$
\boxed{f_{R(t),\,C(t)}(x,1) = \frac{1}{xt} \int\limits_{\frac{\ln(\frac{x}{r_0})}{t}}^{\infty} \frac{f_{B_1}(b_1)}{b_1}\, db_1 \cdot 1_{(r_0, r_{switch}]}(x)}
$$

Color 2

$$
\boxed{\begin{aligned} f_{R(t),\,C(t)}(x,2) \quad = \quad & \tfrac{1}{xt} \int\limits_{\frac{\ln(\frac{r_{switch}}{r_0})}{t}}^{\infty} \int\limits_{\frac{\ln(\frac{x}{r_{switch}})}{t-\tau_1}}^{\infty} \tfrac{f_{B_1}(b_1) f_{B_2}(b_2)}{b_2}\, db_2 db_1 \\ & \cdot 1_{(r_{switch},\infty)}(x) \end{aligned}}
$$

3 Application to rat liver foci data

For a typical hepatocarcinogenesis experiment animals, e.g. rats, are treated with a carcinogen and liver sections are stained with special histological markers to observe foci of altered hepatocytes which are known to be precursor lesions of carcinoma. Measurements are made in two-dimensional liver sections and inference about the reality in three-dimensional liver is limited by the stereological problem. This problem is described briefly by the fact that the probability of a focus to be cut increases with its size. The model describes the three-dimensional situation. Moolgavkar and colleagues [5] suggested to translate the expressions for the distributions of size and number of foci in 3D into the corresponding expressions in 2D by the Wicksell-Transformation and to then apply the model to the two-dimensional measurements by maximum likelihood methods.

Consider that only focal transections with radii larger than ε can be detected and that one liver section per animal is evaluated. Kopp-Schneider and colleagues [4] derived the following expressions for the expected number of focal transections of color j at timepoint t in two dimensions[1],

$$\widetilde{n}_{2,j} = 2\mu t \int\limits_{\epsilon}^{\infty} \sqrt{x^2 - \epsilon^2} f_{R(t),C(t)}(x,j)\, dx, \tag{1}$$

and the density of the size distribution of focal transections of color j at timepoint t in two dimensions

$$\begin{aligned} & f_{R^{(2)}(t)|C(t)}(y|j) \\ = \; & \frac{y}{\int_{\epsilon}^{\infty} \sqrt{x^2-\epsilon^2} f_{R(t),C(t)}(x,j)\,dx} \int\limits_{y}^{\infty} \frac{1}{\sqrt{x^2-y^2}} f_{R(t),C(t)}(x,j)\,dx. \end{aligned} \tag{2}$$

Assume that foci of each animal grow and change their color independent of other foci. Let $n_{2,k}$ denote the number of focal transections of color k observed in a liver section of area A and let $r_{2,k,j}$ denote the radius of the j-th focal transection of color k. This liver section contributes the loglikelihood

$$\sum_{k=1}^{2} \left[(n_{2,k} \ln(A\widetilde{n}_{2,k}) - A\widetilde{n}_{2,k}) + \sum_{j=1}^{n_{2,k}} \ln(f_{R^{(2)}(t),C(t)}(r_{2,k,j},k)) \right] + C, \tag{3}$$

where C is a data dependent constant. Assuming that the liver sections of one experiment are independent of each other, the loglikelihood of the complete data set is the sum of the contributions of every section.

4 Example

Data from an NNM-experiment published by Weber and Bannasch in 1994 [8] are chosen to illustrate the methodology. In this study rats were treated

[1] To differentiate between the number of foci and the number of focal transections an additional index was introduced. Here the index 2 stands for two dimensions.

with 6mg NNM[2] per kg body-weight continuously during six different time-periods, 7, 11, 15, 20, 27 and 37 weeks, with each group consisting of five animals. After this time period one liver section of each rat was stained by the marker H&E [3] and different types of focal transections were observed. Here only two different types of foci are considered. The morphometric evaluation of the stained liver sections generated a data set consisting of the area of every liver section and the type and area of every focal transection detected in this section.
A Color-Shift-Model with color dependent and Beta-distributed growth rates is applied to this data set. Random variables B_1 and B_2 , which describe the exponential growth in color 1 and color 2, are Beta-distributed with parameters p_1, q_1, a_1 and p_2, q_2, a_2 . Form parameters, a_i , are introduced additionally to the parameters of the standard Beta-distribution, p_i and q_i ($p_i, q_i, a_i > 0,\ i = 1, 2$), to modify the support of the distribution function. Hence the growth rate in color i , B_i , is a positive random variable with the following density:

$$f_{B_i}(b_i) = \frac{1}{B(p_i, q_i)} \frac{b_i^{(p_i-1)}(a_i - b_i)^{(q_i-1)}}{a_i^{(p_i+q_i-1)}} \cdot 1_{[0,\, a_i]}(b_i) \quad p_i, q_i, a_i > 0,\ i = 1, 2\,,$$

where $B(p, q)$ is the Beta-function

$$B(p, q) = \int_0^1 z^{(p-1)}(1 - z)^{(q-1)}\, dz.$$

Inserting this expression into the joint density of radius $R(t)$ and color $C(t)$ at time t, double integrals are obtained in equations (1) and (2) which cannot be solved analytically. The loglikelihood function (3) depends on eight parameters.

4.1 Implementation

The MATLAB environment is used to compute the loglikelihood function, find the maximum likelihood parameters and visualize the results. Numerical double integration with singularities has to be performed for every single detected focal transection. As about 1000 focal transections are detected the computation of the likelihood is a very time-intensive procedure. Using the MEX-interface, functions for numerical double integration from the Fortran NAg library are included to improve the performance [4]. To find the maximum

[2] The chemical carcinogen N-Nitrosomorpholine (NNM) was administered in the drinking water.

[3] H&E stands for Hemalum&Eosin, a biological marker to identify acidophilic and basophilic cell structures.

[4] Subroutine D01DAF of Numerical Algorithm Groups (NAg), Fortran Library, version Mark 18 [6].

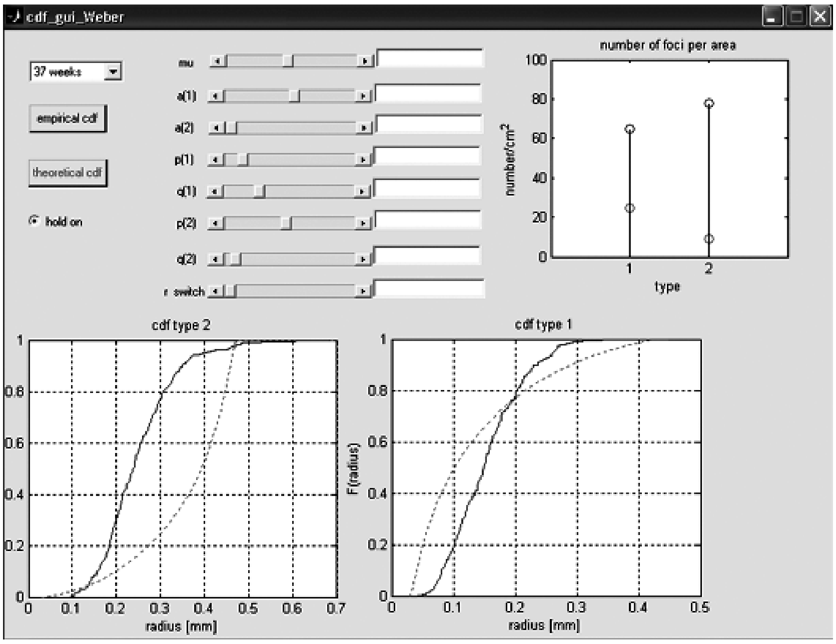

Figure 1: A time-point can be chosen over the pop-up-menue and the parameters can be varied over their corresponding sliders. Depending on the parameters the three axes show the theoretical distributions of size and number of focal transections of type 1 and 2 (dotted lines) compared with the empirical data taken from the NNM-experiment (solid lines). One slider is provided for the Poisson parameter μ, six sliders for the parameters p_1, q_1, a_1 and p_2, q_2, a_2 corresponding to the Beta-distributed growth rates in type 1 and 2 and one slider for r_{switch} .

likelihood parameters it is necessary to define a set of eight starting parameters for the *fmincon*[5] function and to define proper intervals for the range of the eight model parameters. For this purpose a graphical user interface (CSM-GUI) is implemented in MATLAB to test the theoretical distributions of size and number of focal transections in 2D under variation of parameters (Figure 1). After minimizing the negative loglikelihood by the *fmincon* function theoretical results can be compared with the empirical data.

4.2 Results

Figures 2 and 3 illustrate typical visualizations of the results of the modulation of the NNM-Experiment. The empirical size distribution is compared with the theoretical size distributions obtained from two different Color-Shift-Models using maximum likelihood estimates for the parameters. The CSM

[5] *fmincon* is a MATLAB function for nonlinear minimization under constraints used to minimize the negative loglikelihood function [7].

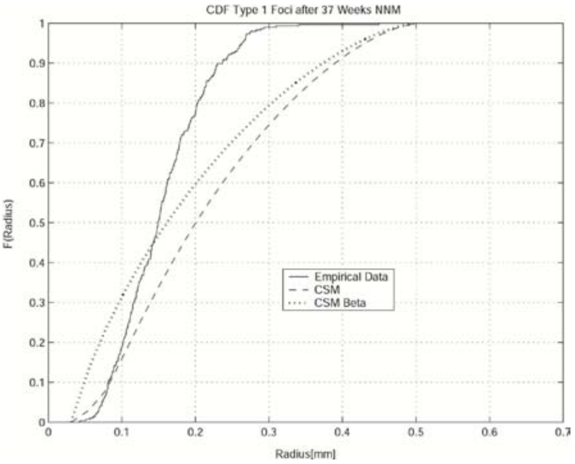

Figure 2: The result of the CSM (dashed line) and CSM with Beta-distributed Growth rates (dotted line) applied on foci of type 1 after 37 weeks. The solid line represents the empirical data.

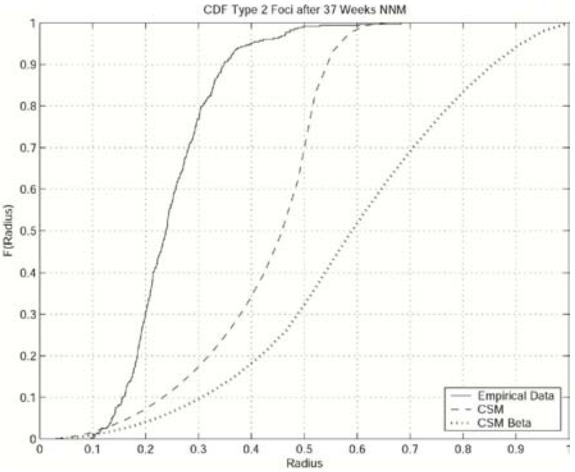

Figure 3: The result of the CSM (dashed line) and CSM with Beta-distributed Growth rates (dotted line) applied on foci of type 2 after 37 weeks. The solid line represents the empirical data.

without modifications is represented by the dashed line, the CSM with Beta-distributed growth rates is illustrated by the dotted line and the solid line stands for the empirical data from the NNM-experiment. Considering only type1-foci the modified CSM seems to predict the size distribution better than the CSM. But the visualizations for the focal transections of type 2 show that the modified CSM expects too large foci of the second type, so that there is an advantage for CSM without modification in this case. The deterministic switch-radius makes the model highly sensitive against outliers in type 1. A single large type 1 focus leads to a large estimate of r_{switch}. To make the model more robust against these outliers a model assuming a stochastic switch-radius has to be formulated.

5 Conclusions

The above mentioned forms of visualization are effective tools to compare different carcinogenesis models with respect to their ability to predict numbers and radii of foci in hepatocarcinogenesis experiments. Especially the CSM-GUI (Color-Shift graphical user interface) is a powerful instrument to test a new model before starting the very time-intensive procedure of finding the maximum likelihood parameters. To improve the CSM with stochastic growth rates a Color-Shift-Model with stochastic color dependent growth rates *and* stochastic switch-radius has to be introduced. The next step could be the integration of the whole process, finding the starting parameters, maximizing the loglikelihood function and visualizing the results in one GUI which could simplify the modulation.

DESIGN ASPECTS OF A COMPUTER SIMULATION STUDY FOR ASSESSING UNCERTAINTY IN HUMAN LIFETIME TOXICOKINETIC MODELS

Harald Heinzl and Martina Mittlboeck

Key words: Dioxin, indeterminability, occupational cohort, Monte Carlo simulation study.

COMPSTAT 2004 section: Biostatistics.

Abstract: The general paradigm for risk assessment of exposures to toxic agents in human environment is the identification and characterization of hazard, assessment of exposure and characterization of risk. Performed in practice risk assessment is addressing particularly the outcome of integrating the data available from epidemiology, long-term mortality and morbidity studies and mechanistic research with information on the type and extent of exposure, as well as statistical analysis properly used. Various technical and non-technical aspects of the design process of the Monte Carlo simulation study will be reported and discussed. Finally, a Monte Carlo computer simulation study was designed in order to examine in detail the influences of various sources of uncertainty and their potential implications on the risk estimates from the Boehringer cohort data is presented.

1 Introduction

The need for risk assessment of exposures to toxic agents in human environment has increased steadily over the last decades. The general paradigm for risk assessment is the identification and characterization of hazard, assessment of exposure and characterization of risk. Performed in practice risk assessment is addressing particularly the outcome of integrating the data available from epidemiology, long-term mortality and morbidity studies and mechanistic research with information on the type and extent of exposure, as well as statistical analysis properly used. A sound, scientifically based risk assessment is an essential tool for risk managers and legislators responsible for security and safety of humans.

The use of toxicokinetic models makes it possible to construct exposure indices that may be more closely related to the individual dose than traditional exposures measures. However, the process introduces a wide array of sources of uncertainty, which inevitably makes risk assessment more difficult. In addition, representing population heterogeneity in the assessment of risks and the identification of sensitive sub-population is of great concern.

The analysis of uncertainty is becoming an integral part of many scientific evaluations. For example, in the risk assessment process, an uncertainty analysis has been recognized as an important component of risk characterization by regulatory agencies [29]. Uncertainty is prevalent in the process of risk assessment of chemical compounds at various levels. Uncertainty of the exposure assessment influences dose estimates. Such effects are exaggerated further by uncertainty in dose-response modelling, mainly caused by limited knowledge about the functional dose-response relationship. Finally, uncertainty is propagated to the risk estimation procedure, which provide the basis for risk management decisions.

It is vital to distinguish uncertainty from variability: The latter is a phenomenon in the physical world to be measured, analysed and where appropriate explained. By contrast, uncertainty is an aspect of knowledge (Sir David Cox as quoted in Vose [28]. Total uncertainty is the combination of variability and uncertainty. To avoid confusion it was suggested to rename total uncertainty by indeterminability [28], a terminology adopted in our work.

Our example focusses on the risk assessment process whether 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD, “Seveso-dioxin”) is a potential human carcinogen. In 1997 TCDD was evaluated as human carcinogen [19], [22]. The decision substantially relied on empirical studies of highly exposed occupational cohorts. The so-called Boehringer cohort was amongst them, and its data were thoroughly analysed [1], [2], [13] [14], [24]. These statistical analyses were a rather delicate task as amongst other things individual lifetime TCDD-exposures starting in the 1950ies had to be reconstructed from TCDD-measurements in the 1980ies and 1990ies when such measurements became feasible and affordable. Inevitably, a lot of uncertainty remained due to lack of longitudinal physiological data, the possibility of measurement errors and workplace misclassification errors, disagreement about the appropriate statistical analysis strategy, limited knowledge about the functional dose-cancerogenic property relationship and the advent of new toxicokinetic insight - just to name a few circumstances.

Now, it is quite common that results of large-scaled statistical or epidemiological analyses will be questioned and disputed. However, the goal of an uncertainty analysis is to tell us how much we can be wrong and still be okay [7]. Therefore we designed a computer simulation study to be able to examine in detail the influences of various sources of uncertainty and their potential implications on the risk estimates from the Boehringer cohort data.

The paper ist organized as follows. In Section 2 our adopted view of uncertainty analysis is defined in brief. Section 3 is devoted to dioxin, that is, general characteristics of the compound, features of the Boehringer cohort data set and various approaches to model lifelong human toxicokinetics are described. Section 4 contains technical and non-technical design aspects of the intended computer simulation study. In Section 5 a brief discussion is given.

2 Indeterminability, variability and uncertainty

Indeterminability (or total uncertainty) denotes the inability to be able to precisely predict what the future holds. The two components of indeterminability are variability and uncertainty [28]. According to Hodges [18] a statistical, a structural and a technical part of indeterminability can be distinguished (see also [12], [17]. The statistical part corresponds to variability, whereas the other two parts correspond to uncertainty. The statistical part of indeterminability is variation given structure or in other words, residuals given a model, a common statistical technique to describe variability in a regression model.

Structural uncertainty emerges from the fact that the model itself – the assumed structure - may be uncertain either due to incomplete or insufficient knowledge about biological, physiological or toxicological mechanisms, or due to the existence of more than one way to explain a specific phenomenon, that is, there are several plausible models. A special and very important aspect of structural uncertainty is the so-called model parameter uncertainty [12], i.e. uncertainty about model assumptions and model constants. In toxicokinetic models e. g., total lipid volume of the body may be assumed non-varying over human life time or the elimination halflife of a certain toxin may be considered known in one approach, whereas it may not in another.

The third part of indeterminability in Hodges' classification is technical uncertainty, which mainly comprises the ordinary and unspectacular circumstances of everyday scientific work. It is usually neglected although occassionally it may allocate a considerable fraction of indeterminability. Examples for technical uncertainty are poor quality of raw data (e.g. typos, rounding errors), numerical estimation problems, in particular in connection with complex nonlinear models, or research limitations due to lack of resources (e.g. software, time, human expertise), which may artificially restrict the spectrum of considered scientific models or employed statistical analysis methods.

3 Dioxin at a glance

3.1 Polychlorinated dibenzodioxins and -furans (PCDD/Fs)

PCDD/Fs are highly lipophilic synthetic chemicals which arise primarily from the production and combustion process of chlorinated chemicals and as a byproduct to chlorinated bleaching and waste incineration. Environmental contamination by PCDD/Fs has been documented worldwide and is ubiquitous. In industrialised countries the PCDD/F burden of the population is assumed to result mainly from intake of contaminated food. Improvements in the analytical techniques used to measure PCDD/F concentrations have allowed for the concentration of these compounds to be assessed in reasonable amounts of human tissue, most notably in adipose tissue, blood serum and plasma. Repeated determinations in humans allow the investigation of the kinetic of these toxins.

TCDD is believed to be the most potent of the PCDD/Fs. Numerous effects in humans have been observed from exposure to TCDD; amongst them are lung cancer and soft-tissue sarcoma. Observed adverse health effects other than cancer include chloracne, altered sex hormone levels, altered development outcomes, altered thyroid function, altered immune function, cardiovascular diseases and neurological disorders to name just a few, e.g. see also the survey of Grassman et al. [15]. The establishment of a causal relationship between exposure to dioxins and diseases in humans is of outstanding significance in public health and disease prevention. To establish such a causal link is extremly difficult since chronic diseases may occur a long time after the actual exposure has ceased and this extended lag time (latency period) between exposure and disease onset may obscure a causal link. This implies the need for proper modelling of the individual intoxination process in order to construct appropriate dose metrics (like area under the concentration-time curve) for quantitative representation of the disease-exposure relationship. Obviously it is essential to relate the occurrence of diseases to dioxin levels experienced during the exposure before disease onset. Previous levels have to be estimated from present ones. Retrospective determination of dioxin levels in humans and their subsequent use in risk assessment are strongly connected to the toxicokinetics of the dioxins. Chronic environmental exposure, route of exposure, storage in adipose tissue, and mechanism of elimination are important determinants of the level of TCDD in serum years after possibly high occupational exposures. Currently available physiologically based pharmacokinetic (PBPK) models try to meet this requirements at least partly.

Occupationally exposed cohorts are an important source of information due to more pronounced effects (occupational exposures are higher in general) and improved ability to control for confounders (easier and more reliable information retrieval among workers registered in files of companies or insurance agencies). For workers in the chemical industry, where occupational exposure to dioxins has occured in past production periods, the establishment of causal relationships is also connected to insurance and compensation issues, which requires an individually-based assessment of exposure, disease onset and their relationship. In 1997 the International Agency for Research on Cancer (IARC) reevaluated TCDD as carcinogenic to humans (IARC group 1 classification) on the basis of limited evidence of carcinogenicity to humans and sufficient evidence of carcinogenicity in experimental animals [19], [22]. The most important studies, which gave evidence with respect to human carcinogenicity, were four cohort studies with adequate follow-up times of herbicide producers, one each in the United States and the Netherlands, two in Germany. The largest and most heavily exposed German cohort is the so-called Boehringer cohort [13], [14], [1], [2]. Main features of the Boehringer cohort are described in the next Subsection.

Overall, the strongest evidence for TCDD carcinogenicity is for all cancers combined, not for a specific site. Due to the lack of a clearly predominating site it was considered by the IARC that there is limited evidence in humans for the carcinogenicity of TCDD [19], [22]. This could be due to still limited power of those epidemiological studies requiring cautious appreciation, or due to an unspecific non-standard carcinogenic action of dioxin. The evidence in humans for the carcinogenicity of all other PCDDs is even more diffuse and was rated inadequate by the IARC in 1997.

3.2 The Boehringer cohort

The Boehringer cohort consists of around 1600 workers occupationally exposed to PCDD/Fs. About a quarter of the workers are women. The cohort members came from two plants operated by the C.H. Boehringer Sohn Chemical Company, one in Ingelheim and the other in Hamburg, Germany. In Ingelheim 2,4,5 trichhlorphenol (TCP) was produced from 1950 to 1954, in Hamburg TCP was produced from 1957 until contamination with dioxins was stopped in April 1983 and the plant was finally closed in October 1984 [5], [21]. Since 1984, an investigation programme independent of the C.H. Boehringer Sohn Chemical Company has been performed by the Institute of Occupational and Social Medicine of the University of Mainz [5]. Comprising 186 persons evaluable for health evaluation in the first phase from 1984 until 1989 and comprising 192 in a second medical investigation program started in 1992 biomonitoring data on TCDD and major PCDD/F congeners and severe polychlorinated biphenyl congeners have been obtained from samples from adipose tissue or blood serum lipids [3]. This cohort was further investigated in a follow-up study using dioxin concentration measurements for 88 persons [4].

The Ingelheim and Hamburg plants can be subdivided into about 20 working areas corresponding to different involvement in the production processes (e.g. bromophos production, trichlorophenol production, 2,4,5-trichlorophenoxyacetic acid production, repair, laundry, administration, etc.), believed to result in different exposures levels to dioxins. Work histories were documented using a recall questionnaire asking for the start of employment, end of employment and sojourn times in the working areas.

3.3 Available toxicokinetic models

A series of PBPK models for lifelong TCDD exposure in humans are available in the literature. Nearly all of them assume a linear elimination kinetic, they only differ in the sophistication how time-dependent physiological variables as body weight, body fat volume or liver fat volume are considered (e.g. [11], [10]; [23]; [20], [14], [26]. The model of Carrier et al. [8], [9] is an exception in terms of the elimination function which is based on a modified Michaelis-Menten function.

Of course, more biologically complex mechanistic models could be suggested. Phenomena such as TCDD absorption, distribution, binding to liver receptors, enzyme induction, and synthesis of binding proteins could be considered. However, such phenomena occur on a much faster time scale (hours to days) than TCDD elimination (years in humans), which finally justifies the assumption of an quasi-equilibrium between TCDD in lipid fraction of blood, liver and adipose tissue. Note that this assumption (or variations of it) is made either explicitly or implicitly in all of the lifelong TCDD models for humans mentioned above.

4 The computer simulation study

The planning of a large computer simulation study comprises of technical and non-technical issues. The technical issues coincide to a large extent with the problem analysis and design step of the common three-step software development process (where the third step is implementation).

The non-technical issues consist of various essential prerequisites and fundamental decisions. Treating them lightly could seriously jeopardise the success of the whole project.

4.1 Problem analysis

At first, it is necessary to analyse plausible PBPK models for human lifetime toxicokinetics of TCDD and integrate them into more comprehensive models. Among others, these model should allow for multiple exposure to different toxins with similar kinetics (PCDD/Fs instead of just TCDD alone), chronical exposure (both background and workplace) and pointwise exposure (e.g. through accidents). Usage of these models is in establishing a dose-response relationship for a proper risk assessment of TCDD. The models have also to allow the construction of individual human exposure profiles over longer time periods. Ideally, one wide-ranging model could be found, from where all others deduce as special cases.

This approach or these different approaches in modelling individual human lifetime toxicokinetics could be mechanistically compared under various realistic scenarios, e.g. temporal change in background exposure, spatial change in workplace exposure, high accidental exposure over a short time, effects of fattening and loosing weight during lifetime, lifetime effects of breastfeeding (both in contaminated women and in persons who during childhood have been breast-fed by a contaminated woman), sensitivity in model parameters, effects of congeners other than TCDD, effects of a confounder variables like smoking status (in particular effects of ignoring them), effects of ignoring interaction terms in the model (interactions among two mutually different congeners or among a congener and a confounder variable). The construction of exposure indices from individual concentration-time curves could also be studied.

The main part of the project are Monte Carlo computer simulations in order to assess uncertainty in the toxicokinetic modelling process up to its implications on risk assessment. The main issues to be studied are amongst other things:

- Uncertainty in choice of PBPK model assumptions: E.g. assume non-linear kinetic for toxin elimination to generate data and use linear kinetic for analysis. The goal is to identify those model assumptions which are particularly sensitive to dose level prediction. A sensitivity in model parameters to interindividual variation: E.g. individualise age-related changes of body fat volume.

- Uncertainty caused by measurement of toxin levels: Different laboratories report different dioxin levels for the same sample. In the Boehringer data differences of 50% or more occur frequently [12, Figure 4b].

- Uncertainty caused by workplace misclassifications: Participants of the Boehringer study have been asked about their working history. These interviews have been repeated at a later time point. Comparisons revealed that 50% of the reported working times and 30% of the reported working areas did not match between two interviews [12].

- Uncertainty caused by different approaches to model the covariance structure of repeated measurements

- Uncertainty due to choice of statistical estimation method

- Effects of missing values and unknown confounders

- Uncertainty in choice of appropriate exposure index, lag time and dose-response relationship: This form of uncertainty concerns the subsequent processing of the toxicokinetic results in dose-response models. Even if the former would yield absolutely correct values, uncertainty in the latter would still distort the results of the risk assessment process.

- Selection effects: They could have been easily occurred in the Boehringer cohort data as participation in the dioxin measurement program was on a voluntary basis. A specific form of selection bias is the so-called “healthy worker survivor effect” (see e.g. [25]).

To meet these requirements a computer program library with a flexible modular structure has to be designed and implemented (see next Subsection). Thereby note that uncertainty analysis can only shed light onto overlooked issues, underrated issues or issues which have not been known at the time of original analysis itself. It is probable that some time after the completion of the uncertainty analyses new scientific theories may evolve, e.g. a new toxicokinetic TCDD model for humans. The design of the computer program library should allow a flexible and smooth integration of currently unknown but supposable future developments.

There are numerous adequate software products available where the computer program library could be implemented so that the actual decision is mainly a matter of personal preference. In the current case the computer program library is implemented in form of SAS macros (SAS Institute Inc., Cary, NC, USA).

4.2 Program library for Monte Carlo simulations

The main goal of the simulation study is to mimick the essential features of both the Boehringer cohort and the corresponding statistical analyses. Four main computer program modules can be distinguished.

4.2.1 Simulation of whole cohort. The simulated plant is operating between 1950 and 1985. Amongst other things five main working areas with different TCDD working exposure levels are assumed. The exposure levels are assumed to follow a lognormal distribution with mean intake of 3500, 150, 40, 5 and 0 TCDD units/year, respectively. Mean background exposure is set to 1 unit/year. The mean values closely resemble the actual exposure estimates as reported in Becher et al. [1]. The highest exposure occurs solely in the 1950ies. Determination of TCDD concentrations in the simulated workers happens in 1990 and 1995. The willingness of the workers to participate in the TCDD screening programme is simulated as well. The numbers of workers in the simulated cohort and in the simulated TCDD screening programme should approximately resemble the corresponding numbers in the Boehringer cohort.

Individual change of working area, termination of work contract, retirement and death of the virtual workers are randomly simulated as well as hiring of new workers. TCDD elimination kinetic is generated according to four different scenarios, that is, simple linear kinetic with constant total lipid volume (TLV) over lifetime, simple linear kinetic with TLV varying with workers age, linear kinetic according to Thomaseth and Salvan [26] with TLV and liver lipid volume varying with workers age, and modified Michaelis-Menten kinetic with body weight varying with workers age [8], [9]. During lifetime the simulated workers are subject to develop one of two kinds of cancer. Development of cancer will increase mortality of a simulated worker and will entail his retirement. The functional dose-cancer response relationship of TCDD is modelled by increasing the hazard for the first kind of cancer proportionally to the individual TCDD exposure during lifetime. Various TCDD exposure indices can be explored (e.g. area under the concentration-time curve (AUC), lagged AUC, etc.).

Due to the hazard increase in the first out of two kinds of cancer the existence of a predominating cancer site is simulated.

4.2.2 Measurement errors. In module 4.2.1 simulated true values are recorded. These will be contaminated with TCDD measuring errors, workplace misclassification errors, etc. in order to get simulated observed values.

4.2.3 Workplace exposure backcalculation. TCDD measurements are available only a long time after the actual workplace exposure. Under plausible assumptions (concerning background exposure, fat fraction of body, form of elimination from body, etc.) the exposure levels in different working areas can be estimated by backcalculation. There have been two different main attempts to perform a backcalculation, one is described in detail by Becher et al. [1], the other is due to Portier et al. [24]. Both attempts can be compared with this program module [16].

4.2.4 Risk estimates. Extract various individual time-dependent exposure indices for all members of the simulated cohort. Assess dose-response relationship between these time-dependent exposure indices and cancer incidence and mortality by use of Cox regression models, Poisson regression models and standardised mortality ratio analyses [1]. The final results of this simulation module are cancer risk estimates which in reality would provide the decision basis for risk managers.

4.3 Miscellaneous non-technical issues

When prearranging uncertainty investigations then their time demand should be accordingly taken into account. The availability of a detailed and profound documentation of the statistical analyses in question is an important prerequisite. Risk assessment for dioxins is an interdisciplinary effort. The integration of research results from various scientific disciplines such as toxicology, molecular biology, biochemistry, medicine, epidemiology and biostatistics is required. It is self-evident that each isolated effort would be doomed to failure. An uncertainty analysis is no exception. Arrangements have to be made in order to allow the permanent discussion of assumptions and results with exponents of the other scientific disciplines.

It is an open question who should do the uncertainty analysis. Two options are obvious: the uncertainty analysis is performed within the team which did the original statistical analysis or outside this team. The pros of the former case are evident, that is, already existing knowledge of the matter will result in efficient work (and usually there will be some kind of uncertainty assessment already during the performance of a statistical analysis). However, the cons are evident as well. That is, if somebody works over a longer period of time on a certain problem, then some sort of factory blindness will be hardly avoidable. On the other hand, if somebody from outside the statistical analysis team performs the uncertainty assessment, then this person will usually have another main focus onto the research problem and new ideas may be developed due to the non-involvement in the original analysis. The cons of this approach are in the greater effort to familiarise with the subject and a possibly difficult relationship to the team members of the original analysis. These considerations should be made an integral part in the projects statistical analysis schedule from the beginning.

Here a rather traditional Monte Carlo simulation study is utilised for uncertainty assessment. It mainly consists of the exploration and evaluation of different interesting scenarios. Alternatively, an uncertainty assessment could be performed within a fully Bayesian framework (see e.g. [6], [7]. A detailed comparison of the pros and cons of both approaches is beyond the scope of this paper.

5 Discussion

Risk assessment is a vital activity in modern society because it provides the scientific basis for effort to identify and control hazards to health and life. However, risk assessment is generally subject to great uncertainty. The scientific knowledge available in this field is far from sufficient. Uncertainty in risk assessment is at present a major but largely unsolved problem to be faced with solid research.

The goal of uncertainty analysis is to provide an evaluation of the limits of our knowledge, or in other words, an uncertainty analysis should tell us how much we can be wrong and still be okay [7].

Uncertainty assessment of large-scaled statistical analyses is obviously a reasonable and essential task in the empirical research process. In our view it is useful to consider the idea of indeterminability which can be subdivided into statistical variability, structural and technical uncertainty [18], [12], [17].

Analytical approaches to assess structural and technical uncertainty will be easily limited by the complexity of the underlying problems. However, elaborate computer simulation studies have evolved as an appropriate tool for the investigation of these types of indeterminability [28].

Obviously, analysis of uncertainty comprises uncertainty itself. During an uncertainty analysis various decisions about parameter settings (e.g. constant or random, distribution type and distribution parameters, etc.) have to be made. Actually, this settings would require an uncertainty analysis of its own. That is, there would be meta-uncertainty - the uncertainty of the uncertainty analysis. And then there would be meta-meta-uncertainty, the uncertainty of the meta-uncertainty analysis such that we would built one layer of uncertainty on another and finally miss the goal. The loophole in this catch is the insight that uncertainty analyses are not done on their own, but are part of the scientific research process. Accordingly, the results of an uncertainty analysis should be communicated to the scientists who posed the research question, collected the data and performed the statistical analysis on the one hand as well as to other experts in the field on the other hand. Together these researchers will be able to assess the validity of the uncertainty analysis and to discuss the consequences of the results [17].

COMPSTAT'2004 Symposium

SIMULTANEOUS INFERENCE IN RISK ASSESSMENT; A BAYESIAN PERSPECTIVE

Leonhard Held

Key words: Risk assessment, Monte Carlo, simultaneous credible bands, simultaneous inference.

COMPSTAT 2004 section: Biostatistics.

Abstract: We consider the problem of making simultaneous inferential statements in risk assessment from a Bayesian perspective. We review a generic algorithm for computing a two-sided simultaneous credible band based on Monte Carlo samples from a multidimensional posterior distribution. A simple modification leads to an upper or lower simultaneous credible bound, which will be described. Such simultaneous credible bands and bounds have attractive properties: they are easy to calculate, completely non-parametric and invariant to monotone component-wise transformations of the variables. We illustrate the proposed approach through an example from low-dose risk estimation, previously analysed in the literature with frequentist methods.

1 Introduction

Statistical risk assessment deals with the probabilistic quantification of potential damaging effects of an environmental hazard. Of particular importance is the formulation and estimation of dose-response relationships based on data from controlled toxicological studies. This paper takes a Bayesian view to the statistical problem of estimating the dose-response relationship and derived quantities. Such an approach has at least two useful features: First, the posterior distribution of any function of the original parameters can be derived *exactly* using Monte Carlo simulation; secondly, pointwise and simultaneous credible bands and bounds can be computed *exactly* up to Monte Carlo error.

From a freqentist perspective, the calculation of simultaneous confidence bands has been developed in Pan, Piegorsch and West [8], and has been applied to risk assessment estimation in Al-Saidy et al. [1] and Piegorsch et al. [9]. Al-Saidy et al. [1] consider quantal response data with a binomial likelihood while Piegorsch et al. [9] apply the methods to continuous measurements based on a quadratic regression model. In this paper we re-analyze the data from Piegorsch et al. [9], but use a Bayesian approach based on Monte Carlo sampling. In particular, we develop methods to calculate *simultaneous credible bounds* for the *benchmark dose* at various *benchmark risks*.

The paper is organized as follows. In Section 2 we review an algorithm to calculate (two-sided) simultaneous credible bands based on Monte Carlo samples from a posterior distribution and outline a straightforward modification to obtain one-sided simultaneous credible bounds. In Section 3 we apply these methods to a problem from low-dose risk assessment and compare our results with those obtained by Piegorsch et al. [9] using frequentist methods. We close with some discussion in Section 4.

2 Monte Carlo estimation of simultaneous credible bands and bounds

2.1 Two-sided credible bands

Assume that we have a sufficiently large sample $\boldsymbol{\theta}^{(1)}, \ldots, \boldsymbol{\theta}^{(n)}$ from a posterior distribution $p(\boldsymbol{\theta}|\boldsymbol{y})$, obtained through simple Monte Carlo, or more advanced Markov chain Monte Carlo (MCMC) simulation. Here $\boldsymbol{\theta}$ is an unknown parameter of dimension p, perhaps obtained after suitable transformation of the original parameters in the model.

The approach proposed in Besag et al. [2, Section 6.3] starts with sorting and ranking the samples separately for each parameter of interest θ_i, $i = 1, \ldots, p$. Let $\theta_i^{[j]}$ denote the corresponding order statistic and $r_i^{(j)}$ the rank of $\theta_i^{(j)}$, $j = 1, \ldots, n$. Let j^* be the smallest integer such that the hyperrectangular defined by

$$[\theta_i^{[n+1-j^*]}, \theta_i^{[j^*]}], \quad i = 1, \ldots, p \tag{1}$$

contains at least k of the n values $\boldsymbol{\theta}^{(1)}, \ldots, \boldsymbol{\theta}^{(n)}$. Besag et al. point out that j^* is equal to the kth order statistic of the set

$$S = \left\{ \max \left\{ n + 1 - \min_i r_i^{(j)}, \max_i r_i^{(j)} \right\}, j = 1, \ldots, n \right\}. \tag{2}$$

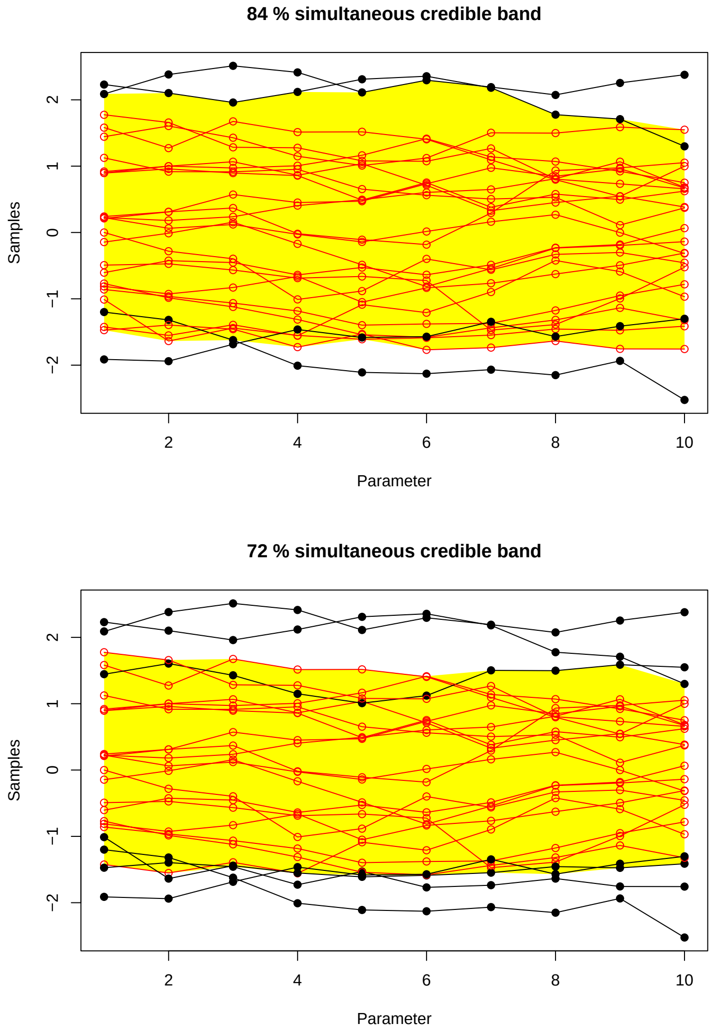
By construction, the credible region (1) will then contain (at least) $100k/n\%$ of the empirical distribution.

Figure 1 illustrates the construction of simultaneous credible bands for simulated data with $n = 25$ and $p = 10$. Each line corresponds to one sample $\boldsymbol{\theta}^{(j)}$ while each column represents a parameter θ_i. The yellow band is a simultaneous credible band of empirical coverage 84 and 72%. The set (2) is in this example

$$S = \{16, 17, 17, 18, 19, 19, 20, 20, 20, 20, 22, 22, 22, 22, 23, 23, 23, 23, 24, 24, 24, 25, 25, 25, 25\}. \tag{3}$$

It is straightforward but tedious to re-calculate (3) based on Figure 1 and formula (2).

Note that the simultaneous credible band is a product of symmetric univariate credible intervals of the same level $(2j^*/n - 1) \cdot 100\%$. Besag et al. [2] also note that the method is slightly conservative in the sense that, for n fixed, the credible region (1) will typically contain slightly more that $100k/n\%$ of the empirical distribution because of ties in the set (2); this is



84 % simultaneous credible band

72 % simultaneous credible band

Figure 1: Illustration of the construction of simultaneous credible bands for simulated data with $n = 25$ and $p = 10$.

evident from out small example where the set (3) has many ties. This problem increases to an extent with p increasing, because the number of ties will then typically increase. However, the method is still consistent as $n \to \infty$. Empirical evidence shows that these credible bands tend to get rather unstable for credibility levels close to unity. In other words, the Monte Carlo will be quite large in these circumstances, but this problem can be easily attacked by taking a larger sample. However, the method requires the storage of all samples from all components of $\boldsymbol{\theta}$ which can be prohibitive is p and n is large.

Furthermore, the sorting and ranking of the samples from each component can be computationally intensive, if n is extremely large. However, in our experience, for $n = 10,000$ samples the method gives stable estimates at the usual credibility levels (95 and 99%) in just a few seconds.

Also note that ranking and sorting has to be done only once, even if simultaneous credible bands are required on more than one level. Only the set (2), the ordered samples $\theta_i^{[j]}$ and the ranks $r_i^{(j)}$ need to be available to calculate simultaneous credible bands at additional levels. The computational effort to calculate these additional simultaneous credible bands is negligible, compared to the initial ranking and sorting.

2.2 One-sided credible bounds

Besag et al. [2] note that "one-sided and other asymmetric bounds can be constructed analogously", but do not give further details. We will now look at this problem more closely. Clearly, the general idea of the approach described above can be easily applied to calculate, say, an upper confidence bound: Let j^* be the smallest integer such that the area defined by

$$(-\infty, \theta_i^{[j^*]}], \quad i = 1, \dots, p \tag{4}$$

contains at least k of the n values $\boldsymbol{\theta}^{(1)}, \dots, \boldsymbol{\theta}^{(n)}$. This procedure thus defines a one-sided upper credible bound of credibility level $100k/n\%$. The only question remaining is if there is also an analogous formula to (2). Indeed, j^* now simply equals the kth order statistic of the set

$$\left\{ \max_i r_i^{(j)}, j = 1, \dots, n \right\} \tag{5}$$

Similarly, a lower bound can be obtained by

$$[\theta_i^{[j^*]}, \infty), \quad i = 1, \dots, p \tag{6}$$

where j^* now equals the kth order statistic of the set

$$\left\{ \min_i r_i^{(j)}, j = 1, \dots, n \right\}. \tag{7}$$

A completely equivalent way to calculate a lower simultaneous credible bound is of course to compute the negative upper simultaneous credible bound of the negative samples.

Given the general applicability of the method proposed by Besag et al. [2] described above, it is surprising how rarely it has been used in practice. We will now describe an application taken from the area of low-dose risk estimation, where simultaneous credible bounds are useful.

3 Applications in low-dose risk estimation

Here we look at a specific problem in low-dose risk estimation, where the observed data $Y(x)$ are continuous, reflecting the *adverse* effect of some toxic exposure x. In other words, $Y(x)$ is expected to decrease with increasing x.

The data come from a study originally described in Chapman et al. [4], where x is a particular concentration of copper in and $Y(x)$ is the germination tube length of giant kelp, exposed to copper at dose x. There were up to five replicate observations for each of six copper concentrations between 0 and 180 μg/L.

Let $Y(x_i) = \mu(x_i) + \epsilon_i$, where $\epsilon_i \sim N(0, \sigma^2)$, $i = 1, \dots, m$ are independent. We follow Piegorsch et al. [9] and assume a simple quadratic regression model $\mu(x) = \beta_0 + \beta_1 x + \beta_2 x^2$. It may perhaps be useful to impose a further monotonicity constraint on the regression coefficients $\boldsymbol{\beta} = (\beta_0, \beta_1, \beta_2)^T$ such that the function $\mu(x)$ is decreasing with increasing x. A weaker requirement is to assume that $\mu(x)$ is monotone at least within the observed range of x values. We will comment on such modifications in the discussion but use for the moment the unconstrained model.

A key quantity in risk assessment is the so-called *risk function* $R(x) = P(Y(x) \leq \mu(0) - \delta\sigma)$, where δ is a constant and typically chosen as $\delta = 2$ or $\delta = 3$. The idea is that a response, which is more than δ standard deviations below the control mean is considered as adverse, and $R(x)$ quantifies the probability of such an event as a function of the dose x. Furthermore, the *additional risk* is defined as $R_A(x) = R(x) - R(0)$, which becomes under the normal model

$$R_A(x) = \Phi(-(\beta_1 x + \beta_2 x^2)/\sigma) - \delta) - \Phi(-\delta), \tag{8}$$

where $\Phi(.)$ is the standard normal distribution function. Finally, a key concept in risk assessment is the notion of the *benchmark risk* and *benchmark dose*. This is often used to establish a low-dose level needed, the *benchmark dose* x_B, to generate a specific additional risk R_A, the benchmark risk $z \in (0, 1)$. Hence model (8) is inverted to find the *benchmark dose* x_B for a fixed benchmark risk z, i.e. solve $R_A(x_B) = z$ for $x_B(z)$.

Piegorsch et al. [9] develop sophisticated methodology to compute a frequentist simultaneous upper confidence bound for $R_A(x)$. The established function is then inverted based on equation (8) to obtain a simultaneous lower confidence bound for $x_B(z)$. Here we will devise an alternative Bayesian approach based on Monte Carlo sampling. For notational convenience, we set $\kappa = 1/\sigma^2$. A non-informative reference prior $p(\boldsymbol{\beta}, \kappa) \propto \kappa^{-1}$ is assumed for the unknown parameters (e.g. [3]) and hence the posterior distribution is of the usual normal-gamma form, known from standard linear model theory:

$$p(\boldsymbol{\beta}, \kappa | \boldsymbol{y}) = p(\kappa | \boldsymbol{y}) p(\boldsymbol{\beta} | \kappa, \boldsymbol{y}).$$

Here $p(\kappa|\boldsymbol{y})$ is gamma distributed with parameters $(m - p)/2$ and $s^2 \cdot (m - p)/2$ where $p = 3$ is the dimension of $\boldsymbol{\beta}$ and s^2 is the classical (unbiased) estimate of the variance σ^2. Furthermore, $p(\boldsymbol{\beta}|\kappa, \boldsymbol{y})$ is normal with mean equal to the least squares estimate $\hat{\beta} = (\boldsymbol{X}'\boldsymbol{X})^{-1}\boldsymbol{X}'\boldsymbol{y}$ and covariance matrix $\kappa^{-1}(\boldsymbol{X}'\boldsymbol{X})^{-1}$. We can thus easily generate independent samples from this posterior distribution by first sampling $\kappa^{(i)}$ from $p(\kappa|\boldsymbol{y})$ and then sampling $\boldsymbol{\beta}^{(i)}$ from $p(\boldsymbol{\beta}|\kappa^{(i)}, \boldsymbol{y})$.

A Bayesian approach using Monte Carlo sampling has the advantage that samples from any function of the parameters can be obtained without any need for approximations, such as, for example, the Delta method. In the current context, $R_A(x)$ as defined in (8) is a simple function of the parameters β_1, β_2 and σ^2. Hence we are able to compute the posterior distribution of $R_A(x)$ for a range of values of x, say $x_1 < x_2 < \ldots < x_M$, and then compute simultaneous credible bounds for the parameters $R_A(x_1), R_A(x_2), \ldots, R_A(x_M)$. For illustration, Figure 2 displays the first $n = 100$ samples from the posterior distribution of $R_A(x)$ for $\delta = 3$.

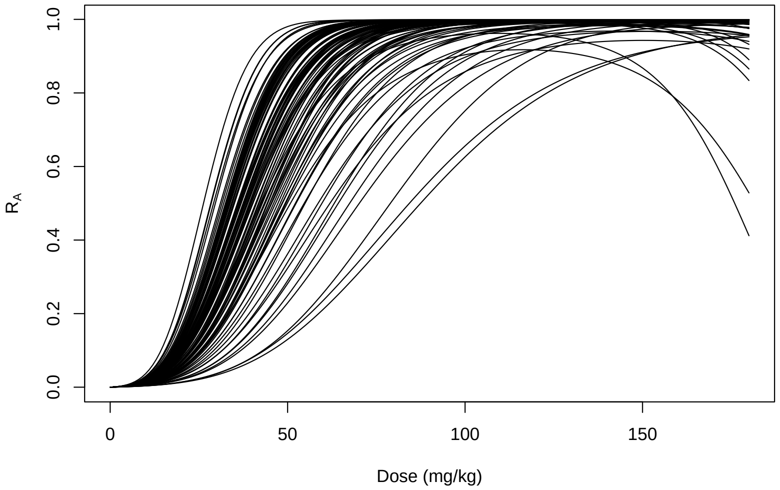


Figure 2: 100 samples from $R_A(x)$ for $x \in [0, 180]$, $\delta = 3$.

Figure 3 now displays the posterior median of $R_A(x)$, as well as the 95% simultaneous upper credible bound for $R_A(x)$, calculated using (4) and (5). Those have been obtained using $n = 10,000$ samples and 181 equally spaced values of $x \in \{0, 1, \ldots, 180\}$. For comparison, we also display the frequentist estimate of $R_A(x)$ as well as the corresponding 95% simultaneous upper confidence bound described in Piegorsch et al. [9].

Note that the Bayesian point estimates are slightly above the frequentist ones. A more pronounced difference can be seen for the simultaneous upper bound, which is again larger in the Bayesian approach.

Piegorsch et al. [9] go on to construct lower simultaneous credible bounds

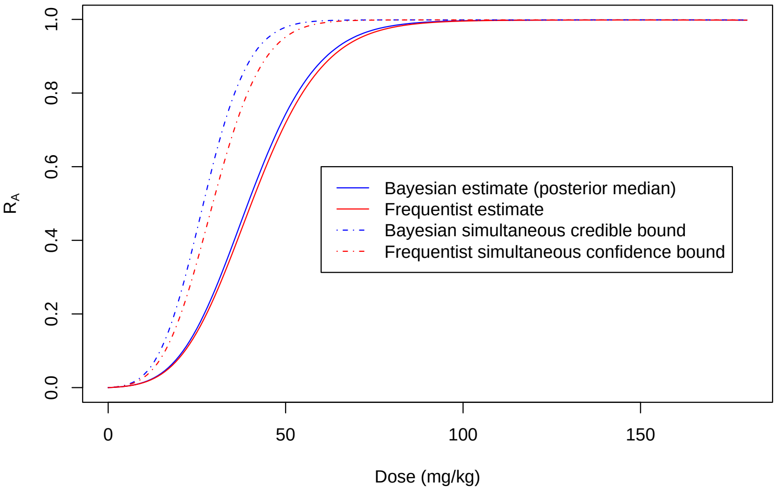

Figure 3: Estimated R_A function and simultaneous upper 95% credible bound, $\delta = 3$.

for $x_B = x_B(z)$ as a function of the benchmark dose $z \in (0, 1)$ by simply inverting the upper simultaneous bounds obtained for $R_A(x_B)$. Here we look at an alternative Bayesian sample-based solution.

Again, we view $x_B(z)$ as a function of the original parameters, i.e. for each benchmark risk z and each sample $\beta_1^{(j)}$, $\beta_2^{(j)}$ and $\sigma^{(j)}$, we solve equation (8) for $x_B^{(j)}$.The two solutions are

$$x_B(z) = \frac{1}{2\beta_2}\left(-\beta_1 \pm \sqrt{\beta_1^2 - 4C_l\beta_2\sigma}\right), \tag{9}$$

where $C_l = \delta + \Phi^{-1}(z + \Phi(-\delta))$. If there are two real positive solutions, we take the smaller value as $x_B^{(j)}$. Note that we have dropped the upper index $^{(j)}$ in (9) for simplicity. For each value of z, this defines samples from the posterior distribution of $x_B(z)$.

If $x_B(z)$ would be well-defined for every value of z and every sample of the parameters β_1, β_2 and σ, we could indeed just invert the simultaneous credible bound for $R_A(x_B)$ to obtain one for $x_B(z)$, just as in the frequentist case. However, there will not always be a positive real solution (9). Here it turns out that for $z = 0.99$, 11% of the samples do not have real solution. For smaller values of z, far less samples do not have a real solution; in fact less than 1% are "missing" for $z <= .83$. For illustration, consider Figure 5, which displays the first 100 samples from the posterior of $x(z)$.

Inverting the credible bound for $R_A(x_B)$ may hence induce bias, and we therefore consider a sample based, direct solution to construct a lower simultaneous bound for a series of benchmark doses z_l, $l = 1, \ldots, L$. We choose $L = 100$ equally-spaced values for z between 0 and 0.99. Note that the upper bound on z_L is $\Phi(\delta) < 1.0$, which in our case equals 0.9987.

We now have two options. First, we may delete all those samples, where $x^{(j)}(z_l)$ is missing for at least one benchmark risk $z_1, \ldots, z_L$ considered. Due to monotonicity properties this corresponds to deleting all those samples, where $x^{(j)}(z_L)$ is missing. However, this may induce bias in the estimation of simultaneous credible bounds, because larger values of BMD are typically missing for larger values of z. Alternatively, we may impute all missing values with their corresponding median, say, and proceed as if the sample would have been observed completely. The two different types of credible bounds are shown in Figure 5, denoted as "complete case" and "median imputed". There seems to be no substantial difference. Also displayed is the lower simultaneous confidence bound proposed by Piegorsch et al. [9], obtained by simply inverting the upper simultaneous confidence bound for $R(x)$.

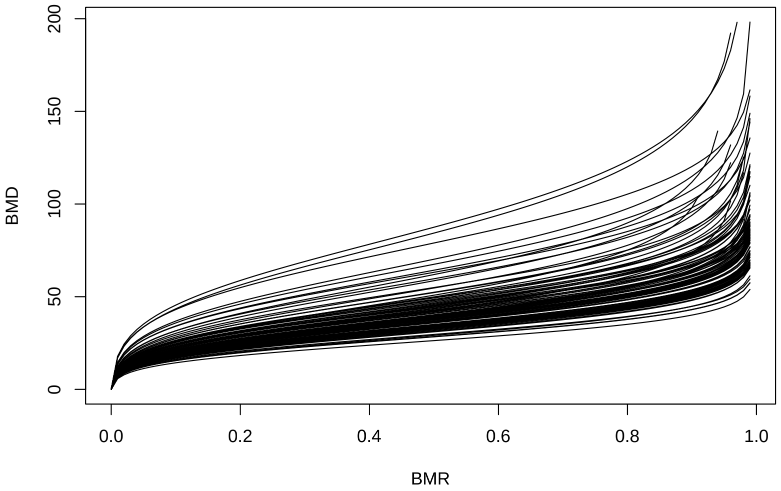

Figure 4: 100 samples of $x_B(z)$ for $\delta = 3$.

4 Discussion

The Bayesian approach to simultaneous inference in risk assessment has much to offer. It does not rely on approximations, is completely general and easy to implement. For example, it will be straightforward to calculate a Bayesian simultaneous credible bound in the application considered in Al-Saidy et al. [1], where the response variable is binomial.

We now close with two final comments. In the current application it

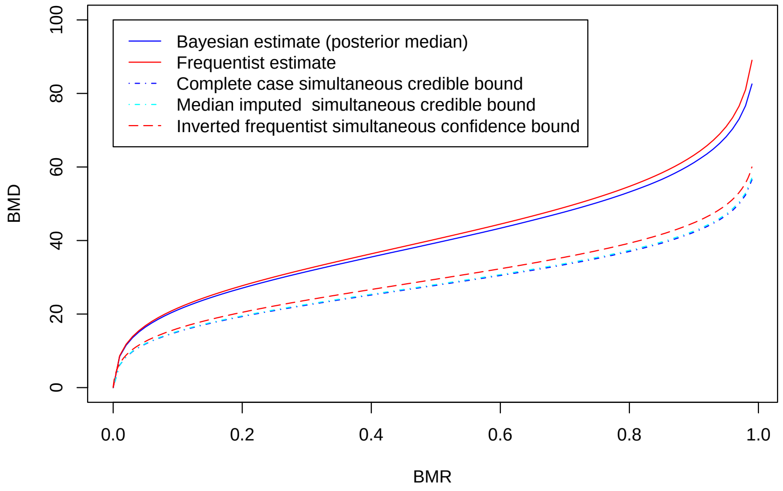

Figure 5: Estimated benchmark dose function and simultaneous lower 95% credible bound, $\delta = 3$.

turned out that a large number of samples did correspond to non-monotone dose-response relationships in the observed range of x. Certainly, the quadratic regression approach to the problem is open to question, and perhaps a monotone model, such as a logistic growth curve model or a nonparametric regression model under monotonicity constraints (e.g. [7] could have been useful. However, we should mention that we could have easily incorporated monotonicity constraints on $\boldsymbol{\beta}$ by simply ignoring all samples that do not fulfill the restriction imposed, see Gelfand, Smith and Lee [5] for more details in the context of Markov chain Monte Carlo simulation.

An alternative way to obtain simultaneous probability statements from Monte Carlo output is based on highest posterior density estimation, and has been described in Held [6]. This approach taken has the advantage that the simultaneous region does not need to be a hyper-rectangular, so is more realistic. Indeed, Held [6] has shown through examples, that simultaneous credible bands using the method described in Besag et al. [2] may include regions in the parameter space, which are not supported by the posterior at all. The difference between the two methods is related to the distinction between credible intervals based on quantiles and highest posterior density intervals in the one-dimensional case. The former intervals may include areas of low posterior density, for example if the posterior is bi-modal, whereas the latter will - by definition - only include regions of high posterior density.

However, the method by Held [6] can only be applied to calculate the posterior support for a series of *reference points*, but there is no easy way to visualize these credible regions in higher dimensions. In the current application there does not seem to be an obvious reference point for $R_A(x)$, say, so the method by Besag et al. [2] is the obvious choice for simultaneous Bayesian inference in risk assessment.

INTERACTIVE BIPLOTS FOR VISUAL MODELLING

Heike Hofmann

Key words: Data visualisation, biplots, univariate linear models, category level points, biplot axis, visual modelling.

COMPSTAT 2004 section: Data visualisation.

Abstract: The link between statistical models and visualisation techniques is not very well explored, even though strong connections do exist. This paper describes how biplots – interactive biplots in particular - can be used for visual modelling. By slightly adjusting the way biplots are constructed they provide the means to display linear models. The goodness of fit of a particular model becomes instantly visible. This makes them a useful addition to the standard set of visualization tools for linear models.

Biplots show predicted values and residuals. This helps, firstly, to assess a model far beyond the mere statistics and to detect structural defects in it. Secondly, biplots provide a link between the modelling statistics and the original data. Additional interactive methods such as hotselection also allow the analysis of outlier effects and behaviour.

1 Introduction

Biplots are a very promising tool for visualising high-dimensional data, which include both continuous and categorical variables. The strategy of biplots is to choose a linear subspace (usually a 2-dimensional space - in order to be able to plot the result using standard techniques), which is in some respect optimal, and project the high-dimensional data onto this space. One criterion for optimality is, for instance, to minimise the discrepancy between the high- and the two dimensional representations of the data. Biplots show only one projection out of infinitely many. They therefore cannot be exact representations of the data but only approximations.

What gave the Biplots their prefix "Bi-" ($\beta\iota$ is the greek syllable for "two") is the simultaneous representation of both data points and original axes within the projection space.

The biplot axis of a continuous variable is represented by a straight line (in case of linear models, to which we will restrict ourselves) with unit points marked by small perpendicular lines. One unit of a variable X_i corresponds to one times the standard deviation of X_i. If the data matrix X is centered and standardized, these units are therefore directly comparable for all i, and the length of a unit vector gives a measure for how well a variable is represented in the chosen projection plane.

Instead of continuous axes, so called *category level points (CLPs)* are used to display a categorical variable X. Using a binary dummy variable for each of the categories of X, an imaginary axis is found as in the continuous case. A CLP is given as the 1-unit point of this axis. Each CLP therefore represents one category of X.

The different gray shades of the points in the figure is the effect of a crude graphical density estimate - light areas in the display correspond to a high number of observations.

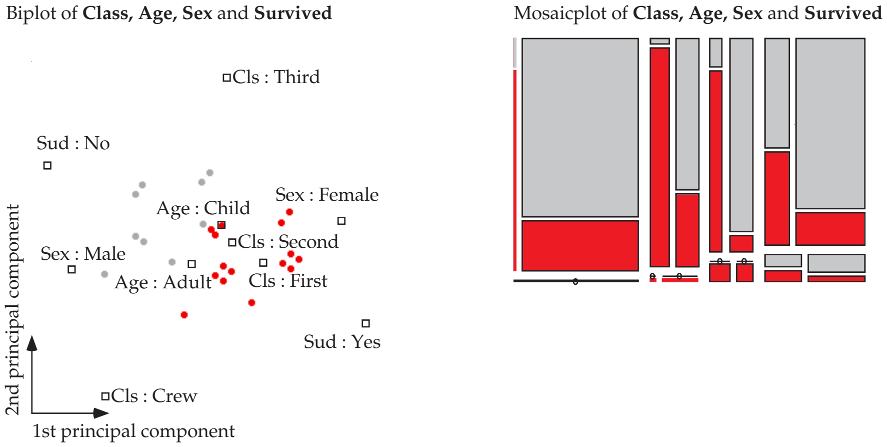

Figure 1: Biplot and corresponding mosaicplot of the Titanic Data [3]. Each dot on the left side corresponds to a cell on the right hand side. Highlighted are survivors.

Figure 1 shows a biplot of categorical variables, based on a Multiple Correspondence Analysis (MCA). Next to the biplot a mosaicplot of the same variables is drawn.

Biplots were first introduced by [5]. A recent monograph on biplots by [6] summarises different types of biplots and embeds various models in the concept. Possibilities for interactive extensions have been examined in [7].

Biplot representation

The graphical representation of a biplot is dot based. This means for categorical variables, that each combination is shown as one single dot. Of course, this does not allow conclusions about this combination's size any more. One solution to this problem is the use of density estimates. This also covers the problem of over-plotting, which, especially in large data sets, is always present in dot based representations.

The graphical representation of a biplot has two components:

- Data points are projected onto the plane spanned by the first two principal components and visualised as dots. The center of the plot is given by the projection of the p dimensional mean $(\frac{1}{n}X_1^t\mathbb{1}, \ldots, \frac{1}{n}X_p^t\mathbb{1})$.

- The unit vectors e_i^t corresponding to the (dummy) variables are also projected onto this plane.
  The graphical representation differs for continuous and categorical variables: For continuous variables, an arrow is drawn from plot center to the projection of the variable, which marks the direction of the original variables. These directions are called the *biplot axes*. The arrowheads mark the unit points on the biplot axes.
  For a categorical variable its projection on the biplot is marked by a square rectangle, the CLPs.

"Reading" a biplot

In a biplot the most important source of information is the distance between objects. The distance gives a measure of how similar or how closely related objects are.

The distance of a CLP to the plot's center (in the middle of the plot) or the length of a unit on a biplot axis reflect how good the projection of the underlying variable is, i.e. with increasing distance the goodness of fit - and with it the "importance" - of this variable increases.

The meaning of objects lying close to each other varies according to their type:

- **point - point**: close points reflect high dimensional "neighbours".
- **axis - axis**: axes with a small angle between them indicate a high positive correlation between the variables, angles near 180° indicate a high negative correlation.
- **CLP - CLP**: Neighbouring CLPs are a hint that the corresponding variables are associated, i.e. that these categories frequently occur together in the data.
- **points - axis/CLPs**: the data values for a point are found by orthogonal projection onto an axis. The axes closest to a point therefore represent the strongest influence for a data point. Accordingly, points are assigned to those categories with the closest lying CLPs. In doing so, one has to remember, that a biplot of more than just two variables cannot be anything but an approximation.

2 Interactive methods

Based on the construction and interpretation of a biplot, interactive methods have to be provided for in the display to facilitate interpretability and ease of use.

2.1 Interactive querying

Interactive querying is context sensitive - querying different objects provides different information. Examples for several querying results are given in figures 2 to 4.

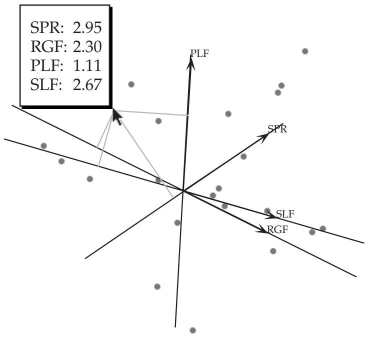

Figure 2: Querying a point or "empty space" of the plot results in drawing perpendicular lines onto the biplot axes. Estimated values of the variables are given for the point in the projection plane.

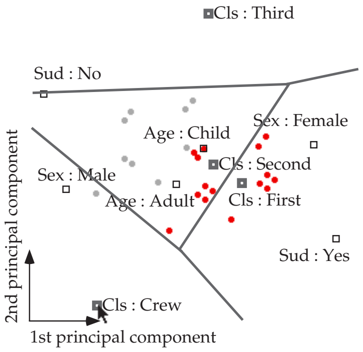

Figure 3: Querying a CLP highlights the other CLPs and the prediction regions of the underlying categorical variable.

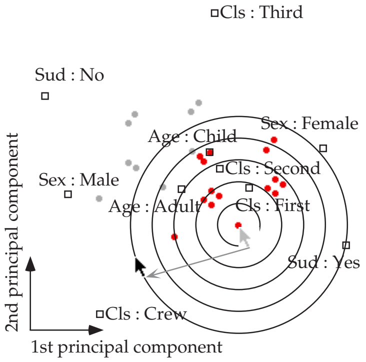

Figure 4: Drag-query: dragging from one point of the plot to another draws circles around the starting point as visual aid for estimating distances between objects.

Figure 3 shows the prediction regions corresponding to the variable'Class'. All categories corresponding to a single variable divide the biplot area in a set of mutually exclusive prediction regions. The prediction region of a CLP is defined as the space closest to the CLP, i.e. no other CLP is closer. From the prediction regions in figure3 it becomes obvious that the representation from the MCA does not fit well: almost all dots are predicted to be second class passengers - there are no combinations predicted as third class passengers.

2.2 Logical zooming and hotselection

The difference between logical and "normal" zooming lies in the fact that by logical zooming an object is not only enlarged but more details appear. Logical zooming in biplots has two main applications: logical zooming in large data sets gives a tool to drill down the data set into smaller parts, which are - hopefully - more homogeneous and therefore easier to analyze.

Another advantage of logical zooming is its possibility of excluding outliers. By focussing on the “main” part, i.e. not regarding outliers, their influence on the model becomes apparent. This is particularly useful for models with a poor behaviour with respect to outliers. If in fact the effect outliers have on a model is of fore-most interest, we will want to use hotselection [8] instead of logical zooming. The boundary between these two tools is fluent - but essentially, the concept of hotselection is less permanent than logical zooming : changes are more readily made and taken back again. In the setting of modelling, hotselection is used to compute a new model based on highlighted values only.

Figure 5 shows a biplot of a correspondence analysis taking all of the descriptive variables into account. Several clearly distinguished groups appear in the plane spanned by the first and second principal component axis. Highlighting shows poisonous mushrooms. These clusters are marked by numbers in the graphic. Using a Mosaicplot of all the descriptive variables, we want to find descriptions (as short as possible) for these groups. The following table gives a short summary of our results:

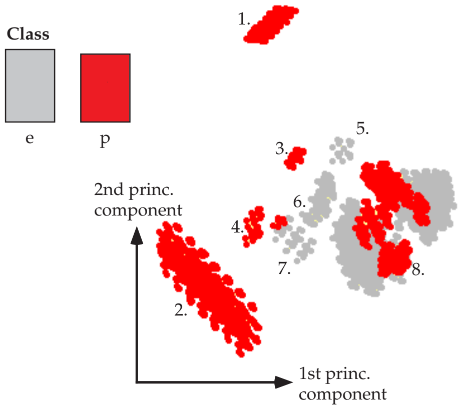

Figure 5: Biplot of an MCA of all of the mushrooms variables. Highlighted are poisonous mushrooms. Some distinct clusters appear (marked by the numbers).

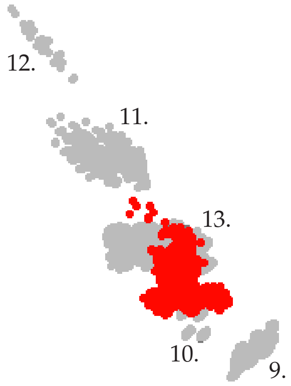

Figure 6: Zoom into group 8.

Zooming is equivalent to hierarchical clustering via MCA. The eight poisonous mushrooms in cluster 7 all have stalk color y setting them off from the rest. Figure 6 shows a zoom into the largest cluster, cluster 8. Several more groups show up in the projection plane. Clusters 9 to 12 consist of edible mushrooms only. For all of these clusters simple descriptions among the explanatory variables exist. Cluster 10 e.g. consists of mushrooms with stalk color o. All of the descriptions are only valid for the zoomed data (i.e. only in combination with all of the description for cluster 8 above). Cluster 13, consisting of 2512 mushrooms, is the only one which needs further inspection - using further logical zooming. After two more steps all poisonous mushrooms can be separated from the edible ones.

Group	Count	Class	Description
1	1296	pois.	ring type = I
2	1728	pois.	gill type: b
3	36	pois.	stalk color above ring: c (or ring type: n)
4	32	pois.	stalk surface below ring:y population: v
5	16	edible	stalk surface above ring:y stalk color above ring:n
6	120	edible	ringtype = f or ringtype = p, stalk surface:k (below and above the ring)
7	56	mixed	48 edible
8	4826	mixed	4010 edible

3 Univariate linear models with continuous response

Based on the graphical representation of a biplot and its interactive features, we will try another approach to visualise linear models among the data. The biplot representation provides a possibility to draw conclusions from a linear model in such a way, that the goodness of fit as well as the most important explanatory variables become instantly visible with one biplot representation.

Let us assume a situation, where we are dealing with a continuous response variable Y and several independent variables $X_1, \ldots, X_p$. The X_i do not necessarily have to be continuous - but we also do not work with categorical variables directly. Instead, for a categorical variable X_i a set of binary *dummy variables* is used as explained before.

Let $X_1, \ldots, X_p$ be a set of independent variables, which has been produced in this way, i.e. a variable is either continuous by default or it is a variable corresponding to a single category.

A *linear regression model* then has the form

$$Y = X\beta + \epsilon, \qquad \epsilon \sim N(0, \sigma^2 I)$$

where $X = (\mathbb{1}, X_1, \ldots, X_p)$ is the *design matrix* and β the *vector of parameters* β_i.

If some of the variables are dummy variables, we have to use a further condition for the parameters of these variables in order to get a unique result. Let $Z_1, \ldots, Z_I$ be the dummy variables for the categorical variable X and $\beta_1, \ldots, \beta_I$ the corresponding parameters of the linear model, then a commonly used constraint (*null-sum-coding*) on the estimates for these parameters is that they sum to zero, i.e.

$$\sum_{i=1}^{I} \hat{\beta}_i = 0,$$

or one of the categories is used as basis and the parameters of the resulting model show the influence a category has with respect to the basis. The constraint *effect-coding* on the parameters then is

$$\beta_i = 0,$$

if Z_i is the dummy variable corresponding to the basis category.

It is well known, that the *hat matrix* $H := X(X'X)^{-1}X'$ is that projection matrix, which minimizes the least squares problem of $\sum_i \epsilon_i^2$ and gives the predicted values $\hat{Y}$ as

$$\hat{Y} = HY.$$

Accordingly, the LS-estimator for β is

$$\hat{\beta} = (X'X)^{-1}X'Y.$$

One of the favourite methods for looking for structure among the residuals $\epsilon_i = Y_i - \hat{Y}_i$ is to plot residuals versus their predicted values, i.e. the data points are projected into the plane spanned by $\hat{Y}$ and $Y - \hat{Y}$. These vectors are indeed orthogonal to each other, since the scalar product vanishes:

$$\begin{aligned}(\hat{Y}, Y - \hat{Y}) &= (HY, Y - HY) = \\ &= (Y, H'(HY - Y)) \overset{H'=H;H^2=H}{=} (Y, HY - HY) = 0.\end{aligned}$$

3.1 Finding the biplot axes and comparing effects

The biplot axes are constructed in this situation in the same way as for standard biplots of PCA or MCA. By projecting the data into the plane spanned by $\hat{Y}$ and $Y - \hat{Y}$ we get $\hat{\beta}_i$ as the coordinate of $e_i' = (0, \dots, 1, \dots, 0) \in \mathbf{R}^p$ in the direction of $\hat{Y}$.

However, while projecting e_i' in the direction of $Y - \hat{Y}$ a problem appears: generally we do not have a value along the Y-axis for any given value of X, particularly for e_i'. A direct calculation therefore is not possible. But we do know that the whole data space X is orthogonal to the direction of the residuals $Y - \hat{Y}$, since

$$X' \cdot (Y - \hat{Y}) = X'Y - \underbrace{X' \cdot X(X'X)^{-1}}_{=I} X'Y = X'Y - X'Y = 0.$$

Therefore the coordinate of the ith biplot axis in the direction of the residuals is also zero.

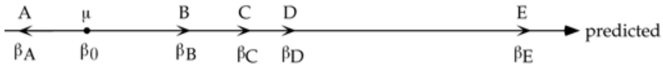

Figure 7: Axis of predicted values together with the five biplot axes for variables A, B, C, D and E.

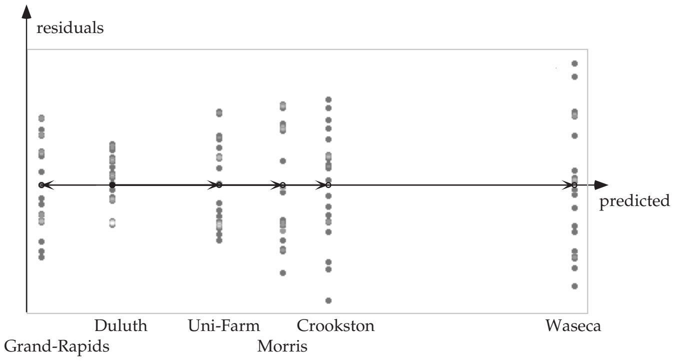

Figure 8: Analysis of variance of the Barley Data. Predicted values are plotted vs. residuals. Six different sites of barley cultivation are drawn as biplot axes. The results of Duluth are used as basis values in the Anova.

Figure 7 shows the vector of the predicted values $\hat{Y}$ together with biplot axes for five variables A, B, C, D and E. We can re-establish the relation of projected data points and their original values by orthogonal projections of the points onto the biplot axes. In the case of an *analysis of variance* this means, that we get very informative "labels" for the predicted values. Figure 8 shows an analysis of variance of the *Barley Data* [4].

We see not only parallel dot plots of the barley yields, but also a natural ordering of the six categories, even (roughly) their distance or closeness. The last point has a caveat: the lengths of their units are not directly comparable, i.e. an axis with large units is not by default a more important factor, since the "importance" of an axis also depends on the variability of $\hat{\beta}_i$. The standard test of judging, whether the ith parameter is significantly different from 0, i.e. $\beta_i = 0$ vs $\beta_i \neq 0$, uses the estimate's variability. The test statistic $\hat{\beta}_i / SE_{\hat{\beta}_i}$, where $SE^2_{\hat{\beta}_i} = \hat{\sigma}^2 e_i'(X'X)^{-1} e_i$, is approximately t distributed with $n - p - 1$ degrees of freedom.

A second choice of units on the biplot axes therefore is the term $\hat{\beta}_i / SE_{\hat{\beta}_i}$. This re-scales the biplot axes in a way that their lengths are proportional to the values of the t-statistic. More important variables in the regression model now have larger parameters, whereas biplot axes with insignificant parameters remain short. Graphically we can support this by highlighting an interval on the axis of predicted values, which corresponds to the 5% level of a t-test. See figure 9: in this example the SE_{β_i} are of the same order of magnitude, and the distances do not change compared to figure 8.

	Difference	std. err.	Prob
Morris - Crookston	-2.02000	2.309	0.978724
Morris - Duluth	7.40333	2.309	0.075985
Morris - Grand-Rapids	10.4683	2.309	0.001805
University-Farm - Morris	-2.73333	2.309	0.923061
Waseca - Morris	12.7083	2.309	0.000052

Figure 9: Comparison of effects: on the top the graphical test via the interval of non-significant values is shown, on the bottom is a table of the corresponding pairwise tests.

When setting the origin of this interval the exact coding, which we used for a categorical variable is important: if we use effect-coding, the origin of the 5% interval will be placed on the predicted value of the basis. When using a null-sum-coding the origin of the interval is set to the expected value of Y.

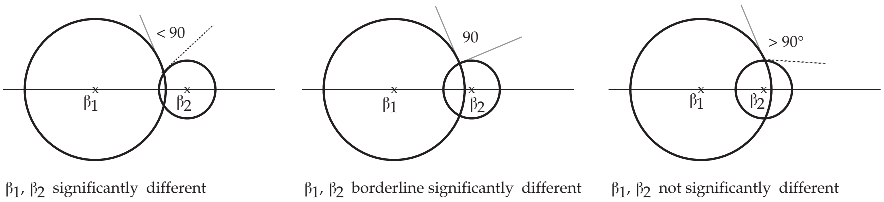
Figure 9 shows the (re-scaled) biplot axes of the example above. The category *Morris* is set as basis value. Around this value the interval of non-significant values is shown as a gray-shaded rectangle. The categories *Uni-Farm* and *Crookston* fall into this rectangle, indicating that these categories have parameters, which are not significantly different from the parameter for *Morris*.

Since the differences between the parameters are not affected by the choice of the coding, we may use these differences for more than one comparison (and with that, multiple tests) in each plot. From a statistical point of view this multiple test situation suggests the use of *Bonferroni-confidence intervals* for each parameter rather than the use of the above significance intervals. The difference between the above intervals and Bonferroni's intervals is essentially a factor, calculated from the level of significance and the number of comparisons made.

The price we have to pay for the re-scaling of the biplot axes with the parameter's variability is that we lose the quantitative connection between data points and biplot axes.

In order to avoid re-scaling we may try another approach to visualise the tests between the effects: the software JMP suggests the use of circles of different size around the parameter values. The size of each circle is given by the standard deviation of the parameter times $t_{\alpha/2}$. Whether two parameters are significantly different is decided by the angle: if the angle at the intersection of their circles is less than 90° the two values are not significantly different, otherwise they are (see figure 10). For a more detailed explanation of the underlying statistics see JMP's "Statistics and Graphics Guide", p.94-95.

The disadvantage of this approach is that angles have to be compared. This makes the decision between significant and not-significant differences between the parameters rather difficult visually.



< 90
β1

β2
β1, β2 not significantly different

Figure 10: Confidence circles around parameter values. Depending on the angles at the circles' intersections the difference between the parameters is significantly different (left), borderline significantly different (middle) and not significantly different (right).

3.2 Projection of the response variable Y

Since we may write Y as the sum of the projection axes $\hat{Y}$ and $Y - \hat{Y}$,

$$Y = 1 \cdot \hat{Y} + 1 \cdot (Y - \hat{Y}),$$

Y has the coordinates (1,1) in the new coordinate system.

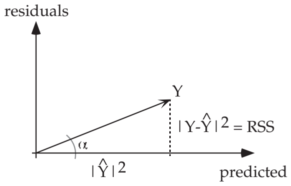

Figure 11: Response variable Y in the projection plane spanned by predicted and residual values.

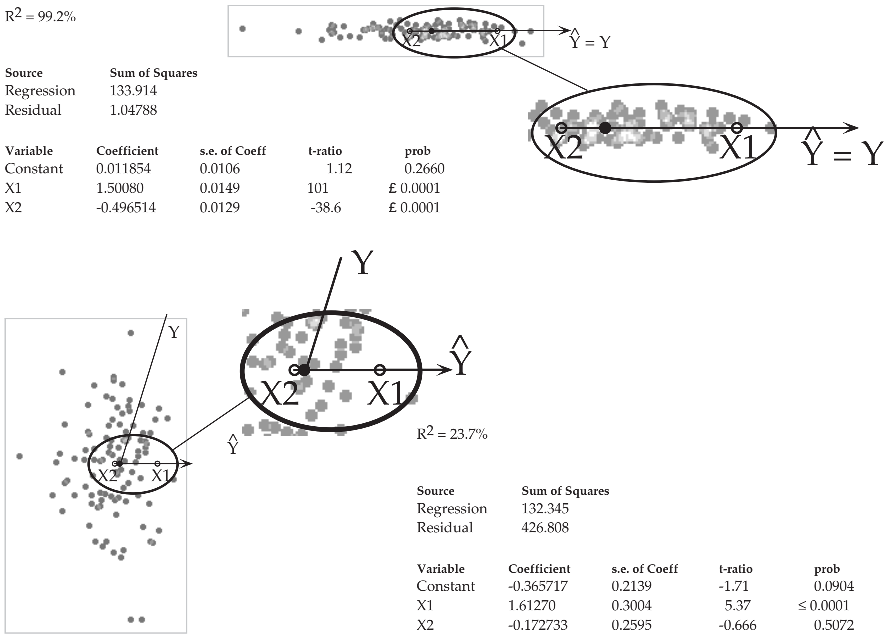
The units on the projection axes are given as $|Y - \hat{Y}|$ and $|\hat{Y}|$, where $|Y - \hat{Y}|^2 = \sum_i (Y_i - \hat{Y}_i)'(Y_i - \hat{Y}_i) = RSS$ and $|\hat{Y}|^2 = TSS - RSS$. RSS is the *residual sum of squares* and TSS is the *total sum of squares*.

The coordinate of Y in direction of $Y - \hat{Y}$ shows the square root of the residual sum of squares, $\sqrt{RSS}$; the coordinate in direction of $\hat{Y}$ gives the square root of the difference between the total sum of squares, TSS, and the residual sum. The angle α between Y and $Y - \hat{Y}$ is therefore related to the goodness of fit statistics R^2 of the regression model:

$$\cos^2(\alpha) = \left(\frac{|HY|}{|Y|}\right)^2 = \frac{TSS - RSS}{TSS} = R^2,$$

i.e. the smaller α is, the better is the fit of the regression model. Of course, the angle depends on the aspect ratio of the display. By fixing the aspect ratio to 1, different plots (and thereby different models) can be compared: a plot with large width and little height indicates a good fit (the residuals are small with respect to the predicted values), while a quadratic plot or, even worse, a tall and thin plot indicates a very bad fit, see figure 12.



R^2 = 99.2%

Source	Sum of Squares
Regression	133.914
Residual	1.04788

Variable	Coefficient	s.e. of Coeff	t-ratio	prob
Constant	0.011854	0.0106	1.12	0.2660

X2	-0.172733	0.2595	-0.666	0.5072

Figure 12: Example of regressions with good fit (above) and bad fit (below). The goodness of fit is emphasized by the shape of the display. The angle between Y and $\hat{Y}$ also corresponds to R^2.

4 Conclusions

Biplots can be used to visualize univariate linear models. They allow, at the same time, an assessment of the model's goodness of fit. Additional interactive methods such as interactive querying provide the analytic goodness of fit statistics, too. This allows a tight link of visual display and the corresponding model. Another interactive method, hotselection, gives a way of examining the influence of single points or group of points on the model, which can be used as a very efficient way of outlier spotting.

In the paper only one-dimensional models are shown - this is just for illustration purposes. The approach itself is, of course, not limited to one dimension.

If using scatterplots for a biplot representation, biplots are restricted to a 2d display - with graphics that allow display of higher dimensionality such as a tour ([1], [2]) for example, more precise displays are possible. In a tour the described approach would mean to fix the x-axis artificially to $Y - \hat{Y}$ (equivalent to fixing Y to be fully included while touring the data) and to tour through the X space. This also allows to deal with higher-dimensional Y.

R: THE NEXT GENERATION

Kurt Hornik

Key words: R, CRAN, S, S-PLUS, Sweave, LaTeX.

COMPSTAT 2004 section: Statistical software.

Abstract: Version 2.0 of R will be released in the course of 2004. Following the 1.0 release on 2000-02-29, the advent of this "next generation" of R mostly indicates the view of the R developers that R has now moved substantially beyond being a reference implementation of S. In this paper, we look at several of these key enhancements. We start with a review of some key facts on "R and S". Sections 2 to 5 then describe the name space mechanism, the new grid graphics system, the packaging system, and Sweave, a tool which allows to embed R code for data analysis into LaTeX documents.

1 Introduction

S is a very high level language and an environment for data analysis and graphics which has been developed at Bell Laboratories for about 30 years. In 1998, the Association for Computing Machinery (ACM) presented its Software System Award to John M. Chambers, the principal designer of S, for *"the S system, which has forever altered the way people analyze, visualize, and manipulate data . . . "*. The evolution of the S language is characterized by four books by John Chambers and coauthors, which are also the primary references for S. The "Brown Book" [1] is of historical interest only. The "Blue Book" [2] describes the "New S" language. The "White Book" [5] documents a concerted effort to add functionality to facilitate statistical modeling in S, introducing data structures such as factors, time series, and data frames, a formula notation for compactly expressing linear and generalized linear models, and a simple system for object-oriented programming in S allowing users to define their own classes and methods. Together with the Blue Book, it describes S version 3 ("S3"). [4], the "Green Book", introduces version 4 of S ("S4"), a major revision of S designed by John Chambers to improve its usefulness at every stage of the programming process, introducing in particular a new "formal" OOP system supporting multiple dispatch and multiple inheritance, and a unified input/output model via "connections". Today, a commercial implementation of the S language called "S-PLUS" is available from Insightful Corporation (`http://www.insightful.com`).

What is now the R project started in 1992 in in Auckland, New Zealand, as an experiment by Ross Ihaka and Robert Gentleman *"in trying to use the methods of LISP implementors to build a small testbed which could be used to trial some ideas on how a statistical environment might be built"* [8]. The decision to use an S-like syntax for this statistical environment, being motivated by both familiarity with S and the observation that the parse trees generated by S and LISP are essentially identical, resulted in a system "not unlike S". In fact, basing the R evaluation model on Scheme (a member of the LISP family) has given R *lexical scoping* as the most prominent difference between R and other implementation of the S language [7]. Since mid-1997 there has been a core group (the "R Core Team") who can modify the R source code CVS archive. The group currently consists of Doug Bates, John Chambers, Peter Dalgaard, Robert Gentleman, Kurt Hornik, Stefano Iacus, Ross Ihaka, Friedrich Leisch, Thomas Lumley, Martin Maechler, Duncan Murdoch, Paul Murrell, Martyn Plummer, Brian Ripley, Duncan Temple Lang, and Luke Tierney. R version 1.0, released on 2000-02-29, provided an implementation of S version 3. The key innovations in S4 were introduced in 1.x series releases (connections in 1.3, a first implementation of the S4 OOP system in version 1.4).

An R distribution provides a run-time environment with graphics, a debugger, access to to certain system functions, and the ability to run programs stored in script files, and contains functionality for a large number of statistical procedures. This "base system" is highly extensible through so-called *packages* (see Section 4) which can contain R code and corresponding documentation, data sets, code to be compiled and dynamically loaded, and so on. In fact, the R distribution itself provides its functionality via "base" packages such as **base**, **stats**, **grid**, and **methods**. The data analytic techniques described in such popular books as [23], [16], or [21] have corresponding R packages (**MASS**, **nlme**, and **survival**). In addition, there are packages for bootstrapping, various state-of-the-art machine learning techniques, and spatial statistics including interactions with GIS. Other packages facilitate interaction with most commonly used relational databases, importing data from other statistical software, and dealing with XML. Currently, more than 300 packages are available via the *Comprehensive R Archive Network* (CRAN, `http://CRAN.R-project.org`), a collection of sites which carry identical material, consisting of the R distribution(s), contributed extensions, documentation for R, and binaries.

It is important to realize that the "R Project" is really a multi-tiered large scale software development effort, with the R Core Team delivering the basic distribution which mostly provides the computational infrastructure on which others can build special-purpose data analysis solutions. In this paper, we discuss four of the key additions to this infrastructure relative to the S reference standard.

2 Name spaces

Name spaces allow package authors to control how global variables in their code are resolved. To see why this is important, suppose that package **foo** defines the function

```
  mydnorm <- function(x) 1 / sqrt(2 * pi) * exp(- x^2 / 2)
```

and has been attached to the search path so that evaluating the expression `mydnorm(0)` uses the above function when looking up a value for the symbol '`mydnorm`'. Now suppose that the user enters

```
pi <- 1
```

at the prompt, so that the symbol '`pi`' is bound to the value 1 in the R workspace ("global environment", `.GlobalEnv`). With the "usual" dynamic lookup mechanism for bindings (of symbols to values) in place, going through the collections of bindings represented by the search path and starting with the global environment, evaluating `mydnorm(0)` would not give the result that the **foo** package author had intended—namely, using the value bound to `pi` in the **base** package. More generally, top level assignments as well as attaching packages to the search path can insert shadowing definitions ahead of the ones intended. Name spaces ensure that this does not happen.

In the above example, all global variables were intended to refer to the definitions provided by the **base** package, which is always attached (at the end of the search path). Suppose that **foo** wanted to make use of functionality provided by another package **bar** which is not necessarily always attached. Traditionally, the package author would then arrange **bar** to be attached at some point. This is not only subject to shadowing as described above, but also has the effect of forcing a possibly undesired change to the search path onto the user. Using name spaces, one can *import* the required functionality (more precisely, exported variables) from other packages. Such imports then cause the other packages to be *loaded* if necessary, without attaching them.

Finally, name spaces also allow the package author to control which definitions provided by a package are visible to a package user and which ones are private and only available for internal use. By default, a definition is private; it is made public by an explicit *export* of the name of the defined variable. Similar to proving mathematical theorems, good programming practice for a high-level language such as R typically suggests providing functionality based on small building blocks which perform simple tasks and are readily comprehended. If all these blocks correspond to functions with a few lines of code, and all these functions are visible to users, these will find determining the key functionality provided by a package rather challenging. (Thus far, coding practices suggested using names starting with a '`.`' for "internal" variables, based on the fact that listing variable names in elements of the search path by default excludes names with a leading dot. This reduces clutter, but does not prevent shadowing.)

A package is given a name space by placing a NAMESPACE file containing name space directives into the top level source directory of the package. This mechanism makes it possible to obtain the information on the package code interface as part of the package meta-data, without the need of processing the package code. The main directives control export and import of variables, and superficially resemble R function calls, with the arguments being syntactic names or string constants (i.e., quoting is only necessary for non-standard names). For example, the directive

```
export(mydnorm, "[<-.myclass")
```

exports two variables. Import directives are used to import definitions from other packages with name spaces. The directive

```
import("survival")
```

imports all exported variables from package **survival**;

```
importFrom("survival", "Surv")
```

would only import its `Surv()` function. There is also a `useDynLib` directive for specifying that external code compiled into a DLL is to be loaded when the package is loaded.

As syntactic sugar, variables exported by a package with a name space can also be referenced using fully qualified references which are obtained by concatenating the package and variable name, separated by a double colon (e.g., `foo::mydnorm` in the above example). This is less efficient than a formal import and also loses the advantage of separating the dependency meta-data from the package code, so this approach is usually not recommended.

Name spaces are *sealed*. This means that once a package with a name space is loaded, one can no longer change the bindings (add or remove variables, or change the values). If it is necessary to record state information on the package level, one can use *dynamic* variables (functions allowing to get and set state information maintained in their environment). Sealing ensures that the bindings cannot be changed at run time, which has been instrumental to the development of a byte code compiler for R.

R supports both the S3 and S4 paradigms for object oriented programming. In the former, there are no "formal" data structures representing the class information, and method dispatch is based on a naming convention (methods are functions the name of which is obtained by concatenating the names of the generic and the class of the argument on which dispatch is based, separated by a period). With the advent of name spaces, this creates a problem: if a package is imported (hence loaded) but not attached to the search path, the S3 method it provides may not be found for dispatch. The name space mechanism therefore also provides facilities for registering S3 methods for dispatch. The directive

```
S3method("print", "foo")
```

registers the function `print.foo` defined in the package as the S3 method for generic `print` and class `"foo"`. (This mechanism in fact pertains to the cases where the generic is defined in a package with a name space. In this case, S3 methods only need to be registered, but not exported.) The "formal" S4 OOP paradigm provides classes and generics with more structure than their S3 counterparts, and hence conceptually allows better integration with name spaces. S4 classes are private by default; they can be made public using the `exportClasses` directive. As of writing this article, all generics for which formal methods are defined need to be declared in an `exportMethods` directive, and where the generics are formed by taking over existing functions, those functions need to be imported (explicitly unless they are defined in the base name space). These mechanisms may be different in R 2.0; the current development efforts will most likely bring the mechanisms in R more in line with those in "related" functional languages in the LISP family which provide both name spaces and a "formal" OOP system (such as Common Lisp or Dylan).

By giving package developers the tools to control the package code interface and the resolution of global variables in their code, name spaces substantially enhance the potential of R for dealing with complex data analysis tasks based on combinations of "many" extension packages, in particular providing a way of resolving conflicts among definitions in these.

3 Grid graphics

Traditional S graphics ("base graphics" in R, although now provided by package **graphics**) divides pages of graphics output into outer margins and possibly several figure regions which in turn each consist of figure margins and plot regions. This places severe limitations on the possibilities for accessing the whole graphics page, e.g. when annotating a high-level plot. (The standard example is that one cannot have arbitrarily rotated text in axis labels, as `text()` supports arbitrary rotation but can only draw inside the plot region, whereas `mtext()` can only write horizontally or vertically.) Each region has one or more coordinate systems associated with it, as controlled via "graphical parameters" (`par()`).

Grid graphics is an alternative graphics engine provided by package **grid** in the R distribution. One of its goals is to remove some of the inconvenient constraints imposed by the base graphics system. In addition, it aims at the development of functions to produce high-level graphical components which would not be very easy to produce using traditional S graphics (such as Trellis graphics [3], [6], where the more natural building block is a "panel" which consists of a plot plus one or more "strips" around it), and the rapid development of new graphics ideas. It serves these aims by providing functionality for the production of low-level to medium-level graphical components, such as lines, rectangles, data symbols, and axes, and sophisticated support for arranging graphical components. Grid does not provide high-level graphical components such as scatterplots of barplots, and hence is primarily targeted at graphics developers rather than "users", with the usual remark that in S, there is at most a gradual transition between these groups, if no such distinction at all.

In grid, there can be any number of graphics regions. A graphics region is referred to as a *viewport* and is created using the `viewport()` function. A viewport can be positioned anywhere on a graphics device (page, window, . . .), it can be rotated, and it can be clipped to. For example,

```
viewport(x = 0.5, y = 0.5, width = 0.5, height = 0.25, angle = 45)
```

describes a viewport which is centered within the page, and is half the width and one quarter of the height of the page, and rotated 45°. Note that the above is only a description of a graphics region—it is created on a graphics device only when the viewport is "pushed" onto that device using the function push.viewport(). Each device maintains a stack of viewports, with the top one being the current one. Pushing places a viewport on top of the stack, while "popping" (using pop.viewport()) removes it from there. When several viewports are pushed onto the viewport stack, later viewports are located and sized within the context of the earlier ones. Graphics output is always relative to the current viewport (on the current graphics device). Hence, selecting the region desired for output is simply a matter of pushing and popping the appropriate viewports.

The viewport mechanism makes it very simple to divide a graphics page into areas as desired. For example, to create a plot with a legend taking up 80% and 20%, respectively, of the width of the current viewport, one can simply use

```
push.viewport(viewport(x = 0, width = 0.8, just = "left"))
```

to set up the plot region, plot to it and pop it from the stack, and then use

```
push.viewport(viewport(x = 1, width = 0.2, just = "right"))
```

to set up the legend region. Grid also provides an alternative way for positioning viewports within each other based on *layouts*, which allows a simple emulation of the multi-figure array mechanism in base graphics. Any viewport pushed immediately after a viewport containing a layout may specify its location with respect to that layout.

Each viewport has a number of coordinate systems available. There are four main types: absolute (e.g., "inches"), normalized (e.g., "npc"), relative (e.g., "native"), and referential coordinates, which allow locations and sizes to be specified in terms of physical coordinates, as proportions of the page size (or the current viewport), relative to a user-defined set of x- and y-ranges, and based on the size of some other graphical object, respectively. The selection of which coordinate system to use within the current viewport is made using the unit() function, which creates an object which combines coordinate value and system information. For example,

```
viewport(x = unit(60, "native"),
         y = unit(0.5, "npc"),
         width = unit(1, "strwidth", "coordinates for everyone"),
         height = unit(3, "inches"))
```

describes a viewport which is centered at the x-value 60 of and half-way up the preceding viewport, is 3 inches high and as wide as the text "coordinates for everyone".

Grid provides a standard set of graphical primitives: lines, text, points, rectangles, polygons, and circles (the names of the corresponding functions are obtained by prefixing the names of the corresponding base graphics functions with '`grid.`'). There are also two higher-level components: x- and y-axes. These functions are mostly similar to their base counterparts, but differ in the way graphical parameters, such as line contour and thickness, are specified.

In grid, there is a much smaller set of graphical parameters, consisting of `col` (the "foreground" color for drawing lines and borders), `fill` (the "background" color for filling shapes), `lty` and `lwd` (line type and width), `fontfamily`, `fontface` (such as bold or italic), `fontsize` (the size of text in points), `lineheight` (the height of a line as a multiple of the size of text), and `cex` (multiplier applied to fontsize: the size of text is `fontsize * cex` and hence the size of a line is `fontsize * cex * lineheight`). Settings of graphical parameters are represented by `"gpar"` objects, and may be specified for both viewports and graphical objects. A setting for a viewport will apply to all graphical output within that viewport and all viewports subsequently pushed onto the viewport stack, unless the graphical object or viewport specifies a different setting. A description of graphical parameter settings is created using the `gpar()` function, which can be associated with a viewport or graphical object via their `gp` slots (as accessed by the `gp` argument to the functions creating viewports and graphical objects). The following piece of code illustrates these mechanisms.

```
push.viewport(viewport(gp = gpar(fill = "grey",
                                 fontface = "italic")))
grid.rect()
grid.rect(width = 0.8, height = 0.6, gp = gpar(fill = "white"))
grid.text(paste("This text and the inner rectangle",
                "have their own gpar settings", sep = "\n"),
          y = 0.75, gp = gpar(fontface = "plain"))
pop.viewport()
```

One of the key applications of grid graphics is in the R implementation of Trellis graphics, provided by the **lattice** package (a so-called recommended package that is available from CRAN, and included in every binary distribution of R), see [20], which illustrates how high-level graphics functionality can be built on top of grid. Because lattice consists of grid calls, it is possible to both add grid output to lattice output, and vice versa.

There is also limited support for combining base and grid graphics using functionality provided by the **gridBase** package. [14] shows how to annotate base graphics using grid (e.g., to add axis labels at arbitrary rotations), and to embed base graphics in grid viewports.

Grid provides more features not discussed here. For information on these, and examples of the use of grid, see in particular the documentation at `http://www.stat.auckland.ac.nz/ paul/grid/grid.html`.

4 Packages

The R package system provides a standardized interface to extending R's functionality. In *source* form, packages can contain

- "core" meta-information, currently serialized as a DESCRIPTION file in Debian Control File format (tag-value pairs)
- additional meta-data, such as a NAMESPACE file defining the package code interface
- code and documentation for R
- foreign code to be compiled/dynloaded (C, C++, Fortran, ...) or interpreted (Shell, Perl, Tcl, ...)
- additional material such as data sets, demos, vignettes, package-specific tests, ...

Only the core meta-information must be present. Mandatory meta-data include name and version of the package, and information on the license and the package maintainer. In a file system "representation", a source package consists of a subdirectory containing the DESCRIPTION and possibly other "top-level" files, and several pre-defined subdirectories, some of which may be missing, such as R for R code and src for foreign source code to the compiled and dynloaded.

To be available for extending R, packages must be *installed* to *libraries*, which are simply locations where R knows to find (installed) packages. Installing from source performs a variety of tasks as needed or desired, such as preformatting R documentation in plain text and HTML formats, creating DLLs from foreign code, generating a binary image of the R code, and setting up several data structures with package index information. This process is plug'n'play if the packages are "self-contained" (so that only the standard tools for processing them are required). Developers can provide configuration scripts for automatically dealing with situations where packages depend on the availability of functionality "outside of R", such as libraries for dealing with XML or accessing a database management system.

Creating packages is straightforward: developers simply need to gather the material to be packaged into the appropriate locations relative to the package source directory. If R code is the starting point, R provides a convenience function `packageSkeleton()` which creates the basic file structures as well as documentation skeletons for the R objects.

Packages are distributed as single files archiving their contents. For source packages, gzipped tar files are used. These are created via the `build` utility (currently, a Perl script) which essentially performs necessary cleanups, adds front-matter information, and creates the archive with a canonical file name obtained from the package name and version (as recorded in the DESCRIPTION file). One can also build and install *binary* packages, which are already set up for use on a particular platform (so that only mimimal processing is needed when installing). E.g., CRAN provides binary packages for the 32-bit Windows platforms, because the tools needed for processing the source packages (Make, Perl, compilers, . . .) might not be available to all users on such systems.

Packages can be distributed over the web through *repositories*, which are suitably indexed collections of packages. The package management tools provided by R allow for directly installing packages from repositories and automatically updating installed packages when newer versions are made available in the repositories. This versioning facility, together with the generality of the package mechanism, makes packages an ideal vehicle for distributing many kinds of R-related material which needs to be kept up-to-date, such as e.g. data sets or manuals (preferably implemented as package vignettes, see Section 5). The Bioconductor project (`http://www.bioconductor.org`), an open source and open development software initiative for the collective creation of extensible software infrastructure for computational biology and bioinformatics which uses R as its primary implementation language, is working on providing the next generation of client and server side tools for repository management, featuring in particular a multi-level package dependency mechanism similar to the ones found in popular GNU/Linux distributions such as Debian (`http://www.debian.org`). These tools are already available via the R extension package **reposTools** from Bioconductor, and will eventually be integrated into the R distribution.

Packages can be submitted to unit testing using the `check` utility (currently, a Perl script). When run on a package source directory, this first verifies that the package can be installed as the basic test of whether it "works", and then goes on to perform a variety of other tests, such as checking

- availability and correctness of meta-information (as recorded in the DESCRIPTION file mentioned above);
- R code, including syntactic correctness, common coding problems (e.g., when loading DLLs or defining replacement functions), consistency of S3 generics and methods, etc.;
- R documentation, including correctness (syntax, presence of all required documentation slots), consistency (of code and documentation), and completeness (all user level objects must be documented);
- whether the package is able to run the code in in the examples of its documentation (which is required). In addition, there are mechanisms for regression and certification testing of code: package maintainers can provide files with R code that will be run and if necessary compared to already certified output.

Repository maintainers can use the package testing facilities for controlling the quality of the packages in the repository, and hence the repository itself. For example, the CRAN repository tracks the R release process by only providing packages which pass the tests against the version of R being released. In addition, the effects of changes in (the development and patched version of) R and updates to contributed packages are monitored on a daily basis. It is this continuous improvement process which markedly distinguishes the R project from most other software initiatives which use repositories for distributing extensions.

Most of the testing tools used by the `check` utility are in fact implemented in R (in particular to ensure portability and availability to all users of R) and distributed in the **tools** package contained in the R distribution. It is very important to realize that whereas `check` is a rather inflexible utility for creating standardized reports on the package "quality" status, the underlying functions from package **tools** provide a flexible and extensible toolbox for computing on packages. For example, `codoc()` is a function for checking code/documentation consistency. More precisely, it analyzes the (usually, function synopsis) information of the `\usage` sections of R documentation files, and compares the documented synopses to what the code actually contains. (Currently, code and documentation for functions in a package are not generated from common sources, and hence may be inconsistent.) What `codoc()` returns is an object containing a variety of information, *including* the information on mismatches found. Printing this object gives a status report on mismatches intended for human readers; if no mismatches were found, nothing is printed. This mechanism is used by `check` to assess and report the basic codoc status. But the object returned contains additional data as well, such as information on `\usage` entries not corresponding to valid R syntax after eliminating special markup for indicating synopses for S3 or S4 methods, or on functions for which documentation was registered (via the `\alias` meta-data markup) without providing a synopsis (which "might" be a problem, and in the case of non-method functions in packages with a name space typically is one). Even though this information is not printed, it is available in the result of the codoc computations, and hence can be used for further processing.

5 Sweave

Sweave [9] is a tool that allows to embed the R code for complete data analyses in LaTeX documents. (In fact, we shall see that the underlying principles are much more general.) In the process of generating the displayed version of the document, first the code in the Sweave source file is processed (by R) and its textual or graphical output inserted as appropriate to create a LaTeX source file. Then, a DVI or PDF file is created (by `latex` or `pdflatex`).

A small Sweave source file is shown in Figure 1. The file contains two R code chunks embedded in a simple LaTeX document. At the beginning of a line, '`<< ... >>`' and '`@`' mark the start of a code and documentation chunk, respectively. Sweave translates this to a regular LaTeX document, which is then compiled to give Figure 2. The results of the Kruskal-Wallis test as well as the box plot have nicely been integrated into the final version.

```
\documentclass[a4paper]{article}

\title{Sweave Example}
\author{Friedrich Leisch}

\begin{document}

\maketitle

In this example we embed parts of the examples from the
\texttt{kruskal.test} help page into a \LaTeX{} document:

<<>>= data(airquality) kruskal.test(Ozone ~ Month, data =
airquality) @ which shows that the location parameter of the Ozone
distribution varies significantly from month to month. Finally we
include a boxplot of the data:

\begin{center}
<<fig=TRUE,echo=FALSE>>= boxplot(Ozone ~ Month, data = airquality)
@
\end{center}

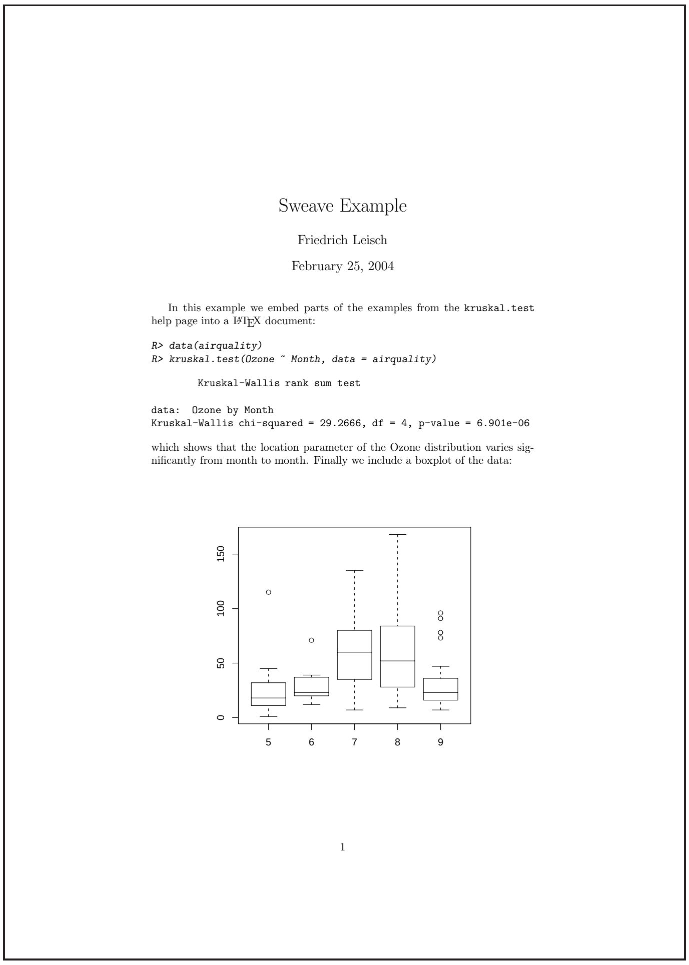
\end{document}
```

Figure 1: A small Sweave source file: example.Snw.

The Sweave source file shown in Figure 1 uses the syntax of noweb [18], a simple literate programming tool which allows to combine program source code and the corresponding documentation into a single file. This syntax is particularly useful if Emacs is used for authoring Sweave documents: then, using *ESS* [19, Emacs Speaks Statistics;], an Emacs extension package, one can connect the document to a running R process while writing it. Code chunks can be sent to R and evaluated using simple keyboard shortcuts or popup menus. Syntax highlighting, automatic indentation and keyboard shortcuts depend on the location of the pointer: in code and documentation chunks one gets the same behavior as when editing “simple” R code or LATEX files, respectively. Using Emacs or the noweb syntax is not necessary to Sweave. There is also a LATEX-based syntax, where ‘Scode’ environments are used for marking code chunks. Using this syntax, the boxplot code chunk in our example file would be typeset as

```
\begin{Scode}{fig=TRUE,echo=FALSE}
  boxplot(Ozone ~ Month, data = airquality)
\end{Scode}
```

Sweave offers fine control on how the code chunks are processed. By default, both the S code itself and its console output are inserted, inside suitable



Sweave Example

Friedrich Leisch

February 25, 2004

In this example we embed parts of the examples from the `kruskal.test` help page into a LaTeX document:

```
R> data(airquality)
R> kruskal.test(Ozone ~ Month, data = airquality)

        Kruskal-Wallis rank sum test

data:  Ozone by Month
Kruskal-Wallis chi-squared = 29.2666, df = 4, p-value = 6.901e-06
```

which shows that the location parameter of the Ozone distribution varies significantly from month to month. Finally we include a boxplot of the data:

1

Figure 2: The final document created from example.Snw.

verbatim-style environments, into the generated LaTeX file. This emulates an interactive session. One can suppress either input to or output from the R process, or indicate that output is already in LaTeX format (e.g., when using one of the CRAN extension packages **xtable** or **Hmisc** to create “pretty” tables), or completely suppress the evaluation of the code chunk. In addition, Sweave can replace S expressions inside `\Sexpr` markup in documentation chunks by their values (provided that these can be coerced into a character string).

Sweave is written entirely in S, and contained in package **utils** in the R distribution. From a user’s view, there are two basic functions. `Sweave()` translates Sweave source files into LaTeX files as described above. `Stangle()` simply extracts only the code.

As apparent from the above description, what Sweave really does is perform certain computations on integrated text documents which contain both code and documentation chunks. S4weave, a re-implementation of Sweave using S4 classes and methods currently under way, enforces this view [11]. Providing more structure also makes it possible to compute a directed graph of chunk dependencies, and hence process chunks conditionally. There is also an XML DTD for Sweave source files for document exchange with other dynamic document systems.

To assess the importance of facilities such as Sweave, one should keep in mind how reports as part of a statistical data analysis project are traditionally written. First, the data are analyzed, and afterwards the results of the analysis (numbers, graphs, ...) are used as the basis for a written report. In larger projects the two steps may be repeated alternately, but the basic procedure remains the same. The basic paradigm is to write the report around the results of the analysis. Using Sweave, one can create dynamic reports, which can be updated automatically if data or analysis change. In particular, the code is always available for *reproduce* the displayed results, which makes Sweave an ideal vehicle for disseminating reproducible research, see e.g. [13].

Sweave also greatly aids in the creation and deployment of documentation for "aggregated" functionality of S code, such as manuals for packages (where the traditional function-based S documentation methods cannot easily deliver a comprehensive view), or books on statistical analysis using S. Using Sweave, there is the additional benefit that one can always extract the code from the document (the term *vignettes* has been introduced for documents with this property) and use it for subsequent manipulating and processing. Vignettes have enough structure to allow for an integrated and interactive presentation of the code they contain. For example, `vExplorer()` from the Bioconductor **tkWidgets** package allows to view vignettes and interact with their code chunks, see e.g. [12] for more details.

6 Summary

In this paper, we have discussed four of the key innovations in the "next generation" of R. There are of course many more, including a new system for exception handling, a byte code compiler, external pointer objects, a mechanism for serialization and unserialization of R objects to and from connections, mathematical annotation of plots [15], as well as many refinements to the S language (such as a thorough distinction of the character string `"NA"` from a missing value for a character string). The NEWS file in the top-level directory of the R distribution has more information.

ROBUST MULTIDIMENSIONAL SCALING

Leanna L. House and David Banks

Key words: Statistical computing, data reduction, robust, multidimensional scaling.

COMPSTAT 2004 section: Statistical software.

Abstract: Modern technology enables the collection of vast quantities of data. Smart automatic data selection algorithms are needed to discover important data structures that are obscured by other structure or random noise. We suggest an efficient and flexible algorithm that chooses the "best" subsample from a given dataset. We avoid the combinatorial search over all possible subsamples and efficiently find the datapoints that describe the primary structure of the data. Although the algorithm can be used in many analysis scenarios, this paper explores the application of the method to problems in multidimensional scaling.

1 Introduction

Although modern technology enables the collection of huge amounts of data, it also exacerbates the problem of data quality control. Spurious or erroneous information caused by either the random nature of the data or human error will inevitably exist within large datasets. But the task of sifting through millions of observations and removing those that are not representative of the true population borders on the impossible. Smart, automated, data cleaning algorithms or robust analysis tools that work in tandem with the collection technologies are needed.

From a statistical perspective, robust analysis methods, including L, M, S, and R estimators, serve as appropriate means to account for contaminated data. However, such methods arguably apply only to parametric approaches and do not extend to unsupervised learning problems or multidimensional scaling. Furthermore, analyzing the data directly, without first reducing the number of observations, may exceed computer software or memory limitations.

To address this problem, we present an efficient data reduction algorithm that actively seeks the primary underlying structure of the data while removing spurious observations. Rather than use graphical methods to hunt for erroneous data as described by Karr, Sanil, and Banks [6], we systematically search among strategically chosen subsets of the collected sample. Ultimately, we find the subsample that provides the best statistical signal, as measured in terms of fit, compared to other subsets of comparable size.

The algorithm we propose does not require the evaluation of every subset within a sample. Instead, it performs a series of greedy searches that allow the method to scale to large datasets. And the algorithm is flexible since it can be applied to any situation in which there is some measure of goodness-of-fit. In this paper, we describe how the method applies in the context of linear regression and multidimensional scaling, where the measures of fit are R^2 and stress, respectively.

We understand that specifying an acceptable degree of lack-of-fit or required statistical signal for a chosen subsample is unclear. Since one is trying to cherry-pick the best possible subset of the data, we consider two options. The first entails the prespecification of the final subset size. The subset with the highest statistical signal (of the specified size) is chosen, regardless of the magnitude of the signal, or lack there of. The second approach requires the inspection of the plot, signal versus subset size. A knee in the plotted curve points to the subset size at which one is forced to include bad data.

In the context of previous statistical work, our approach is most akin to the S-estimators introduced by Rousseeuw and Yohai [9], which built upon Tukey's proposal of the shorth as an estimate of central tendency [2], [9]. Our key innovations are that instead of focusing upon parameter estimates we look at complex model fitting, and also we focus directly upon subsample selection. See [3], [4] for more details on the asymptotics of S-estimators and the difficulties that arise from imperfect identification of bad data.

In the context of previous computer science work, our procedure is related to one proposed by Li [7]. That paper also addresses the problem of finding good subsets of the data, but it uses a chi-squared criterion to measure lack-of-fit and applies only to discrete data applications. Besides offering significant generalization, we believe that the two-step selection technique described here enables substantially better scalability in realistically hard computational inference.

Section 2 describes the algorithm in detail within the context of regression. Section 3 illustrates the flexibility of the algorithm and applies it to a simulated, multidimensional scaling scenario. Section 4 concludes the paper with a discussion and a description of additional applications.

2 Proposed algorithm

Because of the wide familiarity with regression, we describe the steps of the algorithm while referring to the following scenario:

> Given n observations, $\{Y_i, \boldsymbol{X}_i\}$, we assume that the expected structure within the data is a multivariate linear model
>
> $$Y_i = \beta_0 + \beta_1 X_{i1} + \ldots + \beta_p X_{ip} + \epsilon_i$$
>
> with independent errors terms, $\epsilon_i \sim N(0, \sigma)$. And we want to protect our analysis against the the possibility that as much as $1 - Q$ percent of the data either do not have a common linear

relationship or are random noise or follow a different functional relationship with Y. The choice of Q requires domain knowledge or a good sense of the errors in the data collection protocol.

Typical regression analyses fit all the data, and then attempt to identify outliers or high-leverage points. Some robust methods, such as S-estimation, attempt to find the best fit to some prespecified fraction of the data, but those methods do not generalize to, say, nonparametric multivariate regression. In contrast, we search among the data to find a large subset that produces good fit. This entails random selection of starting-point subsamples and the comparison of fits from subsamples of the data.

In a linear regression setting, the coefficient of determination, R^2, provides a natural choice for assessing and comparing the statistical signal of subsamples. The statistic relies on sums of squared deviations to assess lack-of-fit and does not penalize subsets for including more or less observations. Simply, a subsample with a high R^2 is better than another with a low R^2.

In general, it is desirable that the measure of fit not depend upon the size of the subsample. This is true for the coefficient of determination and also for stress in multidimensional scaling. The algorithm, however, can be modified to accommodate other situations, usually by a normalization that allows one to measure the "average" goodness-of-fit. That technique allows one to broaden the field of fit criteria to include average absolute deviation or average complexity, as measured by Mallow's C_p statistic [8] or Akaike's Information Criterion [1].

The remainder of this section describes how we randomly select a set of subsamples from which we ultimately choose the best. We do not enumerate or test all possible subsamples of size Qn. Rather, we propose starting with a series of small, randomly chosen datasets and growing each until they are of size Qn. Done properly, we can ensure that with some prespecified probability at least one of the original subsamples will eventually grow to contain nearly all good data.

2.1 Choosing the initial subsamples

To begin we select the minimum number, d, of subsamples S_i needed to guarantee, with probability c, that at least one S_i contains only "good" data; i.e., data for which the assumption of a linear model is correct. The size of the initial subsamples depends on the scenario and should equal the minimum number of observations needed to calculate the chosen lack-of-fit measure; for the case of multivariate regression in $\mathbb{R}^p$ using R^2 as the criterion, one needs $p + 2$ observations in each starting subsample.

Assuming Q percent of the data are good, then the probability of selecting (with replacement) a starting subsample that contains bad data is $1 - Q^{p+2}$. Hence, after specifying c, we may solve for d using

$$\begin{aligned} c &= \mathbb{P}[\text{ at least one of } S_1, \ldots, S_d \text{ is all good }] \\ &= 1 - \mathbb{P}[\text{ all of } S_1, \ldots, S_d \text{ are bad}] \\ &= 1 - \prod_{i=1}^{d} \mathbb{P}[\ S_i \text{ is bad }] \\ &= 1 - (1 - Q^{p+2})^d. \end{aligned}$$

For example, if we want the probability of selecting at least one good initial sample to equal 95% ($c = .95$) and we assume that 20% of the data are spurious ($Q = .8$), then we have $.95 = 1 - [1 - (.8)^{p+2}]^d$. Setting p = 1 for simple linear regression, the smallest integer greater than d is 5. Thus we need five starting-point subsamples to ensure with probability .95 that one of them will work as we want.

We assume the probability of choosing the same observation twice for one subsample is small enough to justify selecting S_i with replacement. However, one may use finite population methods if necessary (e.g., when the total sample size is small). In that case the calculation of d becomes slightly more complicated when p is very large. Such cases might necessitate the use numerical techniques to find d.

2.2 Select subsamples

Since the exact value for Q is unknown, let k equal the desired proportion of data we wish to select from the large dataset. (The value for k does not necessarily have to equal Q.) One subsample at a time, we sequentially append observations that improve (or cause littel reduction) in the goodness-of-fit measure until S_i contains the target number of kn data points.

To balance the need for computational speed against the risk of adding bad data, we suggest a two-step rule for adding observations. For the sake of creating a time efficient algorithm, we accept the risk of suboptimal selections, but we want to avoid the possibility of a "slippery slope." Specifically, we do not want a selection that only slightly increases the lack-of-fit to lower the standard so that we get a subsequent selection that also slightly increases the lack-of-fit, with the end result that a chain of marginally satisfactory selections eventually produces a subsample that contains bad data.

The addition process begins with a fast search that adds data points as the algorithm sweeps through the data (Step 1). Starting with the statistical fit measured in an original subsample, S_i, we consider the addition of each of the remaining observations in succession. If the union of an observation with S_i either increases the statistical signal or only decreases it by a minute, prespecified amount η, then the observation is added to the subsample. Hence the next candidate data point in the sequence is considered with regard to a new, slightly larger S_i. Setting n_i to represent the number of observations in the current S_i, the algorithm stops when n_i equals kn.

If after sweeping through the data one time we have $n_i < kn$, our algorithm moves to the second, significantly slower step. Here, we search over all data not already in the subsample to find the observation which, when added, reduces the goodness-of-fit by the smallest amount. We then add that observation and either improve the fit measure for S_i t best or decreases the statistical measure by the smallest possible amount (regardless of η). Notice step 2, unlike step 1, guarantees the addition of one observation on each pass through all of the data (excluding observations already in S_i). Step 2 is repeated until $n_i = kn$.

The following pseudo-code describes this two step algorithm. We use $\mathrm{GOF}(\,\cdot\,)$ to denote a generic goodness-of-fit measure.

Pseudocode for a Two-Step Selection

```
Step 1: Fast Search
Initialize: Draw $d$ random samples $S_i$ of size $p+2$ (with replacement).

Search over all observations:
        Do for all samples $S_i$:
            Do for observations $\boldsymbol{Z}_j = (Y_j, \boldsymbol{X}_j)$:
                If $\boldsymbol{Z}_j \in S_i$ goto next $j$
                If GOF($S_i$) - GOF($\boldsymbol{Z}_j \bigcup S_i$) $< \eta$ add $\boldsymbol{Z}_j$ to $S_i$.
                If $n_i = [kn]$ stop.
            Next $j$
        Next $i$.

Step 2: Slow Search
Search over all observations:
        Do for all samples $S_i$:
            Do for observations $\boldsymbol{Z}_j = (Y_j, \boldsymbol{X}_j)$:
                If $\boldsymbol{Z}_j \in S_i$ goto next $j$
                If GOF($\boldsymbol{Z}_j \bigcup S_i$) $> \max_j$ GOF($\boldsymbol{Z}_j \bigcup S_i$) add $\boldsymbol{Z}_j$ to $S_i$.
                If $n_i = [kn]$ stop.
            Next $j$
        Next $i$.
```

The algorithm requires two vital inputs: the goodness-of-fit measure and the choice of η, the tolerated increase in lack-of-fit during step 1. As mentioned previously, we recommend that the goodness-of-fit measure not depend upon the sample size; the lack-of-fit values should be comparable as n_i increases. However, the choice of η offers one way to force comparability by making it depend upon n_i as well.

If one can achieve independence between the lack-of-fit measure and sample size, then the selection of η depends upon one's willingness to accept bad observations. In the regression setting, when $\eta = 0$, step 1 only appends data points that strictly improve the R^2. On the other hand, the value of η can be determined empirically by inspection of a histogram of 100 lack-of-fit values obtained by adding 100 random data points to an initial subsample of size $p + 2$.

After repeating Step 1 and 2 for d subsamples, the final task is to select one S_i as the best or most representative of the underlying structure. If the purpose for implementing the proposed algorithm is strictly to reduce the dataset to kn, then one could select the subsample with the lowest lack-of-fit, regardless of its size. On the other hand, if the inclusion of bad observations is worrisome or the magnitude of the goodness-of-fit measure for the best subsample is unsatisfactory, then we recommend plotting the goodness-of-fit against the order of entry of the observations. Given an initial subsample with only good data, the graph should depict a long plateau with a sudden knee in the curve when bad observations begin to enter the subsample. One may choose the best size for the subsample according to the size at which the knee occurs.

Note the proposed algorithm entails a stochastic choice of starting sets, followed by a deterministic extension algorithm. Even though we can guarantee, with a specified probability, a clean starting set, we cannot make the same guarantee at the conclusion of the algorithm. Since the extension procedure depends slightly upon the order in which the cases are considered, the final result does not quite enjoy the same probabilistic properties as the initial starting sets. Nevertheless, simulation results indicate that the proposed procedure does lead, with probability near the nominal level specified in the initial calculation that determined the number of starting-point subsamples, to the selection of a subsample of good data.

3 Application: multidimensional scaling

The robustness problem in the linear regression example could have been addressed through other means, such as S-estimators, but it provides a convenient test-bed for developing and assessing the proposed methodology. Our real interest lies in more complicated problems, such as arise in nonparametric regression or classification with mislabeled data or non-metric multidimensional scaling.

Here we demonstrate the strengths of the two-step algorithm within the context of multidimensional scaling (MDS). A practical concern in using MDS is that a relatively small proportion of outliers or similar data quality problems can distort the fit into uninterpretability. Essentially, a mulitdimensional analysis attempts to force a fit that is driven largely by the bad data, and thus simple low-dimensional structure in the good data can be overlooked or not represented at all. Our procedure for cherry-picking the best sample allows the fitting procedure to ignore points that cause large increases in lack-of-fit, which in this context is most naturally measured by the stress function.

Given a clean dataset that consists of the latitudes and longitudes of 99 major cities in the eastern United States, we generated six (three groups of two) unclean datasets. The datasets differ with respect to the proportion of bad data and their degree of badness (refer to Table 1). The first set distorts one distance between two cities by 150% and 500%. The remaining sets increase the number of distortions to 10 and 30 interpoint distances. For the latter two groups, some altered distances might share one end-point. Thus we consider the percent of unclean cities, or $1 - Q$ to be greater than or equal to 2%, 10% and 30% for each set respectively.

True 1-Q (%)	Distance Distortion (%)	Original Stress	n^a	n^*	Final Stress
2	150	1.028	80	80	4.78e-12
	500	2.394	80	80	4.84e-12
10	150	1.791	80	80	4.86e-12
	500	28.196	80	80	4.81e-12
30	150	3.345	80	77	4.86e-12
	500	9.351	80	78	4.78e-12

Table 1: Compare 6 data quality scenarios for MDS.

Using Kruskal-Shephard non-metric scaling, we assess the statistical signal of a given dataset by using the stress function

$$\sum_{i \neq i'} = \sum_{i \neq i'} \frac{[g(\|\boldsymbol{x}_i - \boldsymbol{x}_{i'}\|) - d_{ii'}]^2}{\sum_{j \neq j'} d_{jj'}^2}$$

where the $d_{ii'}$ are the distances between the two-dimensional embeddings of the points $\boldsymbol{x}_i$ and $\boldsymbol{x}_{i'}$ and the $g(\cdot)$ is an arbitrary monotonically increasing function (this implies that the fit depends only upon the ranks of the interpoint distances). The fitting is done by alternating isotonic regression to find an estimate of g with gradient descent to find an estimate of the $d_{ii'}$; our implementation used the procedure in the R software package.

For each of the six datasets, the algorithm attempts to find the subset that minimizes the stress function the most. Since the cities lie on the surface of the globe and do not embed perfectly onto a two-dimensional Euclidean space, some stress exists even within the clean dataset. The total stress measures for the perturbed datasets are listed in the third column of Table 1, whereas the stress for the original, clean dataset equals $8.42 * 10^{-12}$. Additionally, we chose to set $\eta = 1.0^{-12}$, a value slightly greater than zero and commensurate with stress in the undistorted sample.

In a real situation, Q, the percent of clean observations, is unknown. Thus, using expert information we must estimate Q in order to calculate d, the required number of starting-point subsamples. Furthermore, k, the percent by which we wish to reduce the original dataset, is typically unclear as well. In this example, for all of the datasets we assumed that $Q = .9$ and we set $k = .8$.

Table 1 describes the effect of implementing the algorithm using each dataset. The columns labeled "Original Stress" and "Final Stress" provide the stress measures for the complete datasets and the chosen subsamples respectively. The column labeled "n^a" gives the number of observations in the best subsample chosen from the direct application of the algorithm. And the column labeled "n^*" gives the number of observations in the chosen subsample after inspecting graphs that plot stress against sample size. Notice $n^a \neq n^*$ in the last two rows, when 30 interpoint distances are perturbed. This is due to the fact that k is greater than the true value of Q. Figure 1 displays the plots of stress against sample size.

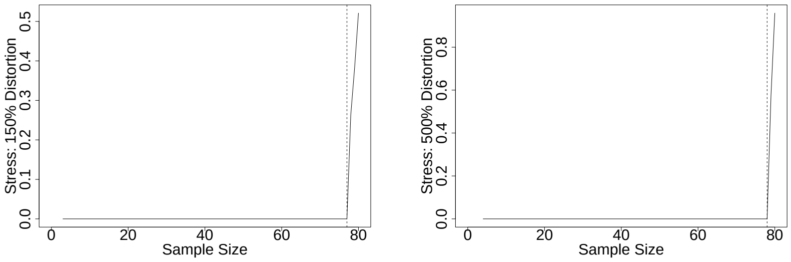

Figure 1: Plot of stress measure versus sample size (in the order of entry) when 30 distances are distorted: (left) 150% distortion; (right) 500% distortion; Notice plateau in graph while including good observations in subsample, but at sample size = 77 (left) and sample size = 78 (right) we start to append bad data.

4 Discussion

In order to take advantage of the full potential of a large dataset, we propose a straightforward method to remove bad data. In essence, we robustify the data using a two-step algorithm to select the subsample that is in best agreement with the assumed structure in the data.

We demonstrate the benefits of the algorithm within the context of multidimensional scaling. In MDS scenarios, even small proportions of bad data can entirely distort the apparent geometric relationships among the cases. Our algorithm successfully isolates the primary structure of six distorted datasets. The stress measures of the final chosen subsamples are dramatically lower than those of the corresponding original datasets.

One distinguishing feature of the algorithm is that it does not require the complete enumeration of all possible subsamples. This saves an enormous amount of computer time, and ensures that the algorithm is essentially of order $\mathcal{O}(n)$ (if one avoids or minimizes the slow-search phase). However, the spirit of our two-step algorithm could be implemented in other ways. For example, solely running the slow search in step 2 might be optimal in terms of only choosing the very best observations to include within a subsample. However, this requires $d(n-p-2)$ separate reviews of the entire pool, which is hard when n is large or the calculation of the lack-of-fit measure is complex.

The procedure we describe extends easily to almost any statistical application, requiring only some measure of fit. In fact, it can even address multiple structures within a dataset. By applying the algorithm repeatedly, each time removing the data that fit the most recently discovered underlying structure, one can retrieve disjoint subsamples representing different models. Subsequent work will extend this technique to such situations and provide a more thorough study of the performance of the search procedure.

IMPROVED JACKKNIFE VARIANCE ESTIMATES OF BILINEAR MODEL PARAMETERS

Martin Høy, Frank Westad and Harald Martens

Key words: PLSR, PCR, bilinear model, jackknife, variance.

COMPSTAT 2004 section: Partial least squares.

Abstract: This paper puts focus on some the remaining issues concerning jackknifing of centred bilinear models. A method improvement is proposed, describing how all the bilinear model parameters can be rotated in order to estimate the uncertainties of all model parameters. The mean values of centred models are also included in the rotation scheme.

The uncertainty information of the bilinear model parameters can be used to perform variable selection, variable weighting and detection of outliers.

1 Introduction

Crossvalidation [1] and especially jackknife [2] can be used in order to estimate the uncertainty of the parameters in a bilinear model [3]. This technique is currently used in commercial software (e.g. The Unscrambler) to estimate the uncertainty in the reduced-rank regression coefficients $\boldsymbol{b}_A$ in the multiple linear approximation model at rank A,

$$\hat{\boldsymbol{y}} = \boldsymbol{X}\boldsymbol{b}_A + b_{0,A} \tag{1}$$

or for multiple y-variables

$$\hat{\boldsymbol{Y}} = \boldsymbol{X}\boldsymbol{B}_A + 1\boldsymbol{b}'_{0,A} \tag{2}$$

Preliminary versions of stability information of the bilinear loadings $\boldsymbol{P}_A$, $\boldsymbol{Q}_A$ and scores $\boldsymbol{T}_A$ for the underlying bilinear regression models (see equation (6) for definitions) are also available. The uncertainty in the regression coefficients is used for e.g. variable selection while the uncertainty in the scores is used to make "stability plots" and e.g. spot sample outliers.

In this article, the method of calculating uncertainty of regression coefficients is expanded to also include the uncertainty of the bilinear model parameters, the loadings and loading weights ($\boldsymbol{p}_A$, $\boldsymbol{Q}_A$, $\boldsymbol{W}_A$) and the scores ($\boldsymbol{T}_A$). The mean value of centred models are also included in the proposed rotation scheme. This has been lacking in commercial applications, and has not yet been described in the literature.

2 Theory

2.1 Notation

Matrices are written as uppercase bold letters ($\boldsymbol{X}$), while vectors are written as lowercase bold letters ($\boldsymbol{x}$). Unless transposed (written as $\boldsymbol{x}'$), vectors are always columns. Uppercase letters (A) denotes constants, while lowercase letters are counters or indexes ($a = 1 \ldots A$).

2.2 Jackknife and segmentation

When crossvalidating or jackknifing a model, the dataset with N samples (objects) are divided into M segments.M sub-models are estimated where model $m = 1 \ldots M$ is estimated from the slightly smaller dataset where the objects in segment m are left out. In the special case of leave-one-out crossvalidation, $M = N$ with $N - 1$ samples in each subset. We have chosen to label the segment that is left out with a subscript m, and the reduced dataset with segment m missing is labelled with a subscript $-m$.

When jackknife is used in statistical literature, the data are often considered to be drawn from the same distribution, and focus is then on creating as many “independent” estimates as possible. The most common way to perform jackknife-validation is the leave-one-out, which gives N estimates of each parameter. One can also perform delete-d jackknife, where d samples are removed in each subset, giving $\binom{N}{d}$ estimates. For $d > 1$ the delete-d jackknife thus shifts the jackknife estimate towards to the bootstrap estimate, which is based on random sampling of errors or samples. The statistical formulae and properties of these estimates are well documented in statistical literature [4], [5], [6].

If the dataset is generated by e.g. a factorial design, it may contain variability on different levels. Take as (a hypothetical) example an experimenter who has tested four different levels (doses) of a treatment on 20 patients twice (two replicates), giving a total of 40 experiments. She might be interested in both the variation between the dose-levels, the variation between the patients, and the variation for a given patient over time. Traditionally, one would use ANOVA to obtain this information, but the same can be achieved by using cross-validated or jackknifed PLSR with the right segmentation of the data (see also [7]).

In this example, one could first place all samples with the same dose-level in the same segment. This would give $M = 4$ segments, and the validation would then show the ability of three of the treatments to predict the third, i.e. how different the response to the dose-levels are. One could also remove one patient at the time giving $M = 20$ segments, to validate how similar or different the patients reacted to the doses. This would be a good segmentation in order to look for outliers between the patients, i.e. whether one (or more) of the patients reacted to the treatment in a very different way than the others. Yet another possibility would be to remove one replicate at the time, giving $M = 2$ segments. The validation would then show whether the patients changed over time. One could also use the leave-one-out method giving $M = 40$ segments. The validation would then be a mix of the above, testing both the dose-levels, replicates and patients at once. These four examples of segmentation will in general give quite different estimates of the variances in the model parameters. Thus, it is very important to be aware of on what level one is validating the results [8].

Even though the jackknife-formulae for different segmentations are given in statistical literature, the authors feel the need for documenting these also in the chemometric literature. The most general expression is that of delete-d jackknife, where one explores all the combinations of data where d samples are removed, $\binom{N}{d}$. The variance of a parameter θ can then be estimated as

$$\hat{s}^2(\theta) = \frac{N-d}{d\binom{N}{d}} \sum_{m} \left(\hat{\theta}_{-m} - \bar{\theta}\right)^2 \tag{3}$$

where $\hat{\theta}_{-m}$ is the value of θ estimated when segment m is removed, and $\bar{\theta}$ is the mean value of all the estimated values.

Like in the example above with treatments and patients, we often don't explore all the combinatorial possibilities of removing d samples at the time. Instead, we only use the $M = N/d$ possible subsets given by removing each of the M segments one at the time. For $d = 1$ these two methods are the same, namely the leave-one-out validation. But for $d > 1$, we have $\binom{N}{d} \gg M$. When only M of the possible subsets is used, equation (3) reduces to

$$\hat{s}^2(\theta) = \frac{M-1}{M} \sum_{m=1}^{M} \left(\hat{\theta}_{-m} - \bar{\theta}\right)^2 \tag{4}$$

When doing significance-testing based on variance estimates from jackknife, one needs to know how many degrees of freedom to use. When using estimates from equation (4), the degrees of freedom in the variance estimate is $M - 1$. To illustrate both the correctness of equation (4) and the $M - 1$ degrees of freedom, the authors performed a Monte-Carlo simulation. The results are documented in section (3.1). The theory and results presented here are in contrast to [8], where the factor $(N - 1)/N$ is used.

In all the above, it is assumed that the size of the different segments is equal (or not very different). For segmentation schemes with unequal segment-sizes, the above formulae are more complicated.

2.3 Variance of regression coefficients

From each of the M bilinear submodels (perturbations of eqs. (1), each time using with A latent variables or factors) we estimate regression coefficients $\boldsymbol{b}_{-m,A}$, and from the complete dataset we estimate $\boldsymbol{b}_A$. One approach to estimate the uncertainty in $\boldsymbol{b}_A$ is then to sum all the squared deviations from $\boldsymbol{b}_A$ [3]:

$$\hat{s}^2(b_{ka}) = \frac{M-1}{M}\sum_{m=1}^{M}(b_{-m,ka} - b_{ka})^2 \tag{5}$$

The correction-factor outside the summation is reduced to the more well-known $(N-1)/N$ for leave-one-out crossvalidation or ordinary jackknife [5].

Note also another difference to the jackknife as described in statistical literature [4], whre each $\boldsymbol{b}_{-m,A}$-estimate is compared to the *mean* of all the M submodel estimates instead of using the value from the complete dataset. The idea behind using $\boldsymbol{b}_A$ as in equation (5) is that this is the "best" estimate we can get, using all the samples that we have available. In most cases, this is also the estimate that would be used as the final model, and we are interested in the variation around that estimate. This bias-including mean squared error estimate eliminates the mean of the perturbed submodel parameter estimates from the jackknife expressions. Since the reduced-rank PLSR models deviates from the theoretical properties of the well understood traditional full-rank OLS regression models, the authors consider the known theoretical properties in full-rank OLS regression models non-applicable for the PLSR solution. Examples will be given in the section "Results and Discussion" that substantiate this choice.

2.4 Rotation of bilinear models

It would be nice to calculate the uncertainty of all the other PCR/PLSR model parameters in the same simple way as the regression coefficients in equation (5), but this is complicated due to certain properties of the bilinear model. The bilinear model as in both PCR and PLSR can be seen as a sum of outer-products, one for each factor:

$$\boldsymbol{X} = 1\bar{\boldsymbol{x}}' + \sum_{a=1}^{A}\boldsymbol{t}_a\boldsymbol{p}'_a + \boldsymbol{E}_A \qquad \text{and} \qquad \boldsymbol{Y} = 1\bar{\boldsymbol{y}}' + \sum_{a=1}^{A}\boldsymbol{t}_a\boldsymbol{q}'_a + \boldsymbol{F}_A \tag{6}$$

where $\bar{\boldsymbol{x}}'$ and $\bar{\boldsymbol{y}}'$ contains the mean value of each variable, $\boldsymbol{t}_a$ is a vector of scores (a linear combination of the $\boldsymbol{X}$-variables), $\boldsymbol{p}_a$ and $\boldsymbol{q}_a$ are loadings for $\boldsymbol{X}$ and $\boldsymbol{Y}$ respectively and $\boldsymbol{E}_A$, $\boldsymbol{F}_A$ contains unmodelled residuals. The only difference between the PCR- and PLSR-algorithms lies in the way $\boldsymbol{t}_a$ is defined.

A property of bilinear models is that the scores and loadings have rotational freedom. We can rotate the scores in any direction, as long as the corresponding loadings are rotated the same amount in the opposite direction. The model will still contain the same information, and the regression coefficients will be the same.

Scores- and loading-vectors for the different submodels m may appear to be quite different due to trivial translations, rotation and mirroring. If e.g. the sign of each element in *both* $\boldsymbol{t}_{-m,a}$ and $\boldsymbol{p}_{-m,a}$ changes, the information explained by their product in that factor will still be the same, but it will be meaningless to compare each value in those vectors to other score- or loading-vectors with different alignment. One way to solve this problem is to *rotate* all the M sub-models toward the model calculated from the complete dataset before we compare them.

Equation (6) represents the model calculated from the complete dataset with all N samples. Rewriting that model using matrix notation, we get

$$\begin{aligned}\boldsymbol{X} &= [1 \quad \boldsymbol{T}_A]\ [\overline{\boldsymbol{x}} \quad \boldsymbol{P}_A]' + \boldsymbol{E}_A\\ \boldsymbol{Y} &= [1 \quad \boldsymbol{T}_A]\ [\overline{\boldsymbol{y}} \quad \boldsymbol{Q}_A]' + \boldsymbol{F}_A\end{aligned}$$

where

$$\boldsymbol{T} = (\boldsymbol{X} - 1\overline{\boldsymbol{x}}'\boldsymbol{W}_A](\boldsymbol{P}'\boldsymbol{W})^{-1} \tag{7}$$

and $\boldsymbol{W}_A$ is the internal loading weight matrix. For each consecutive factor, the corresponding column in $\boldsymbol{W}_A$ is defined as the first eigenvector of residual $\boldsymbol{X}-\boldsymbol{X}$ covariance (in PCR) or $\boldsymbol{X}-\boldsymbol{Y}$ covariance (in PLSR). The linear regression coefficients in eqs. (1), (2) is then defined as

$$\boldsymbol{B}_A = \boldsymbol{W}_A(\boldsymbol{P}'_A\boldsymbol{W}_A)^{-1}\boldsymbol{Q}'_A \tag{8}$$

Similarly, we can write each of the M sub-models in matrix notation, where the index $-m$ denotes that segment m has been left out.

$$\begin{aligned}\boldsymbol{X}_{-m} &= [1 \quad \boldsymbol{T}_{-m,A}]\ [\overline{\boldsymbol{x}}_{-m} \quad \boldsymbol{P}_{-m,A}]' + \boldsymbol{E}_{-m,A}\\ \boldsymbol{Y}_{-m} &= [1 \quad \boldsymbol{T}_{-m,A}]\ \left[\overline{\boldsymbol{y}}_{-m} \quad \boldsymbol{Q}_{-m,A}\right]' + \boldsymbol{F}_{-m,A}\end{aligned} \tag{9}$$

Without changing equation (9), we can insert an invertible matrix $\boldsymbol{C}$ and its inverse $\boldsymbol{C}^{-1}$, since $\boldsymbol{C}\boldsymbol{C}^{-1} = \boldsymbol{I}$.

$$\begin{aligned}\boldsymbol{X}_{-m} &= [1 \quad \boldsymbol{T}_{-m,A}]\ \boldsymbol{C}_{-m}\boldsymbol{C}_{-m}^{-1}\ [\overline{\boldsymbol{x}}_{-m} \quad \boldsymbol{P}_{-m,A}]' + \boldsymbol{E}_{-m,A}\\ \boldsymbol{Y}_{-m} &= [1 \quad \boldsymbol{T}_{-m,A}]\ \boldsymbol{C}_{-m}\boldsymbol{C}_{-m}^{-1}\ \left[\overline{\boldsymbol{y}}_{-m} \quad \boldsymbol{Q}_{-m,A}\right]' + \boldsymbol{F}_{-m,A}\end{aligned} \tag{10}$$

Comparing equation (7) and equation (10), we can define $\boldsymbol{C}_{-m}$ as a rotation matrix, where we try e.g. try to rotate $[1 \quad \boldsymbol{T}_{-m,A}]$ towards $[1 \quad \boldsymbol{T}_A]$. Similarly, we then interpret $\boldsymbol{C}_m^{-T}$ as a rotation of $[\overline{\boldsymbol{x}}_{-m} \quad \boldsymbol{P}_{-m,A}]$ towards $[\overline{\boldsymbol{x}} \quad \boldsymbol{P}_A]$. Thus, if we wanted to estimate the matrix $\boldsymbol{C}_{-m}$, we could use either the relation between the scores or the relation between one of the loadings as targets.

If the data were without noise, perfectly behaved and contained sufficient redundant information, the only difference between the submodel and the total model would be reflections and possibly reorderings (permutations) of the factors. It would then be possible to map the submodel onto the total model with a matrix $\boldsymbol{C}_{-m}$ containing only one ± 1 per column/row, and the rest of the elements 0. But when the data contains noise and insufficient redundant information, rotation at angles that are not multiples of 90° and possibly rescaling of the axis will be necessary to map the submodel perfectly onto the total model.

In order to consume as few degrees of freedom in $\boldsymbol{Y}$ as possible in the estimation of $\boldsymbol{C}$, we have chosen to use the scores matrices as targets. Since cross-validation/jackknife segment m has been removed in $\boldsymbol{T}_{-m,A}$, it has fewer rows than $\boldsymbol{T}_A$. In order to estimate $\boldsymbol{C}_{-m}$, the samples in segment m must also be removed from $\boldsymbol{T}_A$ before comparing them. This shortened version of $[1 \quad \boldsymbol{T}_A]$ is denoted as $[1 \quad \boldsymbol{T}_A]_{\setminus m}$. Since the samples in segment m is now removed from both matrices, fewer degrees of freedom in $\boldsymbol{Y}$ is consumed than if e.g. the loading matrices were to be used as targets. Note that even if the samples in segment m are not used directly when estimating $\boldsymbol{C}_{-m}$, they are not completely left out since they have been influencing $\bar{\boldsymbol{Y}}$ and $\boldsymbol{W}$ in the total model.

In order to estimate the matrix $\boldsymbol{C}_{-m}$, the criteria to be minimised is the difference between $[1 \quad \boldsymbol{T}_A]_{\setminus m}$ from the total model and the rotated $[1 \quad \boldsymbol{T}_{-m,A}]$ from the reduced model. The difference is here denoted $\boldsymbol{G}_{-m,A}$:

$$[1 \quad \boldsymbol{T}_A]_{\setminus m} = [1 \quad \boldsymbol{T}_{-m,A}]\, \boldsymbol{C}_{-m} + \boldsymbol{G}_{-m,A} \tag{11}$$

There are many possible ways to estimate $\boldsymbol{C}_{-m}$ from equation (11). To reduce the degrees of freedom consumed in the rotation, we have chosen to use an orthogonal rotation, which means that the columns in $\boldsymbol{C}_{-m}$ are orthogonal with length one. The procedure for estimating $\boldsymbol{C}_{-m}$ starts with performing an SVD:

$$\boldsymbol{U}\boldsymbol{S}\boldsymbol{V}' = [1 \quad \boldsymbol{T}_{-m,A}]' \; [1 \quad \boldsymbol{T}_A]_{\setminus m} \tag{12}$$

and then $\boldsymbol{C}_{-m}$ is estimated as

$$\boldsymbol{C}_{-m} = \boldsymbol{U}\boldsymbol{V}' \tag{13}$$

There are many possible ways to estimate $\boldsymbol{C}_{-m}$ from equation (11) (or even without using the scores matrices), the above is just one solution. Other possible procedures are discussed in section 3.2.

2.4.1 Rotating the scores

For each left-out segment $m = 1 \dots M$, we estimate $\boldsymbol{C}_{-m}$ using equation (13). With the appropriate matrix $\boldsymbol{C}_{-m}$, we can then calculate values for the rotated versions of the scores in each submodel.

Augmenting the submodel score matrix: Since the score-matrix of submodel $-m$ is calculated with the samples of segment m left out, we would only be able to re-estimate parts of the total score-matrix by rotating the scores from submodel $-m$. In order to fix this, we first insert estimated score values of the left-out samples set m into the score-matrix of submodel $-m$ before we rotate it. These estimated values are calculated in the usual way:

$$\widehat{\boldsymbol{T}}_{m,A} = (\boldsymbol{X}_m - 1\bar{\boldsymbol{x}}')\, \boldsymbol{W}_{-m,A} \left(\boldsymbol{P}'_{-m,A}\boldsymbol{W}_{-m,A}\right)^{-1} \tag{14}$$

By inserting these values into $\boldsymbol{T}_{-m,A}$ at the right positions, we can now calculate the full rotated score-matrix of submodel $-m$. We denote the rotated matrix with a tilde, and the augmented score-matrix from submodel $-m$ is denoted with a subscript $-m$, m.

$$\left[\widetilde{1} \quad \widetilde{\boldsymbol{T}}_{-m,A}\right] = [1 \quad \boldsymbol{T}_{-m,m,A}]\,\boldsymbol{C}_{-m} \tag{15}$$

Using the rotated versions of the score-matrix as calculated in equation (15), we can estimate the variance of each element in the same way we did for the regression coefficients in equation (5). For the elements of the score-matrix, the corresponding equation is

$$\hat{s}^2(t_{ia}) = \frac{M-1}{M}\sum_{m=1}^{M}\left(\widetilde{t}_{-m,ia} - t_{ia}\right)^2 \tag{16}$$

where t_{ia} is the score-value of sample i in factor a of the total model. This equation gives an estimate of the variance of the score-value for each sample in each factor. This can be used e.g. to draw approximate confidence-regions around each sample in the score-plot, and thus determine if two samples are far enough apart to be considered different. Such an approximate confidence-region could e.g. be created by using $\pm 2\hat{s}(t_{ia})$, but it is important to emphasise that the statistical properties of the variance estimate (16) is not known, and that the "confidence-region" should be regarded as approximate. (Further improvements might be attained by degrees-of-freedom correction to compensate for the estimation of the rotation parameters.)

The rotated score-values $\widetilde{t}_{-m,ia}$ are also interesting in themselves. By plotting these values together with the score-values from the total model in the score-plot, the user gets a visual image of the stability of each sample, and such plots are often referred to as *stability plots*. Samples that are outliers will tend to get a very different score-value when they are not used in the calibration, and thus will be easily visible in the stability plot.

2.4.2 Rotating the loadings The matrices of $\boldsymbol{X}$- and $\boldsymbol{Y}$-loadings for submodel $-m$ have the same dimensions as the loading-matrices of the full model. They can therefore be rotated without augmentation.

$$\begin{aligned}\left[\widetilde{\bar{\boldsymbol{x}}}_{-m} \quad \widetilde{\boldsymbol{P}}_{-m,A}\right] &= \left[\bar{\boldsymbol{x}}_{-m} \quad \boldsymbol{P}_{-m,A}\right]\boldsymbol{C}_{-m}^{-T} \\ \left[\widetilde{\bar{\boldsymbol{y}}}_{-m} \quad \widetilde{\boldsymbol{Q}}_{-m,A}\right] &= \left[\bar{\boldsymbol{y}}_{-m} \quad \boldsymbol{Q}_{-m,A}\right]\boldsymbol{C}_{-m}^{-T}\end{aligned} \tag{17}$$

In the present case, $\boldsymbol{C}_{-m}$ is an orthogonal matrix, and thus $\boldsymbol{C}_{-m}^{-T} = \boldsymbol{C}_{-m}$. The notation in equation (17) is general, and also valid for matrices with other properties. In the same way as with the scores, the variance of each element in the loading-matrices can now be estimated:

$$\begin{aligned} \hat{s}^2(p_{ka}) &= \frac{M-1}{M}\sum_{m=1}^{M}\left(\widetilde{p}_{-m,ka}-p_{ka}\right)^2 \\ \hat{s}^2(q_{ja}) &= \frac{M-1}{M}\sum_{m=1}^{M}\left(\widetilde{q}_{-m,ja}-q_{ja}\right)^2 \qquad (18) \end{aligned}$$

As with the score-values, these variances can be used to draw approximate confidence regions in the loading plot and determine whether or not two variables are overlapping and thus contains the same information.

2.4.3 Rotation of the loading weights Rotation of the loading weights $\boldsymbol{W}_A$ (7) is a little more complicated than rotation of scores and loadings.

The rotated version of the loading weights is proposed as:

$$\widetilde{\boldsymbol{W}}_{-m,A} = \left[\bar{\boldsymbol{x}}_{-m} \quad \boldsymbol{W}_{-m,A}\boldsymbol{W}'_{-m,A}\boldsymbol{P}_{-m,A}\right]\boldsymbol{C}_{-m}^{-T}\left[0 \quad \left(\boldsymbol{P}'_A\boldsymbol{W}_A\right)^{-1}\right] \qquad (19)$$

where the column of zeros is needed because the matrix $\boldsymbol{C}_{-m}$ was estimated from equation (12), where an extra column is appended.

Similar to the other model parameters, the variance of each element in the loading weight matrices can now be estimated as:

$$\hat{s}^2(w_{ka}) = \frac{M-1}{M}\sum_{m=1}^{M}\left(\widetilde{w}_{-m,ka}-w_{ka}\right)^2 \qquad (20)$$

Having variance estimates of the individual loading weights opens up a new possibility in variable selection. It will then be possible to do a significance test of each variable k in each factor a. Values w_{ka} that are not significantly different from zero, can be forced to zero after which the vector $\boldsymbol{w}_a$ is re-orthogonalised. This procedure will then yield variable selection where it is possible to remove variables only in some of the factors, while leaving them in for other factors.

As further factors are calculated and the information left in the dataset decreases, more and more variables will become insignificant with their corresponding loading weight set to zero. Finally, the loading vector $\boldsymbol{w}_a$ will be reduced to the zero-vector, and no further factors needs to be calculated. Thus, the procedure would yield automatic selection of the number of factors to calculate, with integrated variable selection. The automatic deletion of insignificant variables is expected to yield more stable models that are also easier to interpret due to the reduced number of variables in each factor.

3 Results and discussion

3.1 Jackknife and segmentation

To confirm that equation (4) gives consistent estimates of variance with $M-1$ degrees of freedom for different segmentation sizes, a Monte-Carlo simulation was carried out. The parameter of interest in the simulation was the variance of regression coefficients in a full-rank OLS solution to MLR regression, i.e. a bilinear PCCR or PLSR model with maximum possible number of factors.

A matrix $\boldsymbol{X}$ with 300 samples and 3 variables was drawn with random, evenly distributed values between 0 and 1. The regressand $\boldsymbol{y}$ was calculated from true regression coefficients $\boldsymbol{\beta} = [0\ 1\ 2]'$ and random noise $\boldsymbol{e}$ which was drawn from the distribution $N(0, 1^2)$.

The dataset was then split up in several different ways with M ranging from 2 to 300, corresponding to the extremes of splitting in two and leave-one-out. For each value of M, the regression coefficients $\boldsymbol{b}$ were estimated and the variance of the second element in $\boldsymbol{b}$ was estimated from equation (4). The whole procedure was then repeated 500 times with different noise $\boldsymbol{e}$ added each time.

Since the true variance of the added noise ($\boldsymbol{e}$) was known, it was possible to compare the jackknife-estimated values of $s^2(\boldsymbol{b})$ with the theoretically expected values. The theoretical variance of the regression coefficients from MLR (given that $\boldsymbol{X}$ is noise-free) is

$$\sigma^2(\boldsymbol{b}) = \operatorname{diag}\left((\boldsymbol{X}'\boldsymbol{X})^{-1}\right)\sigma^2(y) \tag{21}$$

Figure 1 shows the jackknife-estimated variance of the regression coefficient (5) as a function of the number of segments M, together with the theoretically expected variance value (21).

As could be expected, one can see that the variance-estimate is more uncertain when it is based only on only a few segments. But as the number of segments increases, the variance-estimate stabilises towards the theoretical value, and its own variance gets smaller.

Given that $s^2(\boldsymbol{b})$ is the estimated jackknife-variance of $\boldsymbol{b}$ based on M segment "observations", and assuming the underlying distribution is normal with variance $\sigma^2(\boldsymbol{b})$, then

$$\chi^2 = \frac{(M-1)\,s^2(\boldsymbol{b})}{\sigma^2(\boldsymbol{b})} \tag{22}$$

is chi-square distributed with $\nu = M - 1$ degrees of freedom and a variance of 2ν. Reordering this, the variance of the variance-estimate $s^2(\boldsymbol{b})$ is

$$\sigma^2\left(s^2(\boldsymbol{b})\right) = \frac{2}{\nu}\,\sigma^4(\boldsymbol{b}) \tag{23}$$

where ν is the degrees of freedom in the estimate of $s^2(\boldsymbol{b})$. Since the variance of the regression coefficient were estimated a lot of times in the Monte-Carlo simulations, it was possible to estimate also the variance of the variance-estimate, $s^2\left(s^2(\boldsymbol{b})\right)$. If we then "guess" that the degrees of freedom in $s^2(\boldsymbol{b})$ is $\nu = M - 1$, we can plot the variance of our variance-estimate as a function of $2/(M-1)$. If $M - 1$ is the correct number of degrees of freedom, this should give a straight line with intercept zero and slope σ^4.

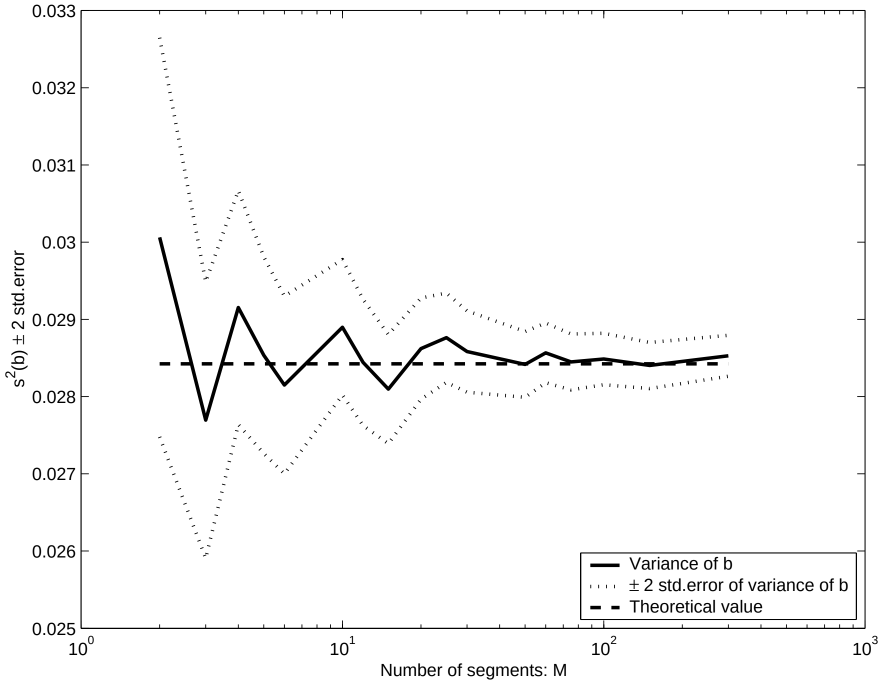

Figure 1: Variance of regression coefficient as a function of the number of segments.

As figure 2 shows, this is indeed the case. The above was also repeated with $\nu = M$ and $\nu = N$ (not shown here), but these (and other) alternatives gave a line with incorrect slope. Thus, we can conclude that equation (4) gives consistent estimates of the variance of $\boldsymbol{b}$ with $M-1$ degrees of freedom.

3.2 Alternative rotation schemes

The estimation of the orthogonal rotation matrix in equation (13) can be made even more conservative. A simpler matrix that only corrects for reflections and permutations can be calculated as

$$\boldsymbol{C}_{-m}^{\text{strict}} = \text{round}\left(\boldsymbol{C}_{-m}\right) \tag{24}$$

where the operator round () means rounding each element in $\boldsymbol{C}_{-m}$ towards the nearest integer; $-1, 0$ or 1. This approach would consume even fewer degrees of freedom than the orthogonal rotation in equation (13). When using the simple rounding procedure above, the norm of $\boldsymbol{C}_{-m}^{\text{strict}}$ must be monitored ($\boldsymbol{C}_{-m}^{\text{strict}}$ should have norm 1). If e.g. the angle between the submodel and the main model is around 45 degrees, the rounding can result in more that one element per row/column being different from zero.

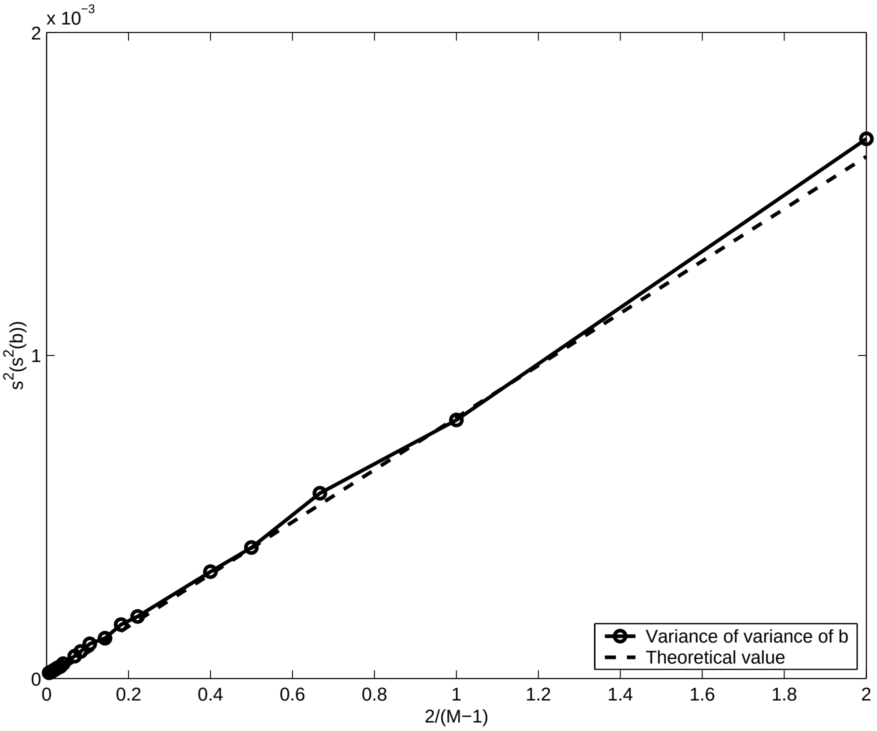

Figure 2: Variance of the variance of the regression coefficients as a function of $2/(M-1)$.

A procedure that solves this problem is to calculate the correlation between a factor in the total model and the factors in the submodel. If the highest absolute value is the diagonal element in the correlation matrix, then set the element in $\boldsymbol{C}_{-m}^{\text{strict}}$ to -1 or 1 depending on the sign of the correlation. All other elements for that factor are set to zero, both for the total model and the submodel elements. Thereafter, the highest absolute correlation for each total model with respect to the submodel is found and set to -1 or 1 in $\boldsymbol{C}_{-m}^{\text{strict}}$. This avoids that two factors in the submodel are assigned to the same factor in the total model, and yields a matrix $\boldsymbol{C}_{-m}^{\text{strict}}$ that is guaranteed to have norm one and only account for reflections and reorderings.

One could also envision other approaches that would consume more degrees of freedom. Starting from equation (11), the matrix $\boldsymbol{C}_{-m}$ could also be estimated by an OLS regression. This corresponds to projecting the total model onto the reduced model. A similar but more numerically stable approach would be to use a rank-reduced regression like PLSR instead of OLS regression in the estimation step.

3.3 The rank of the rotation

An important question regarding the rotation of submodels is *how many bilinear factors to use in the rotation?* The simulations performed suggests that the best solution is to perform the rotation of the models after A_{opt} factors have been calculated. This introduces a problem, as A_{opt} is not known *a priori* but typically estimated from a crossvalidated Root Mean Square Error of Prediction (RMSEP) curve showing estimated prediction errors in $\boldsymbol{Y}$. Thus, the current implementations starts with an ordinary PLSR in order to establish A_{opt}. Then, in a second step, the rotations are performed, and the variances are estimated.

Such a two-step procedure causes problems for the suggested "dynamic" variable selection scheme suggested in section 2.4.3. Further research in this area might solve this problem.

3.4 Large matrices with many predictor variables

If there are many predictor variables in the input data $\boldsymbol{Z}$, one might consider doing an SVD, $\boldsymbol{Z} = \boldsymbol{USV}'$, and then use the much smaller $\boldsymbol{X} = \boldsymbol{US}$ as input to the PLSR algorithm instead of $\boldsymbol{Z}$. This will greatly reduce the time consumed in the calibration, especially when doing leave-one-out crossvalidation. The variable dependent parameters from the PLSR (like $\boldsymbol{B}_A$, $\boldsymbol{P}_A$ and $\boldsymbol{W}_A$) will then have to be multiplied with $\boldsymbol{V}'$ in order to correspond to the original $\boldsymbol{X}$-variables. Since e.g. the regression coefficients are then rotated, it is necessary to estimate *covariance uncertainties* (not just variances), in order for the rotated uncertainty estimate to be applicable to the original variables. It appears that this can be done by modifying equation (5): Let $\boldsymbol{d}_{-m,A} = \boldsymbol{b}_{-m,A} - \boldsymbol{b}_A$. The covariance between the regression coefficients can then be calculated as

$$\operatorname{cov}(\boldsymbol{b}_A) = \frac{M-1}{M} \sum_{m=1}^{M} \boldsymbol{d}_{-m,A} \boldsymbol{d}'_{-m,A} \tag{25}$$

The diagonal of this covariance matrix contains the values calculated from equation (5). This covariance will be applicable to the regression coefficients $\boldsymbol{B}$ from the regression $\boldsymbol{Y} = \boldsymbol{XB} + \boldsymbol{F}$. In order to be applicable to the regression with the large input matrix, $\boldsymbol{Y} = \boldsymbol{ZC} + \boldsymbol{F}$, the covariance matrix must be multiplied with $\boldsymbol{V}$:

$$\operatorname{cov}(\boldsymbol{c}_A) = \boldsymbol{V} \operatorname{cov} \boldsymbol{b}_A \boldsymbol{V}' \tag{26}$$

3.5 Examples of score-plot

A matrix of $\boldsymbol{X}$-data with seven samples and three variables were generated by sampling from a normal distribution. The $\boldsymbol{y}$-data were then calculated by multiplying $\boldsymbol{X}$ with some predefined regression coefficients, and adding

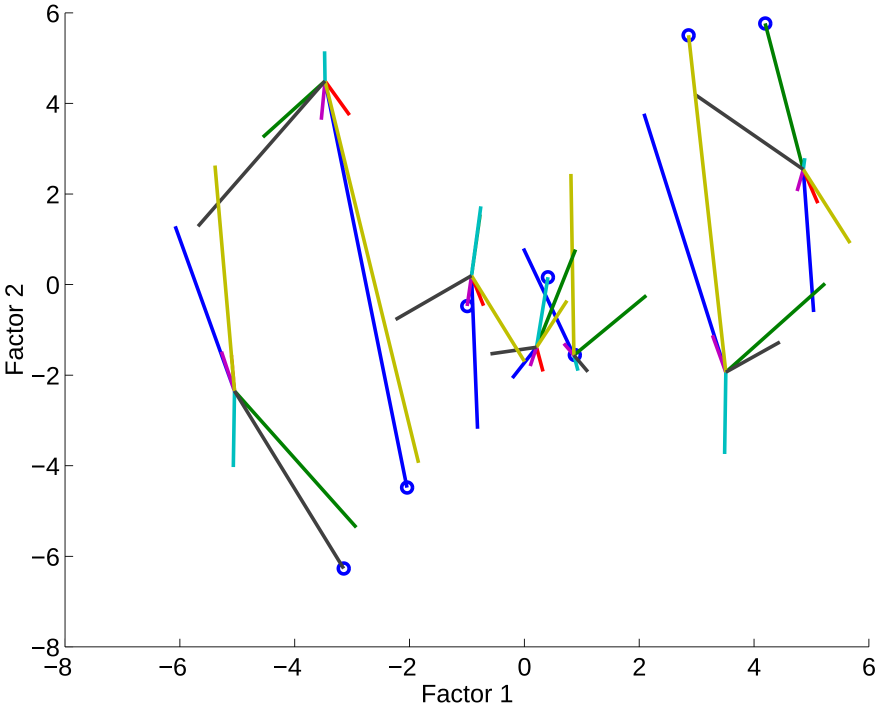

Figure 3: Original score plot with perturbations from leave one out jackknife. The centre of each "star" is the value from the complete model, and the circles denotes the value when that sample is kept out of the model calibration.

normal distributed noise with variance 0.1. Before subjecting these $\boldsymbol{X}$- and $\boldsymbol{y}$-data to a PLSR with full leave-one-out crossvalidation, normal distributed noise with variance 0.1 was also added to $\boldsymbol{X}$.

Figure 3 shows a score plot with all the values from each cross-validation segment, sometimes referred to as a *stability plot*. In the centre of each "star" are the score-values from the model calculated with all the samples. The lines going out from each "star" shows the score-value of that sample in each of the cross-validated models. The value with a circle on it denotes the value of that sample in the segment where the sample itself was left out, and thus had no influence on the model. Samples that are outliers will tend to get a very different score value when they are not included in the model, and thus the score value denoted with a circle will be further away from the centre than the other score values.

Note that several samples flip over, change sign or otherwise show large deviations that are not related to the uncertainty of the sample. This is due to the rotational freedom of bilinear models as described in the beginning of

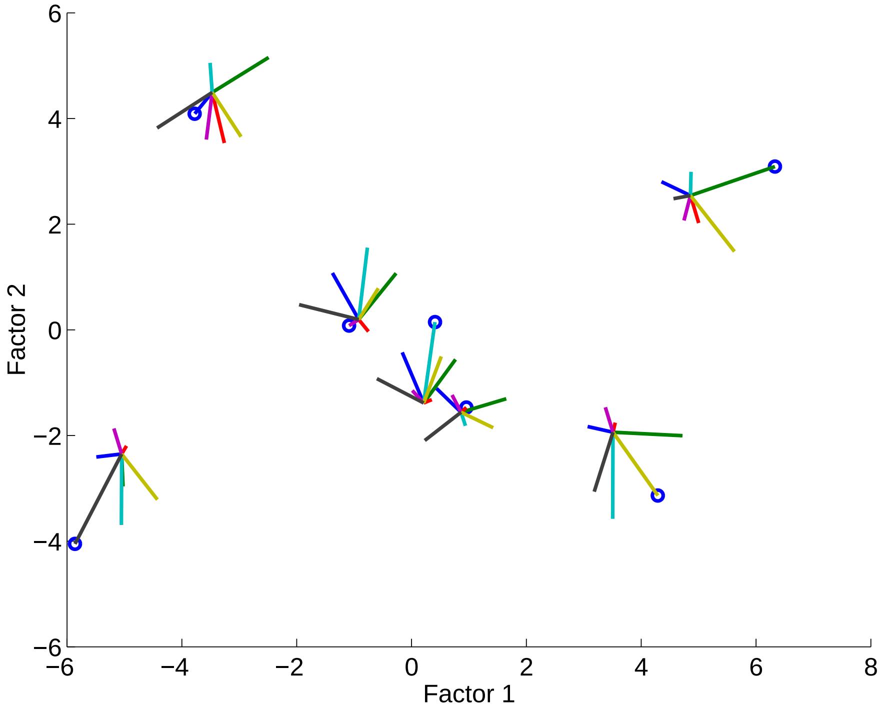

Figure 4: Rotated score plot. The centre of each "star" is the value from the complete model, and the circles denotes the value when that sample is kept out of the model calibration.

section 2.4. As a consequence, the variations between the values in figure 3 are unsuitable for calculating uncertainties.

Figure 4 shows the score plot after each of the submodels have been rotated as described in equation (15). The picture is now much clearer, and the variance left can be assumed to be due to the uncertainty of the score-values. Note that for each sample there can be a quite large difference between the mean of all the obtained values and the value from the total model. This is the rationale for choosing the total model as the reference value and not the mean (c.f. the discussion after equation (5)).

4 Conclusion

An improvement of the jackknife rotation method by Martens & Martens [3] has been proposed for estimating the uncertainty in the bilinear model parameters with the use of jackknife. The method works by rotating each of the submodels towards the main model before the values are used to estimate variances. The rotation matrix can be estimated in several ways, and some of the alternatives are discussed.

Further research is needed to establish the statistical properties of the obtained variance estimates, and alternative procedures for estimating the rotation matrix should be compared.

COMPSTAT'2004 Symposium

LINE MOSAIC PLOT: ALGORITHM AND IMPLEMENTATION

Moon Yul Huh

Key words: Mosaic plot, line mosaic plot, statistical graphics, visual inference, statistical algorithms.

COMPSTAT 2004 section: E-statistics.

Abstract: Conventional mosaic plot is to graphically represent contingency tables by tiles whose size is proportional to the cell count. The plot is informative when we are well trained reading this. This paper introduces a new approach for mosaic plot called line mosaic plot which uses lines instead of tiles to represent the size of the cells in contingency tables. We also give a general straightforward algorithm to construct the plot directly from the data set while the conventional approach is to construct the plot from the cross tabulation. We demonstrate the effectiveness of this tool for visual inference using a real data set.

1 Introduction

Mosaic display introduced by Hartigan and Kleiner [6] has been generalized to multi-way tables and has been extensively worked for visual inference of independence using Mosaic plots by Friendly [4], [5]. Meyer and et. al. [11] considered visual inference of contingency tables using association plots mainly for the case of 2-way tables. Another sources for the works of Mosaic Plots are Hofmann [7], [8] and Unwin [12]. Most of the statistical packages available today have implemented mosaic displays (SAS, S-Plus, R, Minitab, and others).

Conventional mosaic plot is to graphically represent contingency tables using tiles whose size is proportional to the cell count. Figure 1 gives the mosaic plot of the Titanic data [3] as implemented in R [10]. This data will be explained in more detail in the next section. The plot is informative when we are well trained in reading this. Our experiments with the graduate students showed that the features in the mosaic plot is confusing and misleading if more than 2 variables are involved in the plot. The reason behind this could be due to the limitation of human perception. Firstly, this could be explained by the Steven's law of dimensionality. Steven's law states that perceived scale in absolute measurements is the actual scale raised to a power where the scale is as follows: for linear features, power is .9-1.1; for area feature, .6-.9; for volume, .5-.8.

Steven's Law suggests that physical relationships that are not represented in linear features can be grossly misperceived. For example, a lake represented on a map with an area graphically 10 times larger than another will be perceived as only 5 times larger as noted in Catarci, et. al. [1]. Since the

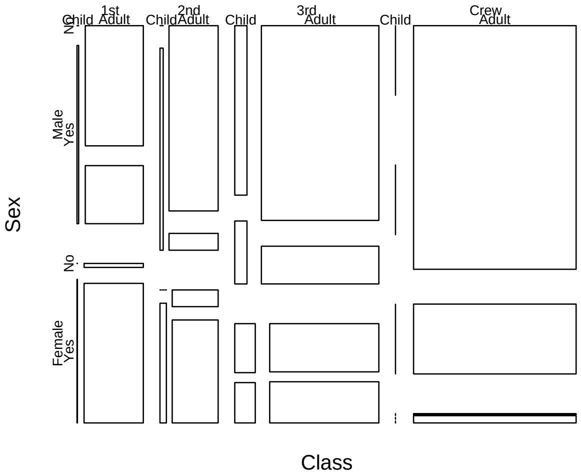

Figure 1: Conventional mosaic plot of Titanic Data using R.

mosaic plot presents all the features using 2-dimensional bars, the perceived scale of the features may be underestimated according to the law.

Secondly, the misperception of mosaic plot could be due to the fact that the columns and rows of the bars of the plot are not aligned, and make "errors in perception" as explained by Cleveland and McGill [2]. They state that the errors in perception from the graphs are in the following order.

- Position along identical, non-aligned scales.
- Length.
- Angle/Slope (though error depends greatly on orientation and type).
- Area.
- Volume.
- Color Hue, Saturation, Density (only informal testing).

Above observations suggest us to use lines instead of bars to represent the cell sizes in contingency tables and to plot the lines along a common aligned scales. Figure 2 gives the 'line' mosaic plot for the Titanic data. Details of the construction and interpretation of this plot will be given in the next section. In line mosaic plot, each cell of the contingency table is given equal sized rectangle, and the size of the frequency of each cell is represented using the total length of the lines drawn inside the rectangle. All the rectangular boxes are aligned horizontally and vertically so that the comparison of the relative size of the lengths in each rectangle can be perceived more easily.

In section 2, we give the algorithm for the line mosaic plot. In section 3, we present the implementation of the algorithm, and demonstrate the usefulness of the plot using a real data set.

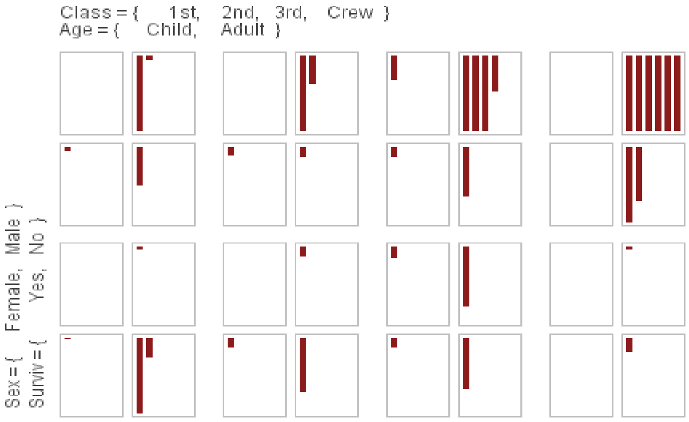

Figure 2: Line mosaic plot of Titanic Data.

2 Algorithm for mosaic array

Algorithms to generate mosaic plots have been approached in two ways as far as the author is aware of at the present time. The first approach is to construct the plot for a specific setting. In other words, suggested algorithm is to build the plot for the contingency table of a specific dimension, and apply similar method for other dimensions. Wang [13] and Friendly [4] give algorithms for 4-dimensions. Second approach is to use recursive structure as implemented in R [10]. To use these algorithms, we need contingency tables.

In this paper, we suggest a simple straightforward algorithm to construct the line mosaic plot directly from the data set. Figure 2 suggests us that line mosaic plot is simply a 2 dimensional array of the frequencies, what we call mosaic array. Mosaic array is the basic building block for our work, and in the next section, we give an algorithm to construct this array directly from the data set. Also, the algorithm for the the converse operation, or constructing data from mosaic array is given. When the problem considered is supervised learning, or when there is the target variable, mosaic array will be 3-dimensional. 3rd dimension corresponds to the target variable, and the number of levels of this dimension will be equal to the number of categories of the target variable. The construction of this case will become clear in section 3 where we give the implementation of the line mosaic plot.

We assume that all the variables are discrete, and let p be the number of variables, and $\mathbf{n}' = (n_1, \ldots, n_p)$ be the vector of the values that each variable can adopt, or number of categories for each categorical variable. Without loss of generality, we can assume that the values of each variable are transformed into integer values starting from 1. For example, the values of the variable *sex* will be $1, 2$. Also, let X be the data matrix of dimension $n \times p$ where

n is the number of observations. For convenience and for the simplicity of notation, let $\mathbf{v}$ be the $p-$ length vector denoting an observation or an instance from the data matrix X. Using this notation, we can write $v_j, j = 1, \ldots, p$ as a realization of the j^{th} variable of an instance from the data matrix X. We finally assume that the variables are ordered according to some measure of importance for mosaic plot. Hence, the first variable will be the first choice, the second one is next choice, and so on for the mosaic plot.

We now build a 2-dimensional mosaic array F which is a representation of multidimensional cross table form for the data matrix X, or the array of the form of Figure 2. The size of F will be $\Pi_{i=1}^{[p/2]} n_{2i}$ and $\Pi_{i=0}^{[(p-1)/2]} n_{2i+1}$ for row and column respectively.

An instance of X, which is denoted as $\mathbf{v}$ in the above, will add 1 to the cell $F_{I,J}$, where I and J will be determined as follows.

$$I = \Sigma_{i=1}^{[p/2]}(v_{2i} - 1)\Pi_{j=i+1}^{[p/2]} n_{2j} + v_{2[p/2]}$$

$$J = \Sigma_{i=0}^{[(p-1)/2]}(v_{2i+1} - 1)\Pi_{j=i+1}^{[(p-1)/2]} n_{2j+1} + v_{2[(p-1)/2]+1}$$

where $[x]$ denotes the integer not exceeding x.

We now give the algorithm to construct the values of the variables, $\mathbf{v}$, when an instance belongs to a cell $F(I, J)$. ¿From the row index I, variables of even indices, or $v_2, v_4, \ldots, v_{2[p/2]}$ will be constructed, and from the column index J, variables of odd indices, or $v_1, v_3, \ldots, v_{2[(p-1)/2]+1}$ will be constructed. The algorithm follows.

Values of odd indices, $v_1, v_3, \ldots, v_{2[(p-1)/2]+1}$ from J are:

$$v_i = \begin{cases} 1 + [\frac{J-1}{\Pi_{j=[(i-1)/2]+1}^{[(p-1)/2]} n_{2j+1}}], & i = 1, 3, \ldots, 2[(p-1)/2] - 1 \\ 1 + Mod\ (J-1,\ n_{2[(p-1)/2]+1}), & i = 2[(p-1)/2] + 1 \end{cases}$$

Values of even indices, $v_2, v_4, \ldots, v_{2[p/2]}$ from I are:

$$v_i = \begin{cases} 1 + [\frac{I}{\Pi_{j=[i/2]+1}^{[p/2]} n_{2j}}], & i = 2, 4, \ldots, 2[p/2] - 1 \\ 1 + Mod\ (I-1,\ n_{2[p/2]}), & i = 2[p/2] \end{cases}$$

where $Mod(x, y) = x - x \times [x/y]$. We have shown above algorithmically, a unique F is constructed for a given data set. Now, to draw a mosaic plot, we need to construct $||F||$ rectangles in total, where $||F||$ denotes the number of the cells that F makes, or is equal to $\Pi_{i=1}^{[p/2]} n_{2i} \times \Pi_{i=0}^{[(p-1)/2]} n_{2i+1}$. The rectangles are separated by some gaps between them, and it is conventional to leave larger gaps for the variables with higher hierarchy. Our implementation for the construction of the rectangles and the gaps between them are given in the following section.

To complete the algorithm, we need to consider several details. At first, we need to standardize mosaic array F according to some criterion. We can consider several options for standardization. In this work, we standardize each cell with respect to the maximum cell frequency, or we use $F(I, J)/max_{I,J}F(I, J)$. Secondly, we need to set some gaps between the rectangles, so that the plot is easier to perceive. An option for this is suggested in Friendly [4]. In this work, we apply the following method.

For horizontal direction, there will be $\Pi_{i=0}^{[(p-1)/2]} n_{2i+1} - 1$ gaps between the rectangles, and for vertical direction, there will be $\Pi_{i=1}^{[p/2]} n_{2i} - 1$ gaps between the rectangles. To implement the horizontal gaps, we leave 1 unit space between the rectangles for the lowest hierarchy, 2 'unit' space for the next hierarchy, ..., $[\frac{p+1}{2}]$ unit space for the highest hierarchy. Here, 'unit' is arbitrary. We may set 5 pixels, for example, for the unit space. For the column, we leave 0.5 unit space between the rectangles for the lowest hierarchy, 1.5 unit space for the next hierarchy, ..., $[p/2] - 0.5$ unit space for the highest hierarchy. An algorithm for the gaps is given in Figure 3.

```
For row bars:
  • Let $G \leftarrow \Pi_{i=0}^{[(p-1)/2]} n_{2i+1} - 1$, which is the total number of gaps.
  • Let the $i^{th}$ gap $g_i = 1$, for $i = 1, \ldots, G$. Let the number of variables for
    the row bars $m = [(p-1)/2]$, and initialize $d$ to 1.
  • if $(m == 1)$ break;
  • for $i = m, \ldots, 1$, step $-1$ {
    $d = d * n_{2i+1}$;
    for $j = d, \ldots, G$, step d{
    $g_j + +$;
    }}

For column bars:
  • Let $G \leftarrow \Pi_{i=1}^{[p/2]} n_{2i} - 1$, which is the total number of gaps.
  • Let $g_i = 1$, for the $i - th$ gap where $i = 1, \ldots, G$. Let the number of
    variables for the column bars $m = [p/2]$, and initialize $d$ as 1.
  • if $(m == 1)$ break;
  • for $i = m, \ldots, 1$, step $-1$ {
    $d = d * n_{2i}$;
    for $j = d, \ldots, G$, step d{
    $g_j + +$;
    }}
```

Figure 3: Algorithm for the gaps between the rectangular bars.

The above procedure works for unsupervised learning. With supervised learning, we have target variable. We assume here that the last variable, or variable p is for the target. In this case, we build F with $p-1$ variables. Frequencies in the cell (I,J), or $F(I,J)$ will be divided into n_p different categories. In this case, it will be convenient to express F in 3 dimensional form such that $F(I,J,K), K=1,\ldots,n_p$.

3 Implementation and demonstration of the line mosaic plot

We illustrate the implementation of line mosaic plot using Titanic data introduced by Dawson (1995, http://ssi.umh.ac.be/titanic.html) goes as follows. Titanic data consists of 2201 cases and 4 variables {*Class, Gender, Age* and *Survival*}. The values of each variables are: *Class*={*1st, 2nd, 3rd, crew*}*; Gender*={*male, female*}*; Age* ={*adult, child*}*; Survived* ={*yes, no*}. Hence, $p=4$, $\mathbf{n}'=(4,2,2,2)$. When a case *(1st, adult, male, yes)* is given, $\mathbf{v}'=(1,1,1,1)$, and the above algorithm give $\{I=1,\ J=1\}$. When a case is *(crew, male, child, no)*, F of Titanic data. Mosaic array F of Titanic data is given in Table 1.

57	5	14	11	75	13	192	0
118	0	154	0	387	35	670	0
140	1	80	13	76	14	20	0
4	0	13	0	89	17	3	0

Table 1: Mosaic array F of Titanic data.

Table 2 gives the mosaic array F for the Titanic data when *survive* is target variable. Implementation of this mosaic plot can be accomplished by assigning different colors for different categories. For Titanic data, we may assign *survived* as the target variable. Conventional mosaic plot and line mosaic plot of the Titanic data for this case is given in Figure 4 and Figure 5 respectively.

when $survive = yes$, or $k=1$

57	5	14	11	75	13	192	0
140	1	80	13	76	14	20	0

when $survive = no$, or $k=2$

118	0	154	0	387	35	670	0
4	0	13	0	89	17	3	0

Table 2: Mosaic array F of Titanic data with *survive* as the target variable.

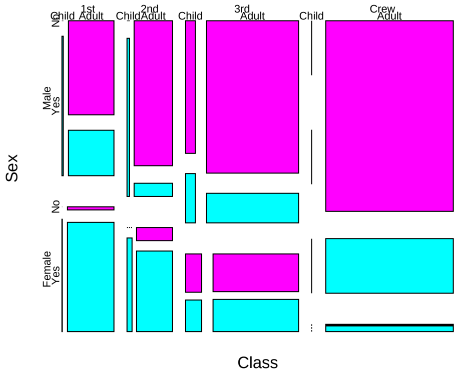

Figure 4: Mosaic plot of Titanic Data when *survived* is target variable.

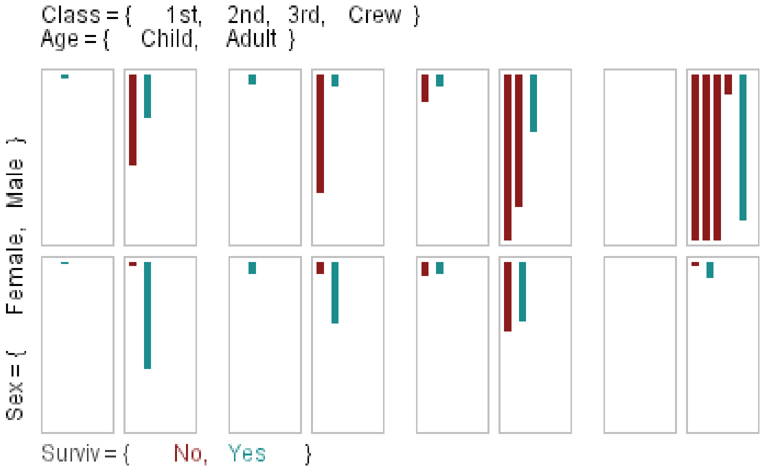

Figure 5: Line mosaic Plot of Titanic Data when *survived* is target variable.

From Figure 5, it is easy to see that most of the passengers are males, and there are very few children passengers. The largest number of passenger groups are crews, then 3*rd* class, 2*nd* class, and 1*st* class passengers are the fewest. In gender-wise, there are very few female crews, and largest class group for females is seen to be 3*rd* class, then 1*st*, and then 2*nd* class. We can visually estimate that the number of female 3*rd* group passengers is about twice the number of female 2*nd* class passengers. Turning our attention to *survive*, it is straightforward to observe that most of the *3rd* and *crew* class passengers could not survive, but most of the 1*st* and 2*nd* class female passengers survived. The proportion of survivals in the *3rd* and *crew* classes can even be estimated visually by reading the number of bars in the plot. For {*crew, adult, male*} combination, the proportion can be estimated as 2/7. For {*3rd, adult, male*} combination, the proportion is less than 1/4. For the female case, we can observe directly from the plot that the survival proportion is much higher except for the {*3rd, adult*} combination. Although there are few *child* passengers, the plot clearly shows that most of the children passengers survived except for the *3rd* class cases.

Figure 6 gives the process of obtaining a line mosaic as implemented in hDAVIS [9]. hDAVIS is freely available on the following website. `http://stat.skku.ac.kr/~myhuh/davis.html.`

	Class	Sex	Age
1	1st	Male	Adult
2	1st	Male	Adult
3	1st	Male	Adult

Target Variable: unSupervised

GRAPHICAL DISPLAYS OF INTERNET TRAFFIC DATA

Karen Kafadar and Edward J. Wegman

Key words: Logarithmic transformation, computational methods, recursive computation, graphical displays, exploratory data analysis.

COMPSTAT 2004 section: Data visualisation.

Abstract: The threat of cyber attacks motivates the need to monitor Internet traffic data for potentially abnormal behavior. Due to the enormous volumes of such data, statistical process monitoring tools, such as those used traditionally on data in the product manufacturing departments, are inadequate. The detection of "exotic" data, which may indicate a potential attack, requires a characterization of "typical" behavior. We propose some simple graphical tools that permit ready visual identification of unusual Internet traffic patterns in "streaming" data. These methods are illustrated on a moderate-sized data set (135,605 records) collected at George Mason University.

1 Introduction

Cyber attacks on computer networks or personal computers have become major threats to nearly all operations in society. Methods to thwart such attacks are seriously needed. The problem of detecting unusual behavior in data streams occurs in many fields, such as in disease surveillance, nuclear product manufacturing, and phone and credit card use. Historically, manufacturing and financial industries have relied on conventional statistical process monitoring tools, such as control charts and process flow diagrams. Such tools are reliable and appropriate, because the data streams can be stratified into reasonably independent series. For example, monitoring a customer's credit card use relies on an analysis of the data from the customer's past charging amounts and frequencies. This data stream is a much smaller data set than the entire database, with events occurring irregularly but not frequently; moreover, one customer's data stream can be considered as independent of other customers' data streams. In contrast, Internet traffic data are virtually continuous (limited only by the resolution of the time clock that captures them), and the data for one system involve hundreds of thousands of other computer or network systems.

Tools for monitoring such data are essential. Conventional statistical analysis often assumes that data follow a mathematically tractable probability distribution function and will yield valid estimates of the parameters of this distribution. Such approaches cannot be used on millions of data points. Graphical tools for streaming data offer hope of identifying potential cyber-attacks, particularly when the tools are tailored for the application. Features of Internet traffic data are described in Section 2.

Even with novel graphical displays for massive data streams, however, a characterization of "typical" behavior is still needed, so relevant graphical tools can be made more sensitive to capturing exotic or abnormal patterns. Two approaches to the detection problem through visualization are discussed in this article. Section 3 describes a "drill-down" approach to viewing large data sets, illustrated on a data set of 135,605 records collected over a one-hour period at George Mason University. Section 4 describes a second approach, "evolutionary graphical displays", which present the data only within a narrow time window (e.g., 10 minutes); early data disappear as new, more recent data, come into view. Two examples are "waterfall diagram" and "skyline display. Section 5 offers a summary and proposals for further work.

2 Features of Internet traffic data

To monitor Internet traffic data for potential attacks, organizations will install anonymous surveillance machines outside a "firewall" to monitor incoming and outgoing traffic. For a discussion of the types of programs that monitor traffic flow, see Marchette [1, Ch. 4]. Data collected during an Internet session includes many features; key features include source and destination addresses, source and destination ports, and measures of size and duration of the session.

IP addresses

Internet traffic proceeds from one machine to another, using a protocol for data transfer known as Internet Protocol (IP), which directs the transmission of data among machines during an Internet session. The "IP header" contains several important pieces of information. Since each IP address is a 32-bit number represented in four 8-bit fields (e.g., 127.0.0.1), 2^{32} = 4,294,967,296 machines can be addressed. Multiplied by the volume of traffic during a given day, conventional static graphs cannot display such tremendous volumes of data on a system with finite resolution. The IP header captures the two addressable machines involved in an Internet session.

Transmission Control Protocol

A common communication protocol is Transmission Control Protocol (TCP). TCP implements a two-way connection between machines and contains the necessary instructions for delivering and sequencing packets. The instructions are captured in a file whose header includes the source and destination port numbers, useful for monitoring traffic flow and detecting potential attacks.

Each host machine has 2^{16} = 65,536 ports, divided into three ranges. The first range includes 1024 (2^{10}) "well-known ports" numbered 0 to 1023; for example, file transfer protocol (ftp) uses port 21; secure shell (ssh) uses port 22; telnet uses port 23; smtp mail operates from port 25; web service (http) operates from port 80; pop3 mail operates from port 110; secure web encryption (https) operates from port 443; real time stream control protocol (rtsp) uses port 554 for quick-time streaming movies. The second range consists of registered ports, numbered 1024 to 49151; for example, Sun has registered port 2049 for its network file system (nfs). The remaining 16384 (2^{14}) ports, numbered 49152 to 65536, are dynamic or private ports. Unprotected ports (source ports or destination ports) are prime candidates for intrusion; too much traffic on a given port within a short time frame may indicate a potential attack. In this data set, all ports numbered 10000 or above were coded simply as “port 10000”.

Size of session

Internet traffic data are sent in “packets”. The “size” of an Internet session can be measured in several ways: duration (e.g., number of seconds), number of packets, and number of bytes. Typically, these numbers will be correlated, but not in any specific deterministic way. However, a machine may send many packets with few bytes, or rather fewer full-sized packets; either situation may signal a potential attack on a system.

Sample data

Internet traffic data are being collected at George Mason University; a sample of ten records from a data set over the course of one hour is shown in Table 1. Column 1 labeled `time` denotes the clock time (in number of seconds from an origin) at which the Internet session began; `duration` or `len` represents the duration or length of the session in seconds; `SIP` and `DIP` are the source and destination ports, respectively; `DPort` and `SPort` are the destination and source port numbers, respectively; and `Npacket` and `Nbyte` indicate the number of packets and number of bytes transferred in the session. In the plots below, the variable `time` is shifted by 39603 seconds and scaled by 1/60, so that the first session starts at 0.01067 minutes past the start of the hour, and the last session starts at 59.971 minutes past the start of the hour. Table 2 summarizes the distribution of the values in each column with the five-number summary [4] supplemented with the 10^{th} and 90^{th} percentiles for each column (minimum, lower 10%, lower fourth, median, upper fourth, upper 10%, maximum). The “size” variables are all very highly skewed towards the upper end; the distance between the 90th percentile and the maximum is 2–3 orders of magnitude greater than the distance from the 90th percentile to the minimum. One session involved over 35 million bytes, and almost 66,000 packets, although sessions of 1,832 bytes and 12 packets were more typical. The next section provides some displays of these data, with the objective of trying to characterize “typical” behavior, so that “atypical” behavior can be noted more readily.

3 Viewing Internet traffic data

Most features collected on Internet traffic data are highly skewed, as seen for the size variables. Thus, a plot of any pair of these variables has a very high density of points in the first quadrant near the origin. By selectively

"zooming in", or "drilling down" into this region, as one does on a geographical map, specific features can be better observed. An alternative to this "drill-down" approach (steps of power magnification) is a logarithmic transformation, which allows one to view the points by scanning *across* the screen rather than by magnifiying regions of the space. We describe this approach below.

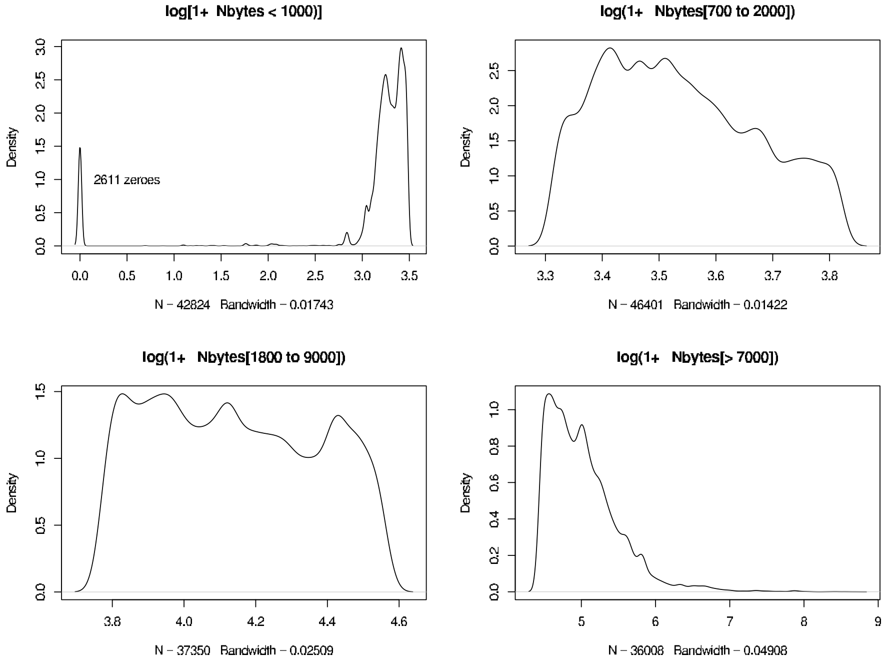

Figure 1: Kernel density estimates of $\log(1+\sqrt{Nbyte})$, four separate ranges.

Density plots

Figure 1 is a kernel density estimate [3] of `log.Nbyte` = `Nbyte*` = f(`Nbyte`), where $f(x) = \log(1+\sqrt{x})$. We use the transformation $f(x) = \log(1+\sqrt{x})$ for all three size variables to spread out their values (values of x near the low end of the scale are not spread out as far as they would be with the simple $\log(x)$ transformation; $f'(x) < 1/x$, much more so for small x). Likewise, `log.len` = f(`duration`) and `log.pkt` = f(`Npacket`). All calculations and graphs are made using the open-source software R, available from `http://www.cran.r-project.org`. A small peak at 0 reflects 2611 zeroes; the next largest byte size is 147. The data are clearly skewed, and local peaks of high density appear where `log.byte` $\approx$ 3.4, 3.8, 4.1, 4.5, and 5.1 (`Nbyte` $\approx$ 840, 1400, 3500, 8000, 26000).

Distributions of session size variables

Boxplots can be useful to display the relationship between two variables, as in Figure 2 for the two variables `log.len` = f(`duration`) (y-axis) and `log.byte` = f(`Nbyte`). The first box contains the 2911 values for which `Nbyte` is zero; the second box contains the next 1216 values where `Nbyte` ranges from 1 to 365 ($0 <$ `log.byte` ≤ 3); subsequent bins are 0.1 wide, except the last five bins. This display shows a relatively stable trend up until the last few bins, but is otherwise not very useful for outlier detection, since outliers are prevalent in each bin. The boxplot display does confirm general

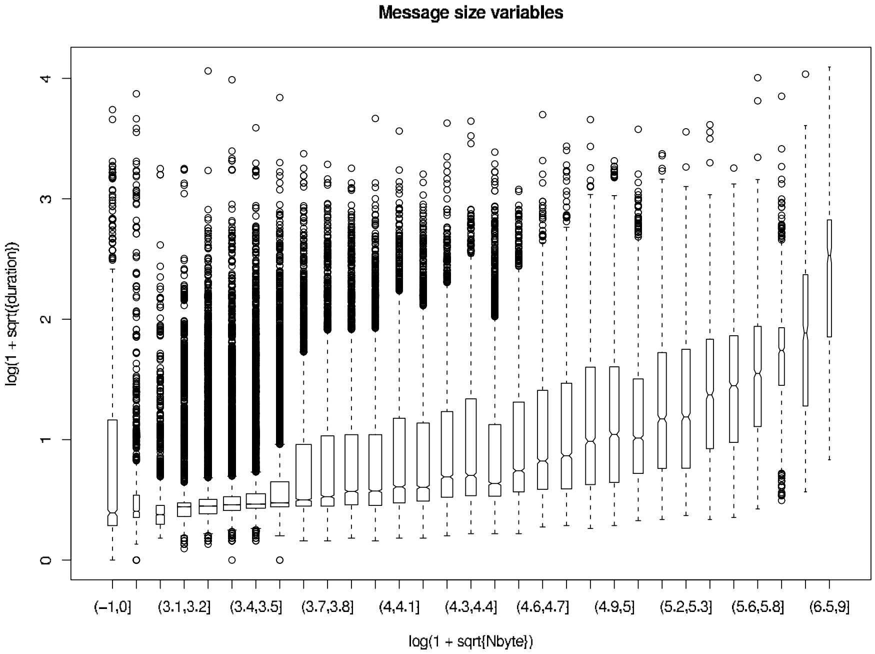

Figure 2: Boxplots of `log.duration` $= \log(1 + \sqrt{duration})$ vs `log.Nbyte` $= \log(1 + \sqrt{Nbyte})$.

trends: sessions with more bytes tend to last longer, and most sessions are short.

The preponderance of relatively short sessions can be seen in Figure 3(a), which displays the session durations as horizontal lines that extend from the start time to the end time. Because these sessions are reported in the order in which they began, the session start times range from time 0 (bottom line) to 59.971 (nearly the end of the hour). Figure 3(b) shows the same information, but each line is shifted back to 0. With continuously monitored data, the session duration lines would continue past the censoring point (illustrated as a red dotted line in Figure 3b). Relatively few sessions are “censored” (i.e., ended within the hour), reflecting the fact that most sessions are short: 93% of the sessions lasted less than 30 seconds. Figure 4 shows a barplot of the number of active sessions during each 30-second subset of this one-hour period (a time frame of 30 seconds is selected to minimize the correlation between counts in adjacent bars). The mean number of active sessions in any one 30-second interval during this hour is 923, with standard deviation 140, suggesting a rough upper “3-sigma limit” of 1343 sessions. [Because these numbers are *counts*, a square root transformation may be appropriate; see Tukey [4]. The mean and standard deviation of the square roots of the counts are 30.29 and 2.23, respectively, resulting in an approximate upper “3-sigma limit" of $(30.29 + 3 \cdot 2.23)^2 = 1367$, very close to the limit on the raw counts, since the Poisson distribution with a high mean is approximately Gaussian.] The maximum number of sessions in any one of these 120 30-second intervals is 1299, below the "3-sigma limit". This plot could be monitored continuously in time, dropping older bars off the left-side of the plot, and adding new bars on the right; the upper 3-sigma limit could depend upon hour, day, or week of the year.

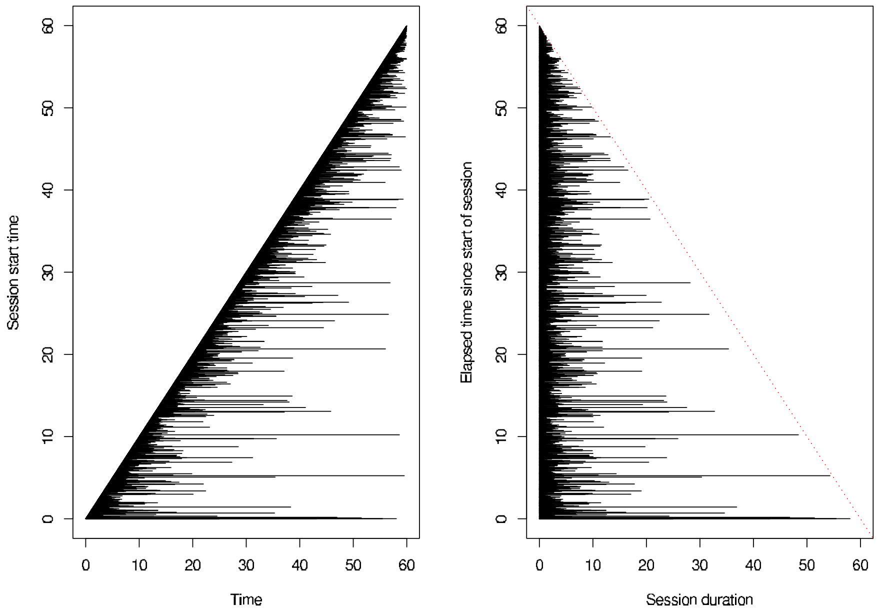

Figure 3: Session duration plot. Panel (a) displays the length of the session, starting at the actual start time. Panel (b), a shifted version of panel (a), displays the length of the session, starting at time 0.

Distribution of session duration by session start time can also be displayed as a scatter plot of points, (`time`, `duration`), as shown in Wegman and Marchette [7, p. 14]. Because the short sessions dominate this plot, Figure 5(a) shows this same plot, but using the log-transformed ordinate instead; i.e., (`time`, `log.len`). This plot shows a nearly straight line of points at `log.len` = 2.2685 between session start times of 23 to 57 minutes. Figure 5(b) expands this part of the plot and marks the identified points with red "+" symbols; they fall into two groups: an early group of 268 points (mean `duration` = 75.05 seconds), and a later group of 152 points (mean `duration` = 75.15 seconds). All 420 points are web sessions (destination port 80) and arise from a single source IP 65246, destination IP 45900, and source ports numbered 10000 or higher. A major challenge is the development of statistical "screening" algorithms to identify such "interesting" patterns in data

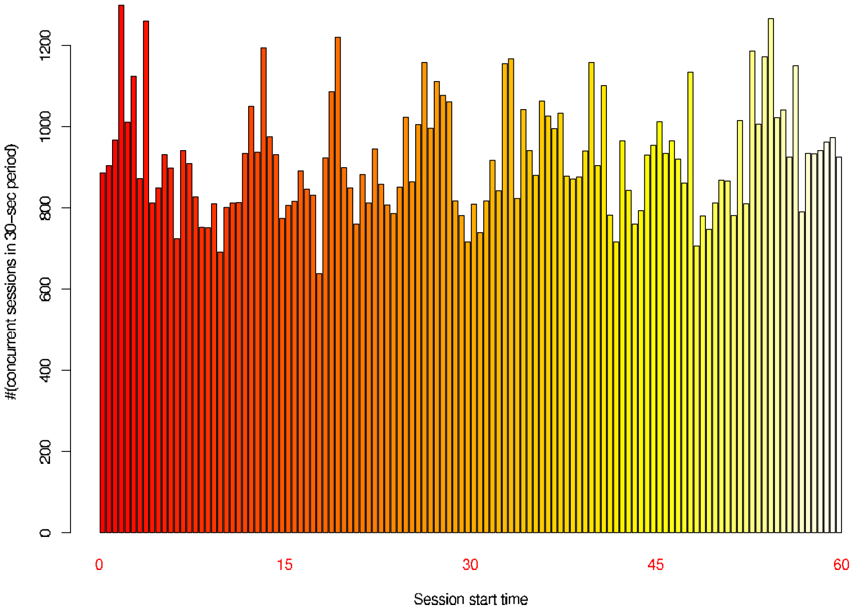

Figure 4: Barplot of the number of session in successive 30-second non-overlapping intervals during the hour (120 intervals). The mean number is 923 (standard deviation = 140), yielding an upper 3-sigma limit of approximately 1343. The maximum of these 120 counts is 1299.

plots such as this one, so that potential attacks to networks can be identified in real time. Since an infinite number of patterns can occur, a collection of likely patterns must be catalogued, so that statistical significance on their detection can be quantified. Algorithms that identify too many false negative patterns would result in an unnecessary number of shutdowns and service denials.

Relationships between pairs of size variables

Figure 6 shows a series of plots of the transformed `Nbyte` variable, `log.byte`, versus the transformed `Npacket` variable, `log.pkt` $= \log(1+\sqrt{Npacket})$, in four separate ranges. Panel (a), observations for which `log.pkt` is between 1 and 2 (`Npacket` between 3 and 40), shows a generally increasing trend, simplified in Panel (b) with boxplot displays (the labels in the x-axis are the same as those in panel (a), multiplied by 10). Panel (c) shows one line of 293 points around `log.pkt` $= 2.77$ (`Npacket` ≈ 226) and `log.byte` $=$ 5.82 (`Nbyte` $\approx$ 112,792) [all come from destination port 80 (web), source IP 23070, and destination IP 443 (`https`)]; and another set of 39 points around `log.pkt` $= 2.84$ (`Npacket` ≈ 259) and `log.byte` $= 5.64$ (`Nbyte` $\approx$ 78,341) [all have `SIP` 4837, `DIP` 56612, `DPort` 80]. Panels (c) and (d) show many points at high values of `log.pkt` along two lines with approximately unit slope but

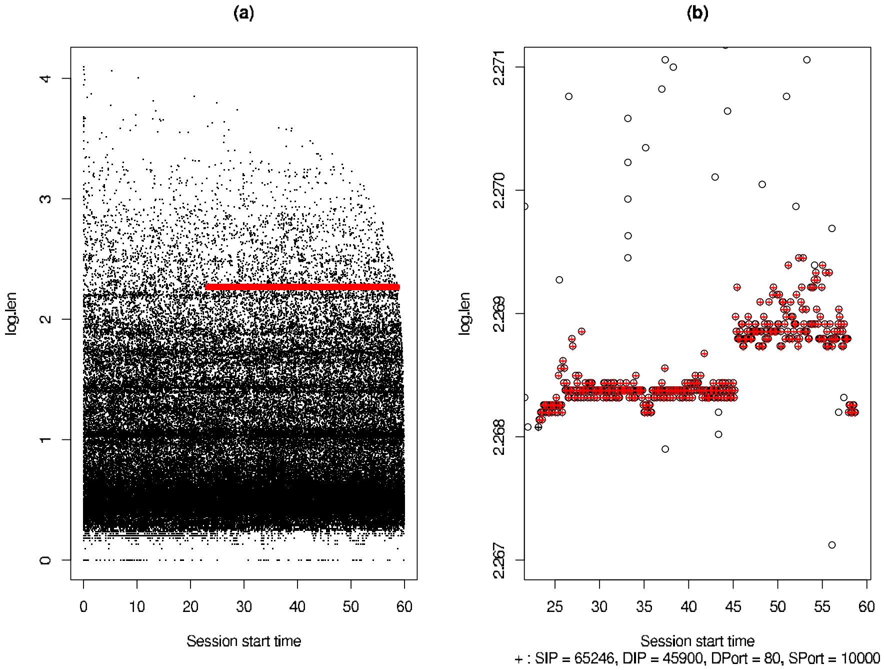

Figure 5: Plot of log-transformed `duration`, `log.len`, as a function of session start time. The left panel (all data) shows an almost perfectly horizontal line of points at `log.len` $= 2.2685$, between 23 and 57 minutes (expanded in the right panel).

with different intercepts; the upper set corresponds mainly to destination IP addresses 25 (smtp mail), 80 (web), and 443 (secure web); the lower set corresponds mostly to `DIP` 554 (rtsp). The dense set of 55 points points in Figure 6(d) ($3.4 <$ `log.pkt` < 3.8) lie near the line `log.byte` $= 3 +$ `log.pkt`, and 43 of them correspond to `DPort` 43. The extent to which such a pattern could occur by chance alone should be investigated.

The relationship between number of bytes, `NByte`, and session duration, `duration` is shown with plots of `log.byte` versus `log.len`, first for the entire data set (Figure 7), and then in 4 subranges defined by the intervals of `log.byte` and `log.len` (Figure 8). This approach to viewing the data can be considered as roughly equivalent to a “drill-down” approach, where all data are displayed in translated regions of the logged variables. Because longer sessions are associated with more bytes, and most sessions are short, plots of `log.byte` $= log(1+\sqrt{Nbyte})$ versus `log.len` $= log(1+\sqrt{duration})$ should be dense near the low end of each scale but much less dense near the upper end. In fact, the points in Figure 7 are especially dense around `log.len` $= 0.5$, then less dense until `log.len` $= 1.1$. Figure 7 also reveals

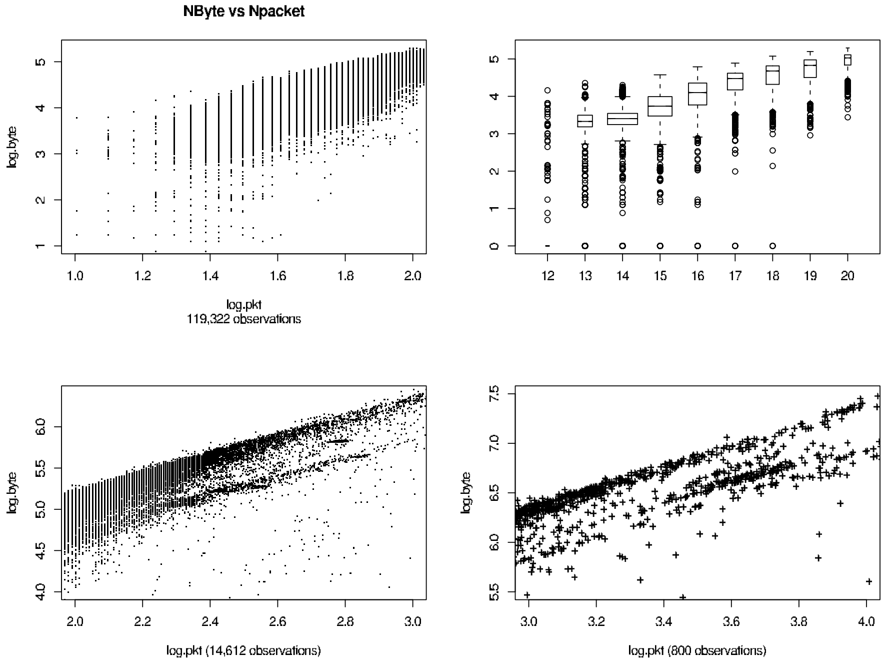

Figure 6: Plots of `log.byte` versus `log.pkt`, in 4 subranges of `log.pkt`.

a set of points in the upper right corner of the plot, 2.5 ≤ `log.len` ≤ 3, and 6 ≤ `log.byte` ≤ 7, which is discussed below in connection with Figure 9(c). Figure 8 shows three uncommonly straight lines of points: 377 points in Figures 8(a), in the region where 1.17 ≤ `log.len` ≤ 1.27 and `log.byte` ≈ 5.0; 292 points in Figure 8(b), where 1.69 ≤ `log.len` ≤ 1.79 and `log.byte` ≈ 5.8; and 60 points in Figure 8(d), where 2.7 ≤ `log.len` ≤ 2.9 and `log.byte` increases from 6.4 to 7. The points in these sets of lines have in common (1) `SIP` = 1681, `SPort` = 10000, `DPort` = 25 (smtp mail) (recall that `SPort` 10000 actually refers to all source ports numbered 10000 or higher); (2) `SIP` = 23070, `DIP` = 336, `DPort` = 80 (web); and (3) `DPort` = 554 (rtsp), `SPort` = 1276 to 2070. For a given session, initial ports are assigned at random, but subsequent ones are assigned by an incrementing pattern characteristic of the operating system. Hence, a string of `SPort` numbers may signal a potential attacker seeking information about operating system to invade.

Stratification by groups of destination ports

This hour of Internet activity involved 380 unique destination ports (Table 2). `DPort` 80 (web) is the most common, comprising 116,134 of the 135,605 records. The next most common destination port is `DPort` 443 (secure web `https`), utilized 11,627 times, followed by `DPort` 25 (mail SMTP) accessed 6,186 times. Ports 554 (rtsp), 113, 10000 (or higher), 8888 occur 200, 128, 97, 94 times, respectively. Twelve destination port numbers during

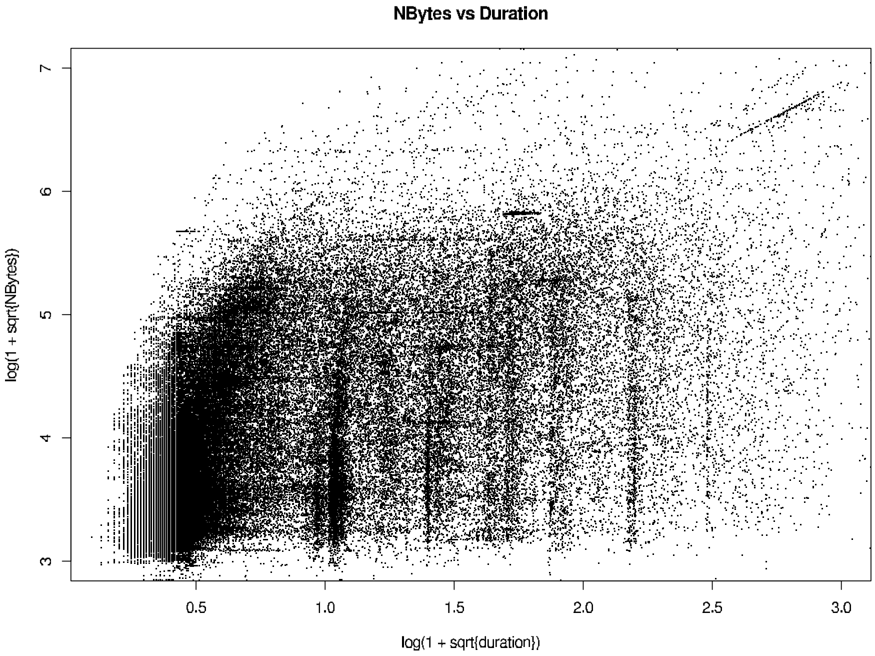

Figure 7: `log.byte` versus `log.duration`.

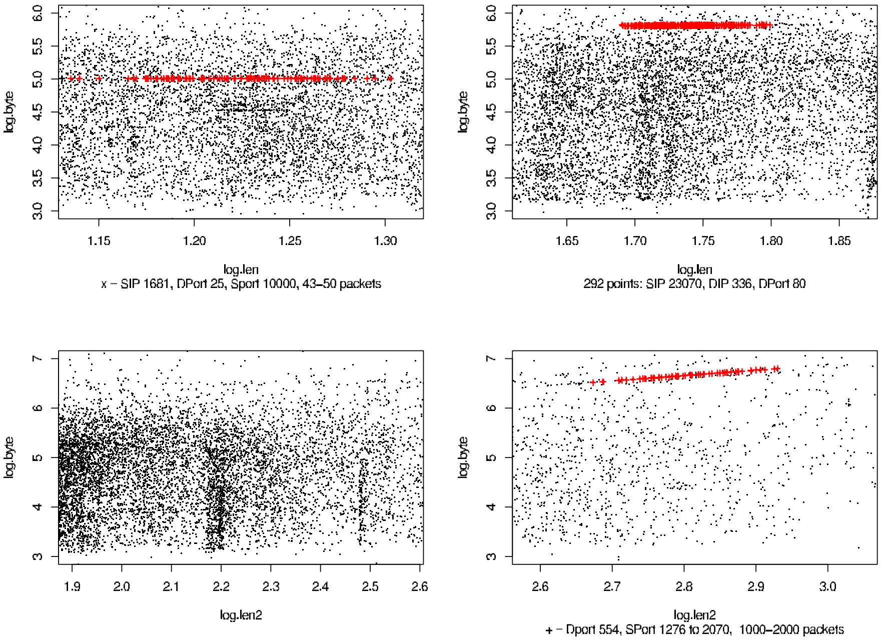

Figure 8: `log.byte` versus `log.duration`, 4 subranges.

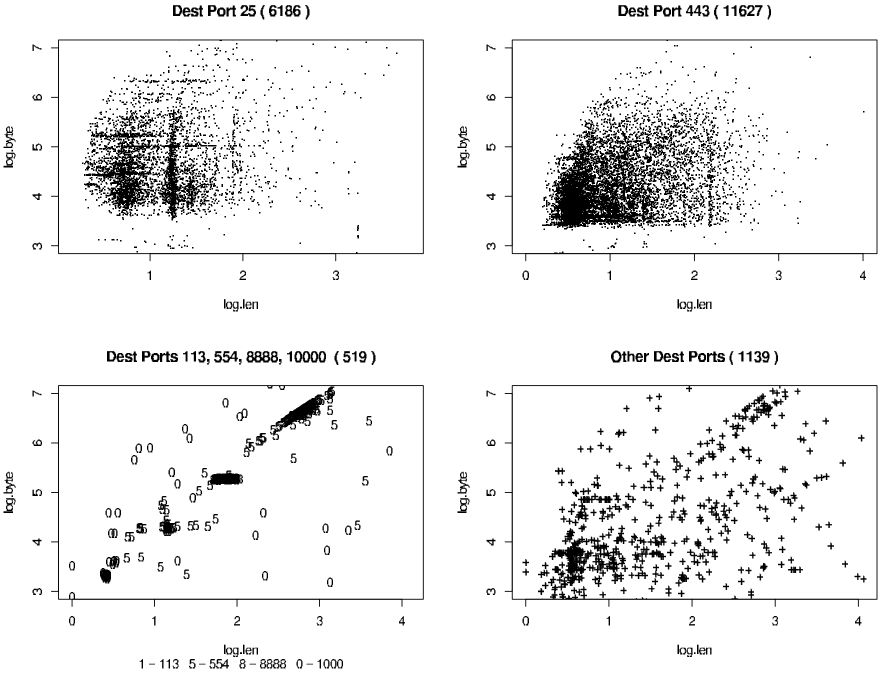

Figure 9: `log.byte` vs `log.len` for other destination ports.

this hour occurred between 5 and 29 times in the file; 5 ports occurred only 4 times, 8 occurred only 3 times, 47 destination ports occurred only twice, and 293 destination ports occurred only once. Displaying all 135,605 points on one plot is not very informative, so instead we subdivide the session records into groups according to their destination ports. Because over 85% of these data are web sessions (`DPort` = 80), a plot of `log.byte` versus `log.len` for only the web sessions looks like Figure 7 (all data). Figure 9 are scatterplots of two variables, conditioned on values of a third (non-web `DPorts`): `DPort` 25 (smtp mail) in panel (a); 443 (`https`) in panel (b); 113, 554, 8888, 10000 in panel (c), and the remaining 310 destination ports in panel (d). Panel (c) shows that the line of points in the upper right corner of Figure 7 arises from sessions with `DPort` 554 (rtsp), and that the sessions from `DPort` 8888 occur in a small cluster near `log.len` = 2 and `log.byte` = 5. Forty of the 52 points in the upper right corner of Figure 9(d), where `log.byte` $\approx 4 +$ 0.5 `log.len`, correspond to `DPort` numbers 119 and 1755, but are otherwise unrelated (some "patterns" can be spurious).

Monitoring frequency of source IP addresses

These same plots can be constructed when the data are subsetted by source IP address (`SIP`), as opposed to destination port number (`DPort`). The number of source IP addresses that may be active during a given hour

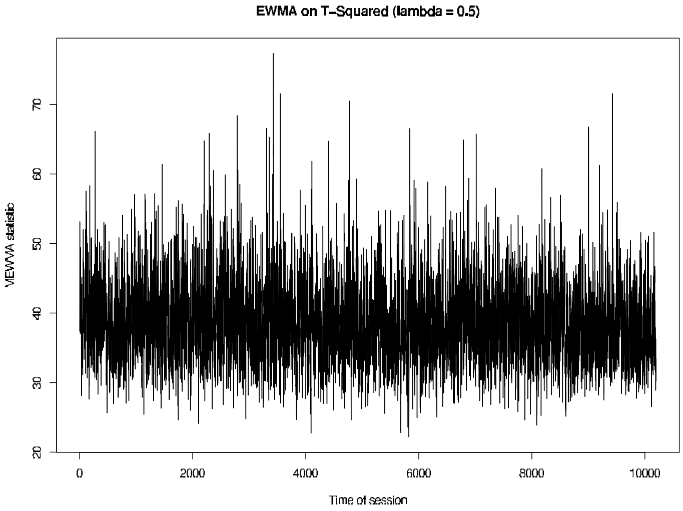

Figure 10: Multivariate EWMA plot of Hotelling's T^2, last 10,000 values.

of activity is likely to be very much higher than the number of destination ports; in this data set, only 380 unique destination ports were accessed, versus 3548 unique source ports. A plot of `log.Nbyte` versus `log.len` shows clumps of observations for certain source IP addresses, often because they correspond to heavy web traffic.

Multivariate charts

The three session "size" variables, `log.len, log.pkt, log.byte`, being somewhat correlated, are amenable to a "control chart' where the statistic being plotted is a weighted linear combination of the previously plotted variable (λ) and the current value of Hotelling's T^2 statistic $(1 - \lambda)$. Vardeman and Jobe (1999) provide tables for the optimal choices of λ. Calculating a Hotelling's T^2 statistic on three successive observations, denoted H_t, a multivariate exponentially weighted moving average (MEWMA) chart using λ = 0.5 is shown in Figure 10 (last 10,202 observations only). Most values (99.7%) are below 60; a successive run of observations above 60 might suggest abnormal session sizes. To minimize the effect of outliers on Hotelling's T^2 statistic, location and scale are estimated using medians and trimmed standard deviations instead of classical sample means and standard deviations (SDs). The SDs were estimated as 1.85, 0.34, 0.74, and the pairwise correlations are 0.53 (`log.len, log.pkt`), 0.56 (`log.len, log.pkt`), 0.90 (`log.pkt, log.byte`).

4 Evolutionary displays

Wegman and Marchette [6] advocate a new approach to visualizing massive data sets, called "evolutionary displays." Massive data sets are too large to display using graphs and plots that are designed for moderate data sets of

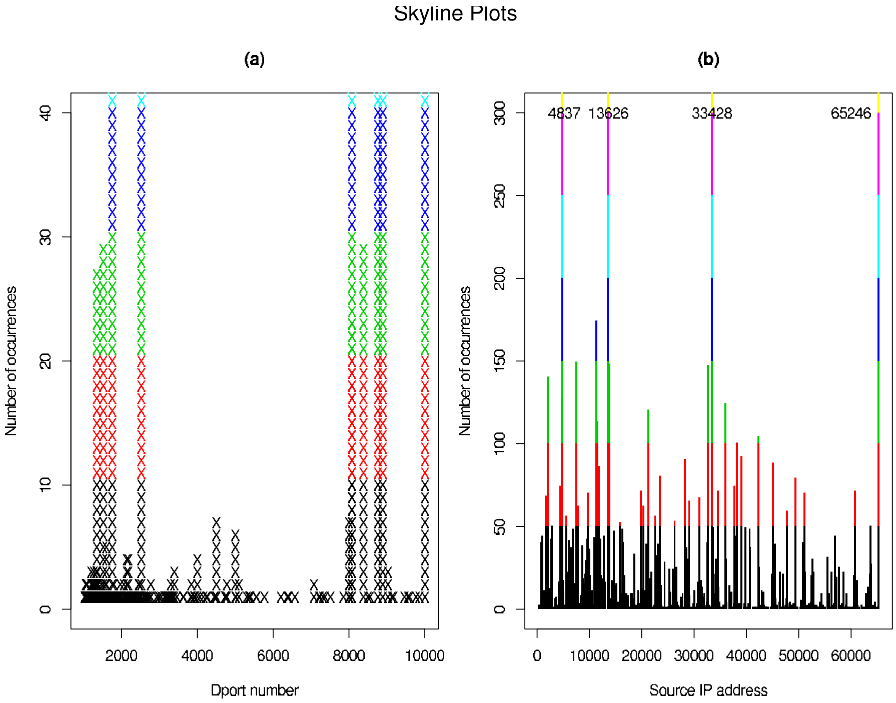

Figure 11: Skyline plots. (a): DPort access; (b): Source IP access.

fixed size. The concept behind evolutionary displays is to exhibit data within the most current time frame, dropping off old data and making room for most recent data. For example, in Figure 10, new data come in on the right as old data on the left are pushed off the screen. Wegman and Marchette [6, p. 906, Figure 4] use this concept to define a waterfall display, useful for monitoring frequency of source ports.

Skyline plots

Most destination port numbers occur only once or twice during the hour; of the 380 distinct DPorts, 293 occurred only once, 47 occurred twice, 8 occurred 3 times, 5 occurred 4 times. The remaining 27 ports occurred over 4 times; the top five are DPort 80 (web, 116,134 times), 25 (mail-smtp, 6,186 times), 443 (secure web, 11,627), 554 (rtsp; 200 times), and 113 (128 times). Setting aside the “well-known” ports 0–1023, we plot the occurrence of destination ports numbered 1024 and above, which should arise more or less at random, and flag as unusual any DPort that is referenced over 10 times. Figure 11 shows two such plots; one for DPort (color changes indicate DPort access counts greater than 10, indicative of potentially high traffic on this destination port), and one for SIP in the first 10,000 session records (color changes indicate SIP occurrences of more than 50). Four unusually frequent source IP addresses are immediately evident: 4837, 13626, 33428,and 65246, which occur 371, 422, 479, and 926 times, respectively, in the first 10,000 sessions. The construction of this plot resembles the tracing of a skyline, so we call it a “skyline plot.” Limits on skyline plots may depend upon time of day, day of week, month, or season.

5 Summary and further work

This article has highlighted several of the challenges that arise in analyzing and displaying massive data sets. Some simple statisitics based on robust quantities are useful for characterizing typical behavior (e.g., number of source and destination ports, and source and destination IP addresses, and frequency of access). These characterizations suggest graphical displays which highlight unusual usage or access. We discussed the role of “evolutionary graphics” on such data, specifically the use of “waterfall diagrams”, and proposed “skyline plots” as a means of monitoring ports and IP addresses. Future work will include massive data sets from Internet sessions and other fields.

COMPSTAT'2004 Symposium

CLUSTERING ALL THREE MODES OF THREE-MODE DATA: COMPUTATIONAL POSSIBILITIES AND PROBLEMS

Henk A.L. Kiers

Key words: Cluster analysis, multiway analysis.

COMPSTAT 2004 section: Clustering.

Abstract: For the analysis of three-mode data sets (i.e., data sets pertaining to three different sets of entities) various component analysis techniques are available. These yield components that are summaries of the entities of each mode. Because such components are often interpreted in a more or less binary way in terms of the entities related strongest to them, it seems logical to actually constrain these components to have binary values only. In the present paper, such constrained models are proposed and algorithms for fitting these models are provided. In one of these variants, the components are constrained such that they correspond to nonoverlapping clusters of entities. Finally, a procedure is proposed for steering component values towards binary values, without actually imposing them to be binary, using penalties.

1 Analysis of three-mode data

Three-mode data sets are data sets pertaining to three different sets of entities. An example of a three-mode data set is a set of scores of a number of individuals, on a number of variables, each obtained under a number of different conditions. For the analysis of three-mode data, various exploratory three-way methods are available. The two most common methods for the analysis of three-mode data are CANDECOMP/PARAFAC [1], [6] and Tucker3 analysis [16], [10]. Both methods summarize the data by components for all three modes, and for the entities pertaining to each mode they yield component weights; in the case of Tucker3 analysis, in addition a so-called core array is given, which relates the components for all three modes to each other.

If we denote our $I \times J \times K$ three-mode data array by $\underline{\boldsymbol{X}}$, then the two methods can be described as fitting the model

$$x_{ijk} = \sum_{p=1}^{P} \sum_{q=1}^{Q} \sum_{r=1}^{R} a_{ip} b_{jq} c_{kr} g_{pqr} + e_{ijk} \,, \tag{1}$$

where a_{ip}, b_{jq} and c_{kr} are referred to as the component weights, which are elements of the component matrices $\boldsymbol{A}$ (for mode A), $\boldsymbol{B}$ (for mode B), and $\boldsymbol{C}$ (for mode C), of orders $I \times P$, $J \times Q$, and $K \times R$, respectively; g_{pqr} denotes the element (p,q,r) of the $P \times Q \times R$ core array $\underline{\boldsymbol{G}}$, and e_{ijk} denotes the error term for element x_{ijk}; P, Q, and R denote the numbers of components for the three respective modes. The difference between CANDECOMP/PARAFAC and Tucker3 analysis is that in CANDECOMP/PARAFAC the core is actually set equal to a superidentity array (i.e., $g_{pqr} = 1$ if $p = q = r$, $g_{pqr} = 0$ otherwise). As a consequence, in the case of CANDECOMP/PARAFAC, for all modes we have the same number of components, and (1) actually reduces to

$$x_{ijk} = \sum_{r=1}^{R} a_{ir} b_{jr} c_{kr} + e_{ijk} \tag{2}$$

Clearly, when these models are fitted to data, we end up with component matrices $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$, and, in the case of Tucker3 analysis, we also get a three-mode core array $\underline{\boldsymbol{G}}$ as outcome of the analysis.

The result of a three-mode analysis is a summary of the observation units, the variables and the conditions by means of a number of components, and possibly a core array describing the relations between them. The componentwise interpretation, however, is not very easy, because it requires one to think in dimensions along which the observation units, variables or conditions vary. Here the component weights indicate to *what extent*, for instance, the individuals can be described by the property defined by the component. Likewise, variables are related to the components for the variables to different extents. Now the interpretation of the components usually proceeds conversely: From the strengths of the relations of the variables to the components, one can interpret the meaning of the components. This interpretation is rather cumbersome if one discriminates precisely between different strengths of relations. Therefore, in practice, one tends to interpret components on the basis of the variables related strongest to it, and one tends to ignore the less related variables. In fact, thus one binarizes the relations, in sufficiently strong, and not sufficiently strong. Thus one could say that the components are interpreted as if they refer to clusters of variables consisting of those variables that have the strongest relations with them. Similar cluster based interpretations can be given to components describing individuals and conditions, if *a priori* information on the individuals and conditions is available. To enhance the interpretability of the component matrices, they are often subjected to simple structure rotations such as varimax [7], see also [8], but the clusters will always remain somewhat fuzzy (i.e., relations are never entirely binarized).

Now if, in practice, components tend to be interpreted as clusters, then would not it seem more rational to model data in terms of cluster membership, and discard the information on strengths of relations? The idea of clustering all three modes simultaneously has been pursued by various authors. Clustering approaches involving the CANDECOMP/PARAFAC model have been proposed by Chaturvedi and Carroll [3] and Leenen et al. [11], where the latter authors use Boolean products rather than ordinary products. An extension of the latter Boolean model to the Tucker3 situation, has been proposed by Ceulemans, van Mechelen and Leenen [2].

Surprisingly, except for a recent paper by Rocci and Vichi [13], straightforward (non-Boolean) generalizations of the Tucker3 model do not seem to have received attention yet, and no algorithms seem to have been published for handling this case. The present paper, therefore, focuses on that particular case. The models described here are in fact three-mode generalizations of the GENNCLUS model [4], [5] PENNCLUS, and the Double k-means clustering model by Vichi [17].

2 Clustering variants of the Tucker3 model

As has been mentioned above, in the Tucker3 model the elements of the component matrices are, in practice, often interpreted in a more or less binary way. That is, when interpreting a component for, say, the variables, for each variable it is specified whether it is associated with the component or not. Thus, a Tucker3 model that fully complies with this binary way of interpretation would simply have binary component weights for the variables: 1 for the variables associated with a component, and 0 for those not associated with the component. In fact, one might want to specify the strength of the association by a value different than 1, but if the same value is used for all variables related to a component, then one can always scale such values to 1 anyway. Therefore, it is here proposed to constrain the elements of each component matrix to be binary, that is to be equal to 0 or 1.

When all elements of the component matrices are binary, one could say that the components refer to clusters of, for example, variables. Without further constraints, such clusters may very well overlap, in the sense that some entities are associated with more than one cluster. The overlap of clusters is nonproblematic for the interpretation of the clusters themselves, but does make the overall model relatively difficult to interpret. Therefore, it can be attractive to impose a further constraint, namely the constraint that clusters do not overlap. Specifically, this constraint implies that each entity is assigned to one and only one cluster.

Models for these two constrained variants of the Tucker3 model are described below, and it is also indicated how this model can be fitted to data. In the next section, algorithms for actually carrying out such fitting procedures are given.

2.1 Tucker3 with overlapping clusters

The Tucker3 model with overlapping clusters is defined as the model

$$x_{ijk} = \sum_{p=1}^{P} \sum_{q=1}^{Q} \sum_{r=1}^{R} a_{ip} b_{jq} c_{kr} g_{pqr} + e_{ijk} \,, \tag{3}$$

where a_{ip}, b_{jq}, and c_{kr} are constrained to be binary (0 or 1). To avoid summation notation, we write the above model in terms of matrices as follows

$$\boldsymbol{X}_a = \boldsymbol{A}\boldsymbol{G}_a(\boldsymbol{C}' \otimes \boldsymbol{B}') + \boldsymbol{E}_a \,, \tag{4}$$

where $\boldsymbol{X}_a$, $\boldsymbol{G}_a$, and $\boldsymbol{E}_a$ denote the A-mode matricized versions of the three-way arrays $\underline{\boldsymbol{X}}$, $\underline{\boldsymbol{G}}$, and $\underline{\boldsymbol{E}}$ (i.e., the matrices obtained upon putting the frontal slabs next to each other, see [9], and $\otimes$ denotes the Kronecker product. To fit this model to an empirical data set, it is proposed here to minimize the sum of squared residuals, hence to minimize

$$f(\boldsymbol{A},\boldsymbol{B},\boldsymbol{C},\underline{\boldsymbol{G}}) = \|\boldsymbol{X}_a - \boldsymbol{A}\boldsymbol{G}_a(\boldsymbol{C}' \otimes \boldsymbol{B}')\|^2 \,, \tag{5}$$

over $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and $\underline{\boldsymbol{G}}$, subject to the constraint that the elements of $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$ are binary. Note that the core array is left fully unconstrained.

It is well known that the Tucker3 model is not unique. That is, nonsingular transformations of the component matrices can be compensated by the inverse transformations in the core, and thus do not affect the model estimates. For example, suppose we transform $\boldsymbol{A}$ by multiplying it by a nonsingular matrix $\boldsymbol{S}$, premultiplying $\boldsymbol{G}_a$ by $\boldsymbol{S}^{-1}$ yields exactly the same model estimates since $(\boldsymbol{A}\boldsymbol{S})(\boldsymbol{S}^{-1}\boldsymbol{G}_a)(\boldsymbol{C}' \otimes \boldsymbol{B}') = \boldsymbol{A}\boldsymbol{G}_a(\boldsymbol{C}' \otimes \boldsymbol{B}')$. In the case of binary constraints, this nonuniqueness is limited to those cases where nonsingular transformations do not affect the binary constraint. This is possible when there are columns in, for instance, matrix $\boldsymbol{A}$ that do not overlap: upon replacing one such column by the sum of such columns, the binary constraint will still be satisfied. Specifically, suppose $\boldsymbol{A}$ has only two columns that do not overlap (i.e., do not have unit elements at the same position), then replacing the second by the sum of the two comes down to postmultiplying $\boldsymbol{A}$ by the nonsingular matrix $S = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$. Clearly, then $\boldsymbol{A}\boldsymbol{S}$ satisfies the binary constraint, and upon replacing $\boldsymbol{A}$ by $\boldsymbol{A}\boldsymbol{S}$, and $\boldsymbol{G}_a$ by $(\boldsymbol{S}^{-1}\boldsymbol{G}_a)$ we get the same estimates as with $\boldsymbol{A}$ and $\boldsymbol{G}_a$. Similar nonuniquenesses can be identified upon describing model (3) using B- or C-mode matricized versions as

$$\boldsymbol{X}_b = \boldsymbol{B}\boldsymbol{G}_b(\boldsymbol{A}' \otimes \boldsymbol{C}') + \boldsymbol{E}_b \,, \tag{6}$$

and

$$\boldsymbol{X}_c = \boldsymbol{C}\boldsymbol{G}_c(\boldsymbol{B}' \otimes \boldsymbol{A}') + \boldsymbol{E}_c \,, \tag{7}$$

where subscripts b and c indicate B- and C-mode matricized versions of the three-way arrays at hand, which are obtained by other ways of positioning slices of the three-way arrays next to each other, see Kiers [9].

2.2 Tucker3 with nonoverlapping clusters

The Tucker3 model with nonoverlapping clusters is the same model as that for overlapping clusters described above, in Section 2.1, with the *additional constraint* on the matrices $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$ that in all rows one and only one element is 1, and all others are 0. The procedure to fit this model is hence to minimize (5) over $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and $\underline{\boldsymbol{G}}$, subject to the constraint that the elements of $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$ are binary with exactly one unit element in each row. As a consequence of the minimization subject to these constraints, the core array now will contain the within cluster average scores in $\underline{\boldsymbol{X}}$, hence the core effectively summarizes the data in such a way that it gives the average score of the individuals in each cluster, averaged across the variables associated to the variable cluster at hand, and averaged across conditions associated with the condition cluster at hand. When the clusters can be interpreted well, then the core has a very easy interpretation too, simply in terms of 'cluster scores'.

3 Algorithm for Tucker3 with overlapping clusters

As mentioned in Section 2.1, fitting the Tucker3 model with overlapping clusters comes down to minimizing (5) over $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and $\underline{\boldsymbol{G}}$, subject to the constraint that the elements of $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$ are binary. To find solutions for this minimization problem, it is proposed here to use an alternating least squares algorithm, which, starting from initial values for $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and $\underline{\boldsymbol{G}}$, finds updates for $\boldsymbol{A}$ keeping the other matrices fixed, then for $\boldsymbol{B}$ keeping the other matrices fixed, next for $\boldsymbol{C}$ keeping the other matrices fixed, and finally for $\underline{\boldsymbol{G}}$ keeping the other matrices fixed. After one complete cycle, the function value is evaluated, and if it has decreased considerably, a new cycle is started. This process is repeated until the function value changes no longer. Each update is found such that it decreases the function value, or, at least does not increase the function value. Because the function value is bounded below by 0, it is thus guaranteed to converge to a stable value.

3.1 Updating procedures

The choice for initial values for $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and $\underline{\boldsymbol{G}}$ will be discussed later. Given that such values are available, the first step is to find improved values for $\boldsymbol{A}$, keeping the other matrices fixed. Hence the problem is to minimize

$$g(\boldsymbol{A}) = \|\boldsymbol{X}_a - \boldsymbol{A}\boldsymbol{F}\|^2 \,, \tag{8}$$

where $\boldsymbol{F}$ is written for $\boldsymbol{G}_a(\boldsymbol{C}' \otimes \boldsymbol{B}')$. Now the columns of $\boldsymbol{A}$ are updated column after column, keeping the other columns of $\boldsymbol{A}$ fixed. Specifically, to update column j of $\boldsymbol{A}$, we find the minimum of

$$g(\boldsymbol{a}_j) = \left\| \boldsymbol{X}_a - \sum_{l \neq j} {}_l \boldsymbol{f}'_l - \boldsymbol{a}_j \boldsymbol{f}'_j \right\|^2 = \|\boldsymbol{X}_{-j} - \boldsymbol{a}_j \boldsymbol{f}'_j\|^2 \,, \tag{9}$$

where $\boldsymbol{X}_{-j}$ is written for $\boldsymbol{X}_a - \sum_{l \neq j} \boldsymbol{a}_l \boldsymbol{f}'_l$, $\boldsymbol{a}_j$ denotes the jth column of $\boldsymbol{A}$, and $\boldsymbol{f}'_j$ denotes the jth row of $\boldsymbol{F}$. A solution for minimizing (9) is given by Chaturvedi and Carroll [3]. A computationally slightly different procedure (with the same solution) can be derived as follows. Function (9) can be written as the sum of independent functions elaborated as

$$\begin{aligned} g(a_{ij}) &= \text{constant} - 2a_{ij}(\boldsymbol{X}_{-j}\boldsymbol{f}_j)_i + a_{ij}^2\boldsymbol{f}_j'\boldsymbol{f}_j \\ &= \text{constant} + (\boldsymbol{f}_j'\boldsymbol{f}_j - 2(\boldsymbol{X}_{-j}\boldsymbol{f}_j)_i)_{aij}, \quad i = 1, \ldots, I, \qquad (10) \end{aligned}$$

where in the second line it is used that $a_{ij}^2 = a_{ij}$ because each element of $\boldsymbol{A}$ is constrained to be binary. Each of the functions $g(a_{ij})$ is now minimized over binary a_{ij} by taking $a_{ij} = 0$ if $(\boldsymbol{f}_j'\boldsymbol{f}_j - 2(\boldsymbol{X}_{-j}\boldsymbol{f}_j)_i) > 0$, and $a_{ij} = 1$ if $(\boldsymbol{f}_j'\boldsymbol{f}_j - 2(\boldsymbol{X}_{-j}\boldsymbol{f}_j)_i) \leq 0$, hence

$$\begin{aligned} a_{ij} = 0 &\quad \text{if } 2(\boldsymbol{X}_{-j}\boldsymbol{f}_j)_i) < \boldsymbol{f}_j'\boldsymbol{f}_j \\ a_{ij} = 1 &\quad \text{if } 2(\boldsymbol{X}_{-j}\boldsymbol{f}_j)_i) \geq \boldsymbol{f}_j'\boldsymbol{f}_j \quad i = 1, \ldots, I\,. \qquad (11) \end{aligned}$$

In practice, it may happen that all elements of column j become zero by the above updates of the elements of column j. This would imply that the Tucker3 model would not use the jth A-mode component. Hence all core elements related to this component (in the jth row of $\boldsymbol{G}_a$), and therefore also the elements in the jth row of $\boldsymbol{F}$, do not have any contribution to fitting the data; in other words, then the term $\boldsymbol{a}_j\boldsymbol{f}_j' = 0$. However, in practice, this will almost never be the optimal solution for $\boldsymbol{a}_j\boldsymbol{f}_j'$, since it would imply that no contribution is better than any conceivable contribution. Furthermore, zero columns in A will cause computational problems later on in the algorithm. Therefore, whenever $\boldsymbol{a}_j = 0$, a special fixing procedure seems in order. Here we use the following. If $\boldsymbol{a}_j = 0$, first the jth row of $\boldsymbol{G}_a$ and hence also the jth row of $\boldsymbol{F}$, is multiplied by -1. This does not affect the fit, because when $\boldsymbol{a}_j\boldsymbol{f}_j' = 0$, then also $\boldsymbol{a}_j(-\boldsymbol{f}_j') = 0$. Next, $\boldsymbol{a}_j$ is updated again according to (11), and this is used as the update for $\boldsymbol{a}_j$. If it so happens that the updated $\boldsymbol{a}_j$ again is a vector with zeros only, then $\boldsymbol{a}_j$ is set back to its original values before updating column j, and likewise the core is set back to its original values.

To update matrix $\boldsymbol{B}$, a completely analogous procedure is followed. Specifically, noting that (4) has equivalently been written as (6) $\boldsymbol{X}_b = \boldsymbol{B}\boldsymbol{G}_b(\boldsymbol{A}' \otimes \boldsymbol{C}') + \boldsymbol{E}_b$, it can be seen that using this version of the model, the process of updating $\boldsymbol{B}$ is the same as that described for $\boldsymbol{A}$ above, after replacing $\boldsymbol{A}$ by $\boldsymbol{B}$, $\boldsymbol{B}$ by $\boldsymbol{C}$, $\boldsymbol{C}$ by $\boldsymbol{A}$, and $\boldsymbol{G}_a$ by $\boldsymbol{G}_b$ in the above description. Likewise, updating matrix $\boldsymbol{C}$ can be carried out by using the procedure for updating $\boldsymbol{A}$, after replacing $\boldsymbol{A}$ by $\boldsymbol{C}$, $\boldsymbol{B}$ by $\boldsymbol{A}$, $\boldsymbol{C}$ by $\boldsymbol{B}$, and $\boldsymbol{G}_a$ by $\boldsymbol{G}_c$ in the above description.

Finally updating the core array can be carried out as follows. The problem now is to minimize

$$g(\underline{\boldsymbol{G}}) = \|\boldsymbol{X}_a - \boldsymbol{A}\boldsymbol{G}_a(\boldsymbol{C}' \otimes \boldsymbol{B}')\|^2 \qquad (12)$$

over $\underline{\boldsymbol{G}}$, which in A-mode matricized form is written as $\boldsymbol{G}_a$. Because there is no constraint on $\boldsymbol{G}_a$, the solution to this problem is given by

$$\begin{aligned} \boldsymbol{G}_a &= (\boldsymbol{A}'\boldsymbol{A})^{-1}\boldsymbol{A}'\boldsymbol{X}_a(\boldsymbol{C} \otimes \boldsymbol{B})(\boldsymbol{C}'\boldsymbol{C} \otimes \boldsymbol{B}'\boldsymbol{B})^{-1} \\ &= (\boldsymbol{A}'\boldsymbol{A})^{-1}\boldsymbol{A}'\boldsymbol{X}_a(\boldsymbol{C}(\boldsymbol{C}'\boldsymbol{C})^{-1} \otimes \boldsymbol{B}(\boldsymbol{B}'\boldsymbol{B})^{-1}) \qquad (13) \end{aligned}$$

see [12], see also [15]. Note that, if the inverses do not exist (as may come about when any of the component matrices has incomplete rank) then the inverse is replaced by a generalized inverse.

The above described steps for updating $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and $\underline{\boldsymbol{G}}$ are followed by the computation of the loss function value. If this has decreased, then a new cycle of updatings is started; if it has remained the same, then the ensuing solution is considered a candidate for the minimum of the loss function. Depending on how the procedure is started, this may be a local minimum of the function rather than the global minimum. It is therefore recommended to run the algorithm from several starts. One approach is to start from (very) many random starts, hoping thus to cover a wide range of (at least) locally optimal solutions for which the chance that it contains the global minimum is high. Alternatively, or in addition, one may use a few starts that can be expected to have a high chance to lead to the global minimum. A suggestion for such 'rational' starts is given in the next subsection.

3.2 Rational starts

Because the algorithm described above very easily leads to local optima, it is important to run the algorithm from various different starts, among which preferably are starts that have a high chance of leading to the global optimum. Experience so far has indicated that a useful starting configuration can be obtained as follows. First, analyze the data by ordinary Tucker3 analysis, leading to columnwise orthonormal component matrices. Next rotate all three component matrices by means of varimax, and multiply all columns that have a negative sum of elements by -1. Then one starting configuration is obtained by setting all values that are higher than their column average to 1 and all others to 0. An alternative is to set, for each matrix, all values above a particular threshold to 1, and all others to 0. The threshold should depend on the number of elements in the component matrix at hand, and it can be varied systematically to yield different starts. By systematically varying the threshold value for $\boldsymbol{A}$ between $I^{-1/2}$ and 0 (not including 0), different starts can be obtained, which in practice seem to lead to at least reasonably good solutions; likewise for $\boldsymbol{B}$ the threshold is to be chosen between $J^{-1/2}$ and 0, and for $\boldsymbol{C}$ the threshold is to be chosen between $K^{-1/2}$ and 0. More experience is needed, however, to evaluate the usefulness of these starts.

4 Algorithm for Tucker3 with nonoverlapping clusters

To fit the Tucker3 model with nonoverlapping clusters comes down to minimizing (5) over $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and $\underline{\boldsymbol{G}}$, but now subject to the constraint that the elements of $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$ are binary, and that each row of these matrices has one and only one unit element. To find solutions for this minimization problem, it is proposed to use an alternating least squares algorithm similar in set up to that for the overlapping clusters situation. The updates for the component matrices $\boldsymbol{A}$, $\boldsymbol{B}$, and $\boldsymbol{C}$ are, obviously, different, while the update for the core is the same, but its computation can now be simplified somewhat. This is because the inverses in the updating formula (13) are now very easy to compute, because, due to the constraints on the component matrices, $\boldsymbol{A}'\boldsymbol{A}$, $\boldsymbol{B}'\boldsymbol{B}$, and $\boldsymbol{C}'\boldsymbol{C}$ now are diagonal matrices with on the diagonal simply the number of unit elements in the corresponding columns of the component matrices.

Below only the updating procedure for $\boldsymbol{A}$ is described. Those for $\boldsymbol{B}$ and $\boldsymbol{C}$ are obtained analogously, after letting the component matrices switch roles (compare Section 3.1), and the update for the core does not need further description.

4.1 Updating procedure for $\boldsymbol{A}$

To update $\boldsymbol{A}$ subject to the constraints at hand, we now minimize

$$g(\boldsymbol{A}) = \|\boldsymbol{X}_a - \boldsymbol{A}\boldsymbol{F}\|^2 , \tag{14}$$

over $\boldsymbol{A}$, where $\boldsymbol{F}$ is again written for $\boldsymbol{G}_a(\boldsymbol{C}' \otimes \boldsymbol{B}')$. This function can be written as the sum of the independent functions

$$g(\boldsymbol{a}_i) = \|\boldsymbol{x}_i' - \boldsymbol{a}_i'\boldsymbol{F}\|^2 = \left\|\boldsymbol{x}_i' - \sum_l a_{il}\boldsymbol{f}_l'\right\|^2 , \tag{15}$$

where $\boldsymbol{x}_i'$ and $\boldsymbol{a}_i'$ denote the ith rows of $\boldsymbol{X}_a$ and $\boldsymbol{A}$, respectively, subject to the constraint that one of the elements of $\boldsymbol{a}_i'$ is 1 and all others are 0. Thus, due to the constraint, in $\sum_l a_{il}\boldsymbol{f}_l'$ all but one term are 0, while the nonzero term (the jth) equals $\boldsymbol{f}_j'$. Hence, the problem is simply to find the value j for which $\|\boldsymbol{x}_i' - \boldsymbol{f}_j'\|^2$ is minimal, and set the associated value a_{ij} equal to 1, and all other elements of $\boldsymbol{a}_i'$ equal to 0. In formulas, the updates for the elements of $\boldsymbol{a}_i'$ are given by

$$\begin{aligned} j &= \arg\min\left(\|\boldsymbol{x}_i' - \boldsymbol{f}_j'\|^2\right) \\ a_{ij} &= 1 \\ a_{il} &= 0, \quad \text{for } l \neq j\,. \end{aligned} \tag{16}$$

If a column of $\boldsymbol{A}$ turns out to have zero elements only, a slightly modified version of the fixing procedure described for the overlapping clusters case can be used. That is, in this case *all* rows of $\boldsymbol{F}$ corresponding to zero columns in $\boldsymbol{A}$ are multiplied by -1, and the whole matrix $\boldsymbol{A}$ is updated again. If this will again result in one or more zero columns in $\boldsymbol{A}$, then $\boldsymbol{A}$ is set back to the original values of $\boldsymbol{A}$.

The problem of fitting the Tucker3 model with nonoverlapping clusters has recently been proposed also by Rocci and Vichi [13], but at the time of writing, their algorithm had not yet been published. Even more recently, Schepers and van Mechelen [14] have proposed an algorithm for fitting this model, which also has not been published yet. It is planned to compare these algorithms in the near future.

4.2 Rational starts

As possibly useful rational starts for the nonoverlapping clusters algorithm, again the results from Tucker3 analysis applied to the data, followed by varimax of the component matrices can be used. This time, after multiplying columns having negative sums by −1, starts are obtained simply by setting all rowwise highest elements to 1, and all other elements to 0. Other rational starts are used in the algorithms by Schepers and van Mechelen [14], and by Rocci and Vichi [13]. Their relative advantages are still to be studied.

5 Should we fully constrain components to be binary?

In the present paper, procedures have been described for constraining components to be binary. However, it is known that fitting models under binary constraints is very difficult, in the sense that it is very hard to find the globally optimal solution. Moreover, the constraints of binarity may for some situations be too strong. In some situations, it may be needed to allow for nonzero component weights with clearly different values within columns. For such purposes, special algorithms are needed, which, to the author's knowledge, are not yet available.

An alternative route to avoid the very strong constraint of binarity could be to require component matrices to be close to binarity rather than to exact binarity. This can be achieved by imposing the binarity constraint as a soft constraint in such a way that it penalizes (rather than prohibits) nonbinarity. In other words, soft constraints can be imposed by minimizing the ordinary Tucker3 loss function to which penalty terms are added whose values increase with increasing deviations from binarity. One procedure for attaining this is to minimize the function

$$f(\boldsymbol{A},\boldsymbol{B},\boldsymbol{C},\boldsymbol{U},\boldsymbol{V},\boldsymbol{W},\boldsymbol{G}) = \|\boldsymbol{X}_a - \boldsymbol{A}\boldsymbol{G}_a(\boldsymbol{C}'\otimes\boldsymbol{B}')\|^2 \\ +\lambda\|\boldsymbol{U}-\boldsymbol{A}\|^2+\mu\|\boldsymbol{V}-\boldsymbol{B}\|^2+\nu\|\boldsymbol{W}-\boldsymbol{C}||^2 \quad (17)$$

over arbitrary $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and $\underline{\boldsymbol{G}}$, and over binary auxiliary matrices $\boldsymbol{U}$, $\boldsymbol{V}$, and $\boldsymbol{W}$; λ, μ and ν are penalty parameters that regulate the strength of the constraint, and that have to be specified in advance. Without further constraints, one will find degenerate solutions in which component matrices tend to 0 (thus annihilating the penalty terms), while the core elements tend to infinity in such a way that the product $\boldsymbol{A}\boldsymbol{G}_a(\boldsymbol{C}'\otimes\boldsymbol{B}')$ still fits the data well. One way to avoid such degeneracies, which in practice turned out to work reasonably well, is to constrain the auxiliary binary matrices to have at least one nonzero element in each column.

An alternating least squares algorithm for minimizing (17) has been devised and programmed. The algorithm tends to require many iterations, but does indeed give solutions with the required properties. For instance, for data constructed on the basis of component matrices that were binary up to a few elements, the method indeed singled out these elements as different from the others. However, much more experience is needed to assess its usefulness in actual practice.

6 Conclusion

The present paper has offered methods for Tucker3 analysis with the component matrices constrained to be binary, and, in a special case also such that the components have no overlap. The algorithms proposed work in the sense that they decrease the loss function value, but they appear, as usual with binary optimization problems, to be prone to hitting local optima. Some starting procedures have been proposed that worked well in some contrived examples, but the algorithms, as well as their starting procedures need further testing, as well as comparison to competitors that have been proposed recently for the nonoverlapping case.

In addition to the methods where components are constrained to be fully binary, a procedure has been proposed for weakly imposing binarity, by using penalty terms. Again, this procedure needs further testing. If it turns out to work well in practice, and if it is not very prone to hitting local optima, it could also be used for fitting the fully constrained model by gradually increasing the penalty parameters that regulate the strength of the constraints. Whether this or other procedures work best in dealing with the local optimum problem of Tucker3 with binary constraints is subject to further research.

FUNCTIONAL DATA ANALYSIS AND MIXED EFFECT MODELS

Alois Kneip, Robin C. Sickles and Wonho Song

Key words: Mixed effects model, functional principal component analysis, nonparametric regression.

COMPSTAT 2004 section: Functional data analysis.

Abstract: Panel studies in econometrics as well as longitudinal studies in biomedical applications provide data from a sample of individual units where each unit is observed repeatedly over time (age, etc.). In this context, mixed effect models are often applied to analyze the behavior of a response variable in dependence of a number of covariates. In some important applications it is necessary to assume that individual effects vary over time (age, etc.).

In the paper it is shown that in many situations a sensible analysis may be based on a semiparametric approach relying on tools from functional data analysis. The basic idea is that time-varying individual effects may be represented as a a sample of smooth functions which can be characterized by its Karhunen-Loève decomposition. An important application is the estimation of time-varying technical inefficiencies of individual firms in stochastic frontier analysis.

1 Introduction

Panel studies in econometrics as well as longitudinal studies in biomedical applications provide data from a sample of individual units where each unit is observed repeatedly over time (age, etc.). Statistical analysis then usually aims to model the variation of some response variable Y. In addition to its dependence on some vector of explanatory variables X, the variability of Y between different individual units is of primary interest.

For simplicity, we will assume a balanced design with T equally spaced repeated measurements per individual. The resulting observations of n individuals can then be represented in the form (Y_{it}, X_{it}), where $t = 1, \dots T$ and $i = 1, \dots, n$. The simplest form of analysis is based on mixed effect models of the form

$$Y_{it} = \beta_0 + \sum_{j=1}^{p} \beta_j X_{itj} + u_i + \epsilon_{it} \tag{1}$$

where ϵ_{it} are i.i.d. error terms, while u_i represents individual random effects.

An important example in econometrics are stochastic frontier models. Then Y_{it} represents production output of an individual firm i in time period t, while X_{it} is a corresponding vector of production inputs. The u_i are then interpreted as technical inefficiencies. Firm i is more efficient than firm j if $u_i > u_j$.

However, in many applications it is too simple to assume constant individual effects u_i. A straightforward generalization is to suppose that $u_i \equiv u_i(t)$ is a function of t.

$$Y_{it} = \beta_0 + \sum_{j=1}^{p} \beta_j X_{itj} + u_i(t) + \epsilon_{it} \tag{2}$$

In the following we will assume that the $u_i(t)$ can be considered as smooth random functions. In many biometrical applications, where for example t indicates age of an individual unit, smoothness can be considered as a standard assumption. In econometrics, where t usually indicates time, for a given unit i the corresponding data $\{Y_{it}, X_{it}\}$, $t = 1, \ldots, T$, represent an individual time series. In this situation model (2) assumes that the residual time series $\{Y_{it} - \beta_0 - \sum_{j=1}^{p} \beta_j X_{itj}\}$, $i = 1, \ldots, n$, can be decomposed into a smooth stochastic trend u_i and i.i.d. white noise.

Traditional analysis relies on parametric models. Very often polynomial approximations to the functions u_i are used. More generally, for some prespecified basis functions $b_1, \ldots, b_L$ the u_i are modelled by $u_i(t) = \sum_r \vartheta_{ir} b_r(t)$, where $\vartheta_{i1}, \ldots, \vartheta_{iL}$ are individual random coefficients. Analysis is then based on the well-known methodology of mixed effect models. If additionally normality is assumed and if X and ϵ are uncorrelated, likelihood estimation based on the EM algorithm is often applied. In stochastic frontier analysis such an approach has been used by Battese and Coelli [1] or Cornwell, Schmidt, and Sickles [2] in order to model time-dependent individual inefficiencies.

In this paper we consider a **nonparametric** approach based on ideas from functional data analysis as proposed by Kneip, Sickles and Song [6]. The functions u_i can be decomposed into $u_i = w_i + v_i$, where $w(t)$ is a general mean function and $v_i(t) = u_i(t) - w(t)$. Model (2) can then be rewritten in the form

$$Y_{it} = \sum_{j=1}^{p} \beta_j X_{itj} + w(t) + v_i(t) + \epsilon_{it} \tag{3}$$

Note that the constant β_0 is incorporated into $w(t)$, and that the mean of $v_i(t)$ is zero.

For a given L functional principal component analysis is then used to estimate a *best possible basis* $g_1, \ldots, g_L$ for approximating v_i by $v_i(t) = \sum_{r=1}^{L} \theta_{ir} g_r(t)$. The approach possess a number of advantages

- The basis $g_1, \ldots, g_L$ to be estimated corresponds to the best possible basis for approximating the v_i by an L-dimensional linear function space. Any approximation $v_i(t) \approx \sum_{r=1}^{L} \vartheta_{ir} b_r(t)$ based on prespecified basis functions $b_1, \ldots, b_L$ (e.g. polynomials or splines) possesses a higher systematic error.

- All $n \cdot T$ observations are used to estimate $g_1, \dots, g_L$. Compared to a completely nonparametric analysis based on simply estimating all v_i by nonparametric regression these functions can be estimated with a much higher degree of accuracy.

Functional principal components are widely used in functional data analysis (see for example [7]). It must be emphasized, however, that the present situation is different from the usual setup in this domain, since the functions v_i of interest are not directly observed. This constitutes a major complication.

The paper is organized as follows. Section 2 presents the theoretical basis of our approach relying on the Karhunen-Loève decomposition. An algorithm for determining g_r and coefficients β_j, θ_{ir} as proposed by Kneip, Sickles and Song [6] is described in Section 3. Section 3.2 presents a new procedure which may be considered as a promising alternative. Section 4 is devoted to the problem of choosing an optimal dimension L.

2 Functional principal components

Let generally $\nu_1, \dots, \nu_n$ be i.i.d. smooth random function on $L^2[0,1]$ and suppose that $E(\nu_i) = 0$. Furthermore, let $\|f\| = \sqrt{\int f(t)^2}$ denote the usual L^2-norm for $f \in L^2[0,1]$, and set $< f^*, v >= \int f^*(t) f(t) dt$. The covariance operator then is a generalization of the concept of a covariance matrix in multivariate analysis of random vectors. The so-called covariance kernel is defined as

$$\sigma(s,t) = E(\nu_i(s)\nu_i(t))$$

and the corresponding covariance operator Γ is defined by the relation

$$\Gamma v = E\left(< \nu_i, v > \nu_i\right) = \int \sigma(s,t) v(s) ds$$

for any function $v \in L^2[0,1]$. Γ is a Hilbert-Schmidt operator and possesses finite eigenvalues $l_1 \geq l_2 \geq \dots$ as well as corresponding orthonormal eigenfunctions $\gamma_1, \gamma_2, \dots$ such that $\|\gamma_r\| = 1$ and $< \gamma_r, \gamma_s > 0 =$ for $r \neq s$. A precise mathematical discussion of properties of Γ can, for example, be found in Gihman and Skorohod [4].

The well known Karhunen-Loève decomposition states that the functions ν_i can be decomposed in terms of the eigenfunctions:

$$\nu_i(t) = \sum_r \vartheta_{ir} \gamma_r(t) \tag{4}$$

where $\vartheta_{ir} =< \nu_i, \gamma_r >$. This decomposition posseses the following properties (see for example [4]):

a) $E(\vartheta_{ir}) = 0$, $r = 1, 2, \dots$, and $Var((\vartheta_{i1}) = l_1 \geq Var((\vartheta_{i2}) = l_2 \geq Var((\vartheta_{i3}) = l_3 \geq \ \dots$

b) ϑ_{ir} is uncorrelated with ϑ_{is} if $r \neq s$

c) For each $L = 1, 2, \ldots$

$$\sum_{r>L} l_r = E\left(\|\nu_i - \sum_{r=1}^{L} \vartheta_{ir}\gamma_r\|\right) \leq E\left(\min_{\alpha_{i1},\ldots,\alpha_{iL}} \|\nu_i - \sum_{r=1}^{L} \alpha_{ir} b_r\|\right) \quad (5)$$

for any possible choice of basis functions $b_1, \ldots, b_L \in L^2[0,1]$.

Uncorrelatedness of the random coefficients ϑ_{ir} for different r simplifies further analysis, which may, for example, rely on the EM algorithm. Note that this is a specific property of the Karhunen-Loève basis. For any *prespecified* basis $b_1, \ldots, b_L$ one will have to take into account that the resulting coefficients are usually correlated.

Property c) may be seen as the most important feature of (4). For any possible dimension L the decomposition provides the best possible basis $\gamma_1, \ldots, \gamma_L$ for approximating the random functions ν_i by a linear combination of L functions. Indeed, it is well-known that in many situation a relatively small number L of components is sufficient to model the underlying functions such that a model of the form

$$\nu_i(t) = \sum_{r=1}^{L} \vartheta_{ir}\gamma_r(t) \quad (6)$$

holds in a good approximation.

Of course, the major problem of (6) consists in the fact that the function γ_r as well as an appropriate dimension L are unknown. In functional data analysis it is usually assumed that n functional realizations can be observed, or at least can be approximated with a negligible error. Estimates $\hat{\gamma}_r$ can then determined from the empirical covariance operator $\Gamma_n v = \frac{1}{n}\sum_{i=1}^{n}(<\nu_i, v>\nu_i)$ Some asymptotic theory is given in Dauxois, Pousse and Romain [3]. Under some additional conditions it is shown that rates of convergence of estimated eigenvalues and empirical eigenfunctions $\gamma_{r,n}$ are of order $n^{-1/2}$.

The present situation is different, since one has to deal with $n \cdot T$ noisy observations. The major point of interest is modelling the functions $v_i(t)$ at the design points $t = 1, \ldots, T$. We may formalize smoothness of $v_1, \ldots, v_n$ by requiring that there are i.i.d. smooth random functions $\nu_1, \ldots, \nu_n \in L^2[0,1]$ with $v_i(t) = \nu_i(\frac{t}{T})$.

Discretizing (6) then leads to the model

$$v_i(t) = \sum_{r=1}^{L} \theta_{ir} g_r(t), \quad t = 1, \ldots, T, \; i = 1, \ldots, n \quad (7)$$

Empirical versions of properties a) and b) as well as of orthonormality of $\gamma_1, \gamma_2, \ldots$ are then obtained by requiring

(α) $\sum_i \theta_{i1}^2 \geq \sum_i \theta_{i2}^2 \geq \dots$

(β) $\sum_i \theta_{ir}\theta_{is} = 0$ for $r \neq s$.

(γ) $\frac{1}{T}\sum_{t=1}^T g_r(t)^2 = 1$ and $\sum_{t=1}^T g_r(t)g_s(t) = 0$ for all $r, s \in \{1, \dots, L\}$ with $r \neq s$.

Moreover, a discretized version of (5) is given by

$$\frac{1}{n}\sum_{i=1}^n \sum_{t=1}^T (v_i(t) - \sum_{r=1}^L \theta_{ir} g_r(t))^2 \leq \frac{1}{n}\sum_{i=1}^n \min_{\alpha_{i1},\dots,\alpha_{iL}} \left(\sum_{t=1}^T (v_i(t) - \sum_{r=1}^L \alpha_{ir} b_r(t))^2 \right) \tag{8}$$

for any possible choice of $b_r(t)$, $t = 1, \dots, T$, $r = 1, \dots, L$.

Note that Conditions (α) - (γ) do not impose any restriction, and they introduce a suitable normalization which ensures identifiability of the components up to sign changes (instead of θ_{ir}, g_r one may also use $-\theta_{ir}, -g_r$). If (6) holds for some suitable L, then there exist some g_r such that (7) as well as (α) - (γ) and (8) are satisfied.

Obviously the components g_r depend on the realized v_i and on the sample size n. Due to different normalization usually $g_r(t) \neq \gamma_{r,n}(\frac{t}{T})$. This does not constitute a serious drawback for an empirical analysis based on (3) and (7). In fact, in model (7) only the L dimensional linear space spanned by $g_1, \dots, g_L$ is identifiable. There are infinitely many possible choices of basis functions, and by using conditions (1) - (3) we select a particularly well-interpretable basis. Asymptotically, as $N, T \to \infty$ $g_r(t)$ as well as $\gamma_{r,n}(t)$ will both converge to $\gamma_t(t)$ in probability. Under (6) the linear subspaces of $\mathbb{R}^T$ spanned by the vectors $\{(g_r(1), \dots, g_r(T))'\}_{r=1,\dots,L}$, $\{(\gamma_{r,n}(1), \dots, \gamma_{r,n}(T))'\}_{r=1,\dots,L}$ and $\{(\gamma_r(1), \dots, \gamma_r(T))'\}_{r=1,\dots,L}$ will coincide with high probability for large samples

How to determine the functional components g_r in (7)? There are essentially two straightforward procedures which could immediately be applied if the realized functions v_i where known. These algebraic methods will serve as a basis of the practical, data-based methods to be presented in Sections 3.

Method 1: Some simple algebra shows that, if the v_i were known, the components g_r could be determined from the eigenvectors of the empirical covariance matrix Σ_n of $v_1 = (v_1(1), \dots, v_1(T))', \dots, v_n = (v_n(1), \dots, v_n(T))'$:

$$\Sigma_n = \frac{1}{n}\sum_i v_i v_i{}' \tag{9}$$

Let $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_T$ as well as $\gamma_1, \gamma_2, \dots, \gamma_T$ to denote the resulting eigenvalues and orthonormal eigenvectors of Σ_n. Then

$$\lambda_r = \frac{T}{n}\sum_i \theta_{ir}^2 \quad \text{for all} \quad r = 1, 2, \dots, L, \tag{10}$$

$$g_r(t) = \sqrt{T} \cdot \gamma_{rt} \quad \text{for all} \quad r = 1, \dots, L, \ t = 1, \dots, T. \tag{11}$$

Also note that $\sum_{j=L+1}^{n} \lambda_j = \frac{1}{n}\sum_{i=1}^{n}\sum_{t=1}^{T}(v_i(t) - \sum_{r=1}^{L}\theta_{ir}g_r(t))^2$. If (7) holds, then obviously $\sum_{j=L+1}^{n}\lambda_j = 0$

Method 2: A second possibility is to consider the $n \times n$ matrix M_n defined by

$$(M_n)_{i,j} = \frac{1}{T}\sum_{t=1}^{T} v_i(t)v_j(t), \quad i,j = 1,\ldots,n \tag{12}$$

By using some further algebra, see for example [5], one can then deduce that all nonzero eigenvalues λ_r and h_r of the empirical covariance Σ_n and of the matrix M_n are related by $h_r = \sum_i \theta_{ir}^2 = \frac{n}{T}\lambda_r$. Moreover, the eigenvectors $\mathbf{p}_1 = (p_{11},\ldots,p_{n1})', \mathbf{p}_2 = (p_{12},\ldots,p_{n2})', \ldots$ of M_n corresponding to nonzero eigenvalues $h_1 \geq h_2 \geq \ldots$ are closely related to the parameters θ_{ir} since

$$\theta_{ir} = h_r^{1/2}\, p_{ir} \tag{13}$$

Finally, g_r can be computed from λ_r and and p_{ir}:

$$g_r(t) = h_r^{-1/2}\sum_{i}^{n} p_{ir}\, v_i(t) = \frac{\sum_i^n \theta_{ir}\, v_i(t)}{\sum_i^n \theta_{ir}^2} \tag{14}$$

3 Algorithms

When combining 3) and (7) one obtains

$$Y_{it} = \sum_{j=1}^{p}\beta_j X_{itj} + w(t) + \sum_{r=1}^{L}\theta_{ir}g_r(t)) + \epsilon_{it} \tag{15}$$

The optimal basis functions g_r satisfying (7)- (11) as well as w, β_j and θ_{ir} are unknown.

Based on the mathematical framework of Section 2 different algorithms can be applied in order to estimate the components w and g_r of the (15). In this section we will rely on a prespecified dimension L. The important question of determining an appropriate L will be considered in Section 4.

3.1 An algorithm based on estimating the covariance matrix Σ_n

In the following we will discuss a straightforward method which can be seen as a simple version of a somewhat more general algorithm proposed by Kneip, Sickles and Song [6].

The idea is easily described: In a first step partial spline methods as introduced by Speckman [8] are used to determine estimates $\hat{\beta}_j$ and $\hat{v}_i$. The mean function w is estimated nonparametrically, and then estimates $\hat{g}_r$ are determined from the empirical covariance matrix $\hat{\Sigma}_n$ of $\hat{v}_1,\ldots,\hat{v}_n$.

Let us first introduce some additional notations. Let $\bar{Y}_t = \frac{1}{n}\sum_i Y_{it}$, $\bar{Y} = (\bar{Y}_1, \dots, \bar{Y}_T)'$, $Y_i = (Y_{i1} \dots, Y_{iT})'$ and $\epsilon_i = (\epsilon_{i1}, \dots, \epsilon_{iT})$. Furthermore, let $X_{ij} = (X_{i1j}, \dots, X_{iTj})'$, $\bar{X}_{tj} = \frac{1}{n}\sum_i X_{itj}$, and $\bar{X}_j = (\bar{X}_{1j}, \dots, \bar{X}_{Tj})'$. We will use X_i and $\bar{X}$ to denote the $T \times p$ matrices with elements X_{itj} and $\bar{X}_{tj}$.

The algorithm now can be described as follows:

Step 1: Determine estimates $\hat{\beta}_1, \dots, \hat{\beta}_p$ and $\hat{v}_i(t)$ by minimzing

$$\sum_i \sum_t (y_{it} - \bar{y}_t - \sum_{j=1}^{p} \beta_j (x_{itj} - \bar{x}_{tj}) - u_i(t))^2 + \sum_i \kappa \int_1^T (v_i''(s))^2 ds \tag{16}$$

where $\kappa > 0$ is a preselected smoothing parameter and v_i'' denotes the second derivative of v.

Spline theory implies that any solution $\hat{v}_i$, $i = 1, \dots, n$ of (16) possess an expansion $\hat{v}_i(t) = \sum_j \hat{\zeta}_{ji} z_j(t)$ in terms of a natural spline basis $z_1, \dots, z_T$. If Z and A denote $T \times T$ matrices with elements $z_j(t)$ and $\int_1^T z_j''(s) z_j''(t)$, the above minimization problem can be reformulated in matrix notation: Determine $\hat{\beta} = (\hat{\beta}_1, \dots, \hat{\beta}_p)'$ and $\hat{\zeta}_i = (\hat{\zeta}_{1i}, \dots, \hat{\zeta}_{Ti})'$ by minimizing

$$\sum_i \left(\|Y_i - \bar{Y} - (X_i - \bar{X})\beta - Z\zeta_i\|_2^2 + \kappa \zeta_i' A \zeta_i \right), \tag{17}$$

where $\| \cdot \|_2$ denotes the usual euclidean norm in $\mathbb{R}^T$, $\|a\|_2 = \sqrt{a'a}$.

It is easily seen that with

$$\mathcal{Z}_\kappa = Z(Z'Z + \kappa A)^{-1} Z'$$

the solutions are given by

$$\hat{\beta} = \left(\sum_i (X_i - \bar{X})'(I - \mathcal{Z}_\kappa)(X_i - \bar{X}) \right)^{-1} \sum_i (X_i - \bar{X})'(I - \mathcal{Z}_\kappa)(Y_i - \bar{Y}) \tag{18}$$

as well as

$$\hat{\zeta}_i = (Z'Z + \kappa A)^{-1} Z'(Y_i - \bar{Y} - (X_i - \bar{X})\hat{\beta}).$$

Therefore,

$$\hat{v}_i = Z\hat{\zeta}_i = \mathcal{Z}_\kappa (Y_i - \bar{Y} - (X_i - \bar{X})\hat{\beta}) \tag{19}$$

estimates $v_i = (v_i(1), \dots, v_i(T))'$.

Remarks:

- An obvious problem is the choice of κ. A straightforward approach then is to use (generalized) cross-validation procedures in order to estimate an optimal smoothing parameter $\hat{\kappa}_{opt}$. Note, however, that the goal is not to obtain optimal estimates of the $v_i(t)$ but to approximate the functions g_r in (15). Estimating g in the subsequent steps of the algorithm involves a specific way of averaging over individual data which substantially reduces variability. In order to reduce bias, a small degree of undersmoothing, i.e. choosing $\kappa < \hat{\kappa}_{opt}$, will usually be advantageous.
- Our setup is based on assuming a balanced design. However, in practice one will often have to deal with the situation that there are missing observations for some individuals. In principle, the above estimation procedure can easily be adapted to this case. If for an individual k observations are missing, then only the remaining $T-k$ are used for minimizing (16). Estimates of $\hat{v}_i(t)$ at all $t = 1, \ldots, T$ are then obtained by spline interpolation.

Step 2: An estimate $\hat{w}$ of the mean function w is calculated by minimizing

$$\sum_t \left(\bar{Y}_t - \sum_{j=1}^{p} \hat{\beta}_j \bar{X}_{tj} - w(t) \right)^2 + \kappa \int_1^T (w''(s))^2 ds.$$

Step 3: Determine the empirical covariance matrix $\hat{\Sigma}_n$ of $\hat{v}_1 = (\hat{v}_1(1), \hat{v}_1(2), \ldots, \hat{v}_1(T))', \ldots, \hat{v}_n = (\hat{v}_n(1), \hat{v}_n(2), \ldots, \hat{v}_n(T))'$ by

$$\hat{\Sigma}_n = \frac{1}{n} \sum_i \hat{v}_i \hat{v}_i'$$

and calculate its eigenvalues $\hat{\lambda}_1 \geq \hat{\lambda}_2 \geq \ldots \hat{\lambda}_T$ and the corresponding eigenvectors $\hat{\gamma}_1, \hat{\gamma}_2, \ldots, \hat{\gamma}_T$.

Step 4: Set $\hat{g}_r(t) = \sqrt{T} \cdot \hat{\gamma}_{rt}$, $r = 1, 2, \ldots, L$, $t = 1, \ldots, T$, and for all $i = 1, \ldots, n$ determine $\hat{\theta}_{1i}, \ldots, \hat{\theta}_{Li}$ by minimizing

$$\sum_t (Y_{it} - \bar{Y}_t - (X_i - \bar{X})\hat{\beta} - \sum_{r=1}^{L} \vartheta_{ri} \hat{g}_r(t))^2$$

with respect to $\vartheta_{1i}, \ldots, \vartheta_{Li}$.

Based on this algorithm the unknown model components w and g_r in (15) can be replaced by $\hat{w}$ and $\hat{g}_r$. Further analysis may then be based on the "estimated" model

$$Y_{it} \approx \sum_{j=1}^{p} \beta_j X_{itj} + \hat{w}(t) + \sum_{r=1}^{L} \theta_{ir} \hat{g}_r(t)) + \epsilon_{it} \tag{20}$$

The algorithm automatically also yields estimates $\hat{\beta}_j$ and $\hat{\theta}_{ir}$. However, variability of these estimates may be reduced by re-estimating these coefficients by relying on (20):

Step 5: Re-estimate the coefficients $\hat{\beta}_j$ and $\hat{\theta}_{ir}$ by fitting the estimated model $Y_{it} = \sum_{j=1}^{p} \beta_j X_{itj} + \hat{w}(t) + \sum_{r=1}^{L} \theta_{ir}\hat{g}_r(t)) + \epsilon_{it}$ to the data.

Kneip, Sickles and Song [6] also study the asymptotic behavior of the resulting estimators as $n, T \to \infty$.

Let $\kappa_T = T\kappa$. If the underlying function ν_i, as discussed in Section 2, is twice continuously differentiable, then the bias in estimating v_i is of order κ_t, while variance is of order $\frac{1}{\kappa_T^{1/4} T}$. Choosing κ_T to be of order $T^{-4/5}$ then leads to the optimal *individual* rates of convergence $\frac{1}{T}\sum_t (\hat{v}_i(t) - v_i(t))^2 = O_P(T^{-4/5})$.

Under some technical assumptions (mainly concerning smoothness as well as the correlation between X_{it} and $v_i(t)$) a theorem by Kneip, Sickles and Song [6] then implies that for all $r = 1, \ldots, L$

$$T^{-1} \sum_{t=1}^{T} \left(g_r(t) - \hat{g}_r(t)\right)^2 = O_P\left(\kappa_T + \frac{1}{T^2} + \frac{1}{\kappa_T^{1/4} nT}\right) \tag{21}$$

Further results concern rates of convergence and asymptotic distributions of parameter estimates. As can be seen from (21) variance of $\hat{g}_r$ also decreases with the number n of individual units. By undersmoothing, i.e. choosing $\kappa_T = o(T^{-4/5})$, the components g_r can be estimated with better rates of convergence than those obtainable for the individual functions v_i.

In Kneip, Sickles and Song [6] finite sample performance of the estimators is additionally examined via Monte Carlo simulations. The method is then applied to the analysis of technical efficiency of the U.S. banking industry.

3.2 An algorithm based on estimating the matrix M_n

Model (3) obviously implies that

$$v_i(t) = Y_{it} - \sum_{j=1}^{p} \beta_j X_{itj} - w(t) - \epsilon_{it}$$

Hence, if the parameters β_j were known, the matrix

$$(\tilde{M}_n)_{i,j} = \frac{1}{T} \sum_{t=1}^{T} (Y_{it} - \bar{Y}_t - \sum_{j=1}^{p} \beta_j (X_{itj} - \bar{X}_{tj}), \quad i, j = 1, \ldots, n \tag{22}$$

provides an estimate of M which by Method 2) discussed in Section 2 can be used to calculate estimates of g_r.

The basic idea of the following algorithm is now easily described: Under (15) the "true" matrix M possesses only L nonzero eigenvalues, and therefore $\sum_{j=L+1}^{n} \lambda_j = 0$. Based on (22), different matrices $\tilde{M}_n(\beta)$ can be determined in dependence of all possible values of β_j. Estimates $\hat{\beta}_j$ and $\hat{M}_n$ can be obtained by minimzing the sum of the smallest $n - L$ eigenvalues of $\tilde{M}(\beta)$ with respect to β.

The precise algorithm now can be described as follows:

Step 1*: For all possible values $\tilde{\beta}_j$ of β_j, $j = 1, \ldots, p$ compute

$$(\tilde{M}_n(\tilde{\beta})_{i,j} = \frac{1}{T}\sum_{t=1}^{T}(Y_{it} - \bar{Y}_t - \sum_{j=1}^{p}\tilde{\beta}_j(X_{itj} - \bar{X}_{tj}), \quad i, j = 1, \ldots, n$$

and its eigenvalues $h(\tilde{\beta})_1 \geq h(\tilde{\beta})_2 \geq \cdots \geq h(\tilde{\beta})_n$.

Then determine estimates $\hat{\beta}_1, \ldots, \hat{\beta}_p$ by minimizing

$$\sum_{j=L+1}^{n} h(\tilde{\beta})_j$$

with respect to $\tilde{\beta}$.

Step 2*: Set $\hat{M}_n = \tilde{M}_n(\hat{\beta})$ and determine eigenvalues $\hat{h}_1 \geq \hat{h}_2 \geq \ldots$ and corresponding orthonormal eigenvectors $\hat{p}_1, \ldots, \hat{p}_n$.

Estimates $\hat{g}_r$ are then calculated by a weighted sum of residuals:

$$\hat{g}_r(t) = \hat{\lambda}_r^{-1/2}\sum_{i}^{n}\hat{p}_{ir}\left((Y_{it} - \bar{Y}_t - \sum_{j=1}^{p}\hat{\beta}_j(X_{itj} - \bar{X}_{tj})\right) \tag{23}$$

In spite of averaging over individuals, (23) may lead to fairly noisy estimates of g_r. Some addition smoothing will usually improve the performance of the estimator. Using a spline approach, an estimate of g_r may thus alternatively be determined by minimizing

$$\sum_{t}\left(\lambda_r^{-1/2}\sum_{i}^{n}\hat{p}_{ir}(Y_{it} - \bar{Y}_t - \sum_{j=1}^{p}\hat{\beta}_j(X_{itj} - \bar{X}_{tj}) - g_r(t)\right)^2 + \kappa\int_1^T (g''(s))^2 ds$$

instead of using (23).

Step 3*: An estimate $\hat{w}$ of the mean function w is calculated by minimizing

$$\sum_{t}\left(\bar{Y}_t - \sum_{j=1}^{p}\hat{\beta}_j\bar{X}_{tj} - w(t)\right)^2 + \kappa\int_1^T (w''(s))^2 ds.$$

As in the procedure of Section 3.1 accuracy of coefficient estimates may be improved by a final re-estimation:
Step 4*: Re-estimate the coefficients $\hat{\beta}_j$ and $\hat{\theta}_{ir}$ by fitting the estimated model $Y_{it} = \sum_{j=1}^{p} \beta_j X_{itj} + \hat{w}(t) + \sum_{r=1}^{L} \theta_{ir}\hat{g}_r(t)) + \epsilon_{it}$ to the data.

Recall that that the procedure of Section 3.1 requires smoothing of the *individual* data of each of the n units in order to estimate v_i, $i = 1, \ldots, n$. An important advantage of the above algorithm thus is that it only requires some *global* smoothing over weighted averages of observations in Steps 3* and 4*. The choice of the smoothing parameter κ will thus be less critical, and a possible smoothing bias will not affect the estimates of the parameters β_j. One may expect a superior behavior of this method if the number T of repeated measurement is fairly small.

On the other hand, a drawback is the fact that already for estimating β_j in Step 1* a sensible selection of the dimension L in (15) has to be made. Indeed, usually 15) will have to be satisfied in a very good approximation in order to avoid biased estimates of the parameters. In practice, one may apply the algorithm for different values of L and choose an appropriate dimension by using some goodness-of-fit criterion.

Theoretical properties of the above algorithm have not yet been studied and remain a topic of future research.

4 Choice of dimension

Any analysis based on (15) requires a sensible choice of the dimension L. If L is too small, there may exist a large systematic error in approximating the v_i. On the other hand, if L is too large, then estimates will possess an unnecessarily large variance.

Note that for a given sample the eigenvalues of the estimated covariance matrix $\hat{\Sigma}_n$ will usually satisfy $\hat{\lambda}_r > 0$ for $r > L$. This will even be true if (15) holds exactly and if therefore the eigenvalues of true matrix Σ_n are such that $\lambda_r = 0$ for $r > L$. In other words, the noise term ϵ_{it} will “create” additional (small) components in the PCA decomposition. It is obvious that any component generated or strongly influenced by noise should *not* be included into model (15).

From this point of view one may tend to choose L in such a way that each component g_r, $r = 1, \ldots, L$, possesses an influence on the model fit which is significantly larger than that of any noise component. This idea has been adopted by Kneip, Sickles and Song [6] in order to estimate a dimension L. Under the hypothesis that (15) holds for some L, i.e. $\sum_{r=L+1}^{n} \lambda_r = 0$, they derive asymptotic approximations of mean $m(L)$ and variance $s(L)^2$ of $\sum_{r=L+1}^{h} \hat{\lambda}_r$, and it is shown that $C(L) = \frac{\sum_{r=L+1}^{h} \hat{\lambda}_r - m(L)}{s(L)}$ asymptotically possesses a standard normal distribution. For any possible value of L, $m(L)$ and $s(L)$ can be approximated from the data.

An estimate of L is then obtained by choosing the smallest $l = 1, 2, \ldots$ such that

$$C(l) \leq z_{1-\alpha},$$

where $z_{1-\alpha}$ is the $1 - \alpha$ quantile of a standard normal distribution.

USING WEIGHTS WITH A TEXT PROXIMITY MATRIX

Angel R. Martinez, Edward J. Wegman and Wendy L. Martinez

Key words: Bigram proximity matrix, k nearest neighbors classifier, natural language processing.

COMPSTAT 2004 section: Applications, Classification.

Abstract: In previous work, we introduced a way of encoding free-form documents called the bigram proximity matrix (BPM). When this encoding was used on a corpus of documents, where each document is tagged with a topic label, results showed that the documents could be classified based on their tagged meaning. In this paper, we investigate methods of weighting the elements of the BPM, analogous to the weighting schemes found in natural language processing. These include logarithmic weights, augmented normalized frequency, inverse document frequency and pointwise mutual information. Results presented in this paper show that some of the weights increased the proportion of correctly classified documents.

1 Introduction

The bigram proximity matrix (BPM) was first developed by Martinez and Wegman [8], [9], [10] as a way of encoding text so it can be used in applications such as document clustering, classification or information retrieval. Previous studies with the BPM indicated that documents can be successfully classified using k nearest neighbors and other methods when they are encoded in this way. The objective of the current work is to define bigram weights analogous to the term weights found in natural language processing and to investigate the utility of using them in document classification.

In Section 2, we present some background information on the BPM and include an illustrative example. We then provide definitions of the bigram weights in Section 3. Section 4 contains information about the experiments that were conducted, as well as the results. Finally, we offer a summary and some comments about future work in Section 5.

2 Bigram proximity matrix

The BPM is a non-symmetric matrix that captures the number of word co-occurrences in a moving 2-word window. It is a square matrix whose column and row headings are the alphabetically ordered entries of the lexicon, plus one more element for end of sentence punctuation. The BPM matrix element ij is the number of times word i appears immediately before word j in the unit of text. The size of the BPM is determined by the size of the

	.	crowd	his	in	father	man	sought	the	wise	young

wise										1
young						1				

Table 1: Example of Bigram Proximity Matrix. (Note: Zeros in empty boxes are removed for clarity.)

lexicon created by listing alphabetically the unique occurrences of the words in the text. Additionally, it should be noted that all end of sentence punctuation is replaced with a period, and the period is treated as a word. By convention, the period is designated as the first word in the ordered lexicon. It is asserted that the BPM representation of the semantic content preserves enough unique features to be semantically separable from BPMs of other thematically unrelated collections.

The rows in the BPM represent the first word in the pair, and the second word is given by the column. For example, the BPM for the sentence or text stream,

$$The\ wise\ young\ man\ sought\ his\ father\ in\ the\ crowd.$$

is shown in Table 1. We see that the matrix element located in the third row (*his*) and the fifth column (*father*) has a value of one. This means that the pair of words '*his father*' occurs once in this unit of text. It should be noted that in most cases, depending on the size of the lexicon and the size of the text stream, the BPM will be very sparse. So, while the dimensionality of the BPM can be very large, sparse matrix techniques makes the analysis fast and the storage requirements small.

3 Definition of weights

We can see from the definition of the BPM, that the elements of the matrix represent the number of times that a bigram or word pair occurs in the document. Some of the measures of semantic similarity for classification cited in Martinez [8] employed the raw frequencies, others used binary values (if the frequency is non-zero, then it is replaced with a 1), and some required conversion to probabilities or relative frequencies. In this paper, we will only be concerned with the first case, where raw bigram frequencies are compared to weighted values. Because of this, we will use one measure of semantic similarity - the *normalized correlation coefficient* (NCC). This is similar to the cosine measure used in information retrieval [7].

Let **A** represent a BPM that has been converted to a column vector by concatenating the columns, one on top of the other. We do this conversion so the usual definition of the normalized correlation coefficient can be used. Let **C** denote another BPM that has been similarly converted to a vector. The cosine of the angle between these two 'vectors' is given by

$$\mathrm{NCC} = \cos\theta_{\mathbf{AC}} = \frac{\mathbf{A}^T\mathbf{C}}{\|\mathbf{A}\|\,\|\mathbf{C}\|} = \frac{\sum_{i=1}^{M} a_i c_i}{\sqrt{\sum a_i^2}\sqrt{\sum c_i^2}}, \tag{1}$$

where $\|\mathbf{A}\|$ denotes the magnitude of vector **A**, and M is the number of words in the lexicon squared, i.e., the total number of elements in the BPM.

The NCC given in Equation 1 is a similarity measure, whose range in this case is between 0 and 1. Larger values of the NCC correspond to observations that are close together. For example, the NCC similarity between a document BPM and itself is 1. If the two document BPM 'vectors' are orthogonal to each other, then the NCC similarity is 0. We convert the NCC similarity values to Euclidean distance using the following transformation

$$d_{ij} = \sqrt{2(1 - s_{ij})}\,, \tag{2}$$

where s_{ij} represents the similarity between document i and j, and d_{ij} is the distance between document i and document j.

3.1 Local – global – document weights

We will denote the ij-th element (the ij-th bigram or word pair) of the k-th weighted BPM as a_{ijk}. We can write this in terms of local, global and document components as follows

$$a_{ijk} = l_{ijk} g_{ij} d_k, \tag{3}$$

where l_{ijk} is the local weight for bigram ij that occurs in document k, g_{ij} is the global weight for bigram ij in the corpus, and d_k is a document normalization factor. We represent the frequency or the number of times bigram ij appears in document k as f_{ijk}. We use the following to indicate the conversion of a frequency f to a binary value:

$$I(f) = \begin{matrix} 1 \text{ if } f > 0 \\ 0 \text{ if } f = 0 \end{matrix} \tag{4}$$

The two local weights we use are called the *logarithmic* and the *augmented normalized bigram frequency.* Before we define these, we make one small change in notation for ease of understanding. We denote the ij-th bigram with the subscript b, where some arbitrary order or labeling has been imposed on the bigrams (elements of the BPM). The logarithmic weight is defined as

$$l_{bk} = l = \log(1 + f_{bk}), \tag{5}$$

and the augmented normalized bigram frequency is given by

$$l_{bk} = n = \frac{I(f_{bk}) + f_{bk} \div \max_b\{f_{bk}\}}{2}. \tag{6}$$

If no local weights are used, then we denote that as just the bigram frequency

$$l_{bk} = t = f_{bk}. \tag{7}$$

Note that the letters l, t, and n are used in the information retrieval literature to denote the type of local weight [1].

We use only one global weight in this study called the *inverse document frequency* (IDF); others can be found in Berry and Browne [1]. The IDF for bigrams is defined as

$$g_b = f = \log\left(K \div \sum_{k=1}^{K} I(f_{bk})\right), \tag{8}$$

where K is the total number of documents in the corpus. When choosing a global weight, one needs to consider the state of the corpus. If the corpus changes, the BPM changes first and then the global weight must be revised. Thus, if the corpus is unstable or constantly changing, then using a global weight might not be a good idea.

We now come to the document normalization factor. The *cosine normalization* seems to be used often with term-document matrices [1], so this is what we use here. For our bigrams, this is given by

$$d_k = c = \left(\sum_{b=1}^{M} \{l_{bk} g_k\}^2\right)^{-1/2}. \tag{9}$$

This simply normalizes the BPMs, or one could think of this as ensuring that the magnitude of the BPM 'vector' is 1. We note that with the normalized correlation coefficient, the document normalization does not really qualify as a weight because this normalization would take place anyway with the distance measure. What it means is that the denominator in Equation 1 is one, so we do not need to calculate it for the similarity measure.

We can designate the weighting scheme by using a three letter code as follows:

txx	bigram frequency - no weights
nfc	augmented normalized frequency - IDF - cosine normalization
tfc	bigram frequency - IDF - cosine normalization
lfc	logarithmic - IDF - cosine normalization

3.2 Mutual information

In general, mutual information is a measure of the common information between two random variables [7]. *Pointwise mutual information* is defined on two particular points in the distributions. In natural language processing, pointwise mutual information is often calculated between elements and is used for clustering words and word sense disambiguation. We define a pointwise mutual information for bigrams, following the work by Pantel and Lin [11], where they discuss the pointwise mutual information between a word and a context (i.e., words around it). We use documents in place of contexts to define pointwise mutual information between a bigram and a document. The idea of using contexts as analogous to documents has been explored by Gale, Church and Yarowsky [5].

The pointwise mutual information between bigram b and document k is denoted as MI_{bk}. The idea is to substitute this value for each corresponding element in the document's BPM. Recall that the number of times bigram b occurs in document k is represented by f_{bk}. We then calculate the number of times bigram b occurs across *all* documents in the corpus, which is given by

$$f_{b\,\cdot} = \sum_{i=1}^{K} f_{bi} \ . \tag{10}$$

Next we need the total number of bigrams occurring in document k. This is given as

$$f_{\cdot\,k} = \sum_{i=1}^{M} f_{ik} \ . \tag{11}$$

The pointwise mutual information is defined as

$$MI_{bk} = \log\left(\frac{f_{bk} \div N}{f_{b\,\cdot} \div N \times f_{\cdot\,k} \div N}\right) = \log\left(\frac{N \times f_{bk}}{f_{b\,\cdot} \times f_{\cdot\,k}}\right) , \tag{12}$$

where N is the total number of bigrams and contexts, given by

$$N = \sum_{i=1}^{M} \sum_{j=1}^{K} f_{ij} \ .$$

One of the problems with pointwise mutual information is that it is biased toward infrequent words (bigrams) and contexts [11], so Pantel and Lin recommend multiplying Equation 12 with a discounting factor. For bigram b and document k, this is

$$C_{bk} = \frac{f_{bk}}{f_{bk} + 1} \times \frac{\min\{f_{b\cdot}\,;\, f_{\cdot\,k}\}}{\min\{f_{b\cdot}\,;\, f_{\cdot\,k}\} + 1} .$$

We did not use this factor in our research; only Equation 12 was implemented.

Topic Number	Topic Description

4 Experiments

The goal of our experiments is to assess the usefulness of weighting the BPMs. In particular, to answer the question: Can documents be classified more successfully using weighted bigrams? In the next subsections, we describe some of the background and details of the experiments, followed by results. All experiments and analyses, including reading the documents and creating the BPMs, were done on a PC using MATLAB^{TM}, Version 6.5.

4.1 Description of corpus

We use the Topic Detection and Tracking (TDT) Pilot Corpus (Linguistic Data Consortium, Philadelphia, PA) to evaluate the utility of weighting the BPMs. This corpus of documents contains over 16,000 news stories from various wire services and were classified in terms of their meaning in the following way. A set of 25 topics were initially chosen and documents were tagged as either belonging to one of those topics (*yes*), partially belonging (*brief*) or not belonging (*no*). We chose a set of 503 documents encompassing 16 topics as shown in Table 2 and created a BPM for each one with weighting schemes as described in the previous section.

As for pre-processing the documents, we remove all punctuation (except for the end of sentences) and symbols such as hyphens, etc. As stated previously, all end of sentence punctuation is converted to a period, which is then treated as a word. We also investigate the effect of another pre-processing scheme - removing noise or stop words [8]. For the full text case, the size of the lexicon is 11,103. When noise words are removed, the lexicon contains 10,997 words.

4.2 Classification and dimensionality reduction

We are interested in seeing whether or not weighting the bigrams improves the results when we try to classify documents from the TDT corpus. To this end, we use a simple k nearest neighbor (k-nn) classifier [3]. This type of classifier works in the following way. We have a document with an unknown classification. We find its k nearest neighbors using the normalized correlation coefficient and look at their class labels. The document is assigned the class label that corresponds to the class that occurs with the highest frequency among the k nearest neighbors.

The k nearest neighbor classifier is easy to use and is suitable for high-dimensional data. It would be interesting to reduce the dimensionality of the space, so we can use some other method of investigation such as clustering or being able to visualize the data. In keeping with Martinez [8], we use the Isometric Feature Mapping or ISOMAP [12] procedure to reduce the dimensionality of the BPMs and repeat our classification experiments. This is particularly useful in our case, because it requires the interpoint distance matrix as its only input. Before we explain ISOMAP, we first briefly describe multidimensional scaling.

The purpose of multidimensional scaling is to represent points or observations in a lower dimensional space (usually 2-D or 3-D) in such a way that points that are close together in the higher dimensional space will also be close together in the lower dimensional space [2]. However, if the observations live along a lower dimensional nonlinear manifold, then the Euclidean distance between the points might not be the best measure of the distance between the points along the manifold. To illustrate this idea, we show a 2-D nonlinear manifold embedded in 3-D in Figure 1. The Euclidean distance between 2 random points on this manifold is shown in Figure 2, and we see that a better measure of the distance between them would be along this manifold.

ISOMAP seeks a mapping from a higher dimensional space to a lower dimensional one such that the mapping preserves the distances between observations, where the distance in the higher dimensional space is measured along the geodesic path of the nonlinear manifold. The first step in the ISOMAP algorithm is to convert the interpoint Euclidean distance matrix into geodesic distances. The geodesic distances are then used as input to classical multidimensional scaling. Besides the interpoint distance matrix, ISOMAP requires a value for the number of nearest neighbors (k) that is used in determining the geodesic distance. We use a value of $k = 10$ in this body of work.

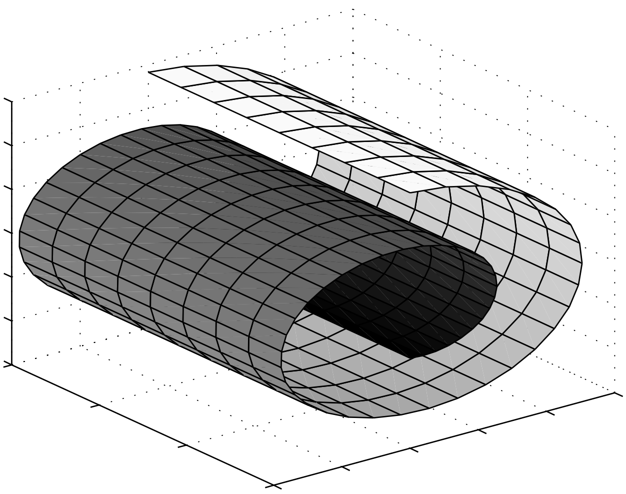

Figure 1: This illustrates a 2-D manifold (or surface) embedded in a 3-D space.

4.3 Results

To summarize, we varied the weights and other parameters and performed the following experiments with the weighted BPM.

- Text pre-processing conditions were full and denoised lexicon.
- Bigram weights were MI_{bk}, *lfc*, *nfc*, *tfc*, and *txx*.
- Dimensionality of the space for using k-nn was either full dimensionality or 4-D and 6-D from ISOMAP.
- The values of k for the k-nn classifier were $k = 1, 3, 5, 7, 10$.
- The Euclidean distance was used for the 4-D and 6-D k-nn classification.

The results from the experiments are shown in Tables 3 through 5.

Several things can be noted from these results. First, we see that in the full BPM case, using the pointwise mutual information increases the proportion of documents correctly classified. Secondly, denoising the data seems to produce poorer or similar results in the weighted case, but better results in the unweighted case (*txx*). Finally, it is interesting to note that the weighting scheme *tfc* allows us to compare the use of the IDF global weight alone. By comparing the *tfc** and *txx** entries, we see that using the IDF global weight increases the correct classification.

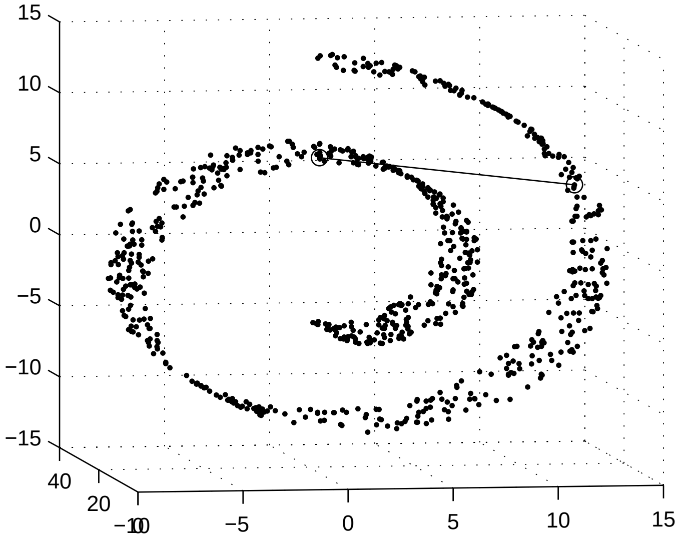

Figure 2: This is a data set randomly generated according to the manifold given in Figure 1. The Euclidean distance between two points is given by the straight line shown here. If we are seeking the neighborhood structure along the manifold, then it would be better to use the geodesic distance (the distance along the manifold or the roll) between the points.

determine whether or not weighting the BPMs improve document recognition. Results show that in some cases, where local weights were used, such as the normalized augmented frequency, did improve the classification performance. Additionally, using the pointwise mutual information, taking the context into account, significantly improved the results.

A lot of work in this area of weighting the BPMs remains to be done. One interesting possibility is to change the pointwise mutual information to include the topic. In other words, instead of using the document as the context, we might use the topic or class as the context. Of course in this case, we would have to use a training set of documents that are tagged with their topic to estimate the context. This can then be used with new untagged documents and their BPMs. Additionally, we could use the discounting factor with the mutual information. Other bigram weights can be defined and examined, such as entropy, probabilistic inverse and pivoted-cosine normalization [1]. We might also examine other real-valued measures of distance or similarity other than the NCC.

We looked at pre-processing the text by removing noise words. We could also perform some experiments using a stemmed and denoised lexicon [8], [1]. We could also examine the affect of the dimensionality reduction procedure. As stated previous, ISOMAP seeks a nonlinear manifold; we might try something like classical multidimensional scaling [2] (using the NCC similarity directly rather than the geodesic distance). Finally, we could use some other methods to analyze the reduced BPMs, such as model-based clustering [4], linear or quadratic classifiers [3], non-metric multidimensional scaling, self-organizing maps [6] etc.

COMPSTAT'2004 Symposium

ON CANONICAL ANALYSIS OF VECTOR TIME SERIES

Wanli Min and Ruey S. Tsay

Key words: Hankel matrix, Kronecker index, canonical correlation.

COMPSTAT 2004 section: Time series analysis.

Abstract: In this paper, we establish some asymptotic results for canonical analysis of vector linear time series when the data possess conditional heteroscedasticity. We show that for correct identification of a vector time series model, it is essential to use a modification, which we prescribe, to a commonly used test statistic for testing zero canonical correlations. A real example and simulation are used to demonstrate the importance of the proposed test statistics.

1 Introduction

Since proposed in [13], canonical correlation analysis has been widely applied in many statistical areas, especially in multivariate analysis. Time series analysis is no exception. [6] proposed a canonical analysis of vector time series that can reveal the underlying structure of the data to aid model interpretation. In particular, they showed that linear combinations of several unit-root non-stationary time series can become stationary. This is the idea of co-integration that was popular among econometricians in the 1990s after the publication of [10]. [22] applied canonical correlation analysis to develop the smallest canonical correlation method for identifying univariate ARMA model for a stationary and/or non-stationary time series. [17] introduced the concept of scalar component models to build a parsimonious VARMA model for a given vector time series. Again, canonical correlation analysis was used extensively to search for scalar component models. Many other authors also used canonical analysis in time series analysis. See, for instance, [15].

To build a model for a k-dimensional linear process, it suffices to identify the k Kronecker indexes or k linearly independent scalar component models, because we can use such information to identify those parameters that require estimation and those that can be set to zero within a dynamic linear vector model. Simply put, the Kronecker indexes and scalar component models can overcome the difficulties of curse of dimensionality, parameter explosion, exchangeable models, and redundant parameters in modelling a linear vector time series. For simplicity, we shall consider the problem of specifying Kronecker indexes in this paper. The issue discussed, however, is equally applicable to specification of scalar component models. The method of determining Kronecker indexes of a linear vector process with Gaussian innovations has been studied by [1], [7], [18], [20], among others. These studies show that canonical correlation analysis is useful in specifying the Kronecker indexes under normality. On the other hand, the assumption of Gaussian innovations is questionable in many applications, especially in analysis of economic and financial data that often exhibit conditional heteroscedasticity. See, for instance, the summary statistics of asset returns in Chapter 1 of [21]. In the literature, a simple approach to model conditional heteroscedasticity is to apply the generalized autoregressive conditional heteroscedastic (GARCH) model of [9] and [3]. We shall adopt such a model for the innovation series of multivariate time series data.

In this paper, we continue to employ canonical analysis in vector time series. However, we focus on statistical inference concerning canonical correlation coefficients when the distribution of the innovations is not Gaussian. Our main objective is to identify a vector model with structural specification for a given time series that exhibits conditional heteroscedasticity and has high kurtosis. Specifically, we study canonical correlation analysis when the innovations of the series follow a vector GARCH model.

1.1 Preliminaries

Based on the Wold decomposition, a k-dimensional stationary time series $\mathbf{Z}_t = (z_{1t}, \cdots, z_{kt})'$ can be written as $\mathbf{Z}_t = \mu + \sum_{i=0}^{\infty} \psi_i \mathbf{a}_{t-i}$, where $\mu = (\mu_1, \cdots, \mu_k)'$ is a constant vector, ψ_i are $k \times k$ coefficient matrices with $\psi_0 = \mathbf{I}_k$ being the identity matrix, and $\{\mathbf{a}_t = (a_{1t}, \cdots, a_{kt})'\}$ is a sequence of k-dimensional uncorrelated random vectors with mean zero and positive-definite covariance matrix $\mathbf{\Sigma}$. That is, $E(\mathbf{a}_t) = \mathbf{0}$, $E(\mathbf{a}_t \mathbf{a}'_{t-i}) = \mathbf{0}$ if $i \neq 0$, and $E(\mathbf{a}_t \mathbf{a}'_t) = \mathbf{\Sigma}$. The $\mathbf{a}_t$ process is referred to as the innovation series of $\mathbf{Z}_t$. If $\sum_{i=0}^{\infty} \|\psi_i\| < \infty$, then $\mathbf{Z}_t$ is (asymptotically) weakly stationary, where $\|\mathbf{A}\|$ is a matrix norm, e.g. $\|\mathbf{A}\| = \sqrt{\text{trace}(\mathbf{AA}')}$. Often one further assumes that $\mathbf{a}_t$ is Gaussian. In this paper, we assume that

$$\sup_{i,t} E(|a_{it}|^{\eta} | F_{t-1}) < \infty \quad \text{almost surely for some } \eta > 2, \tag{1}$$

where $F_{t-1} = \sigma\{\mathbf{a}_{t-1}, \mathbf{a}_{t-2}, \cdots\}$ denotes information available at time $t-1$. Writing $\psi(B) = \sum_{i=0}^{\infty} \psi_i B^i$, where B is the backshift operator such that $B\mathbf{Z}_t = \mathbf{Z}_{t-1}$, then $\mathbf{Z}_t = \mu + \psi(B)\mathbf{a}_t$. If $\psi(B)$ is rational, then $\mathbf{Z}_t$ has a VARMA representation

$$\mathbf{\Phi}(B)(\mathbf{Z}_t - \mu) = \mathbf{\Theta}(B)\mathbf{a}_t \tag{2}$$

where $\mathbf{\Phi}(B) = \mathbf{I} - \sum_{i=1}^{p} \mathbf{\Phi}_i B^i$ and $\mathbf{\Theta}(B) = \mathbf{I} - \sum_{j=1}^{q} \mathbf{\Theta}_j B^j$ are two matrix polynomials of order p and q, respectively, and have no common left factors. For further conditions of identifiability, see [8] for more details. The stationarity condition of $\mathbf{Z}_t$ is equivalent to that all zeros of the polynomial $|\mathbf{\Phi}(B)|$ are outside the unit circle.

The number of parameters of the VARMA model in Eq. (2) could reach $(p+q)k^2 + k + k(k+1)/2$ if no constraint is applied, making parameter estimation unnecessarily difficult in some applications. Several methods are available in the literature that can simplify the use of VARMA models when the innovations $\{\mathbf{a}_t\}$ are Gaussian. For instance, specification of Kronecker indexes of a Gaussian vector time series can lead to a parsimonious parametrization of VARMA representation, see [19]. In many situations, the innovational process $\mathbf{a}_t$ has conditional heteroscedasticity. In the univariate case, [3] proposed a GARCH(r_1, r_2) model to handle conditional heteroscedasticity. The model can be written as

$$a_t = \sqrt{g_t}\epsilon_t, \qquad g_t \quad = \quad \alpha_0 + \sum_{i=1}^{r_1} \alpha_i a_{t-i}^2 + \sum_{j=1}^{r_2} \beta_j g_{t-j}, \tag{3}$$

where $\alpha_0 > 0$, $\alpha_i \geq 0$, $\beta_j \geq 0$, and $\{\epsilon_t\}$ is a sequence of independent and identically distributed random variables with mean zero and variance 1. It's well-known that a_t is asymptotically second order stationary if $\sum_{i=1}^{r_1} \alpha_i + \sum_{j=1}^{r_2} \beta_j < 1$. Generalization of the GARCH models to multivariate case introduces additional complexity to the modelling procedure because the covariance matrix of $\mathbf{a}_t$ has $k(k+1)/2$ elements. Writing the conditional covariance matrix of $\mathbf{a}_t$ given the past information as $\mathbf{\Sigma}_t = E(\mathbf{a}_t\mathbf{a}_t'|F_{t-1})$, where F_{t-1} is defined in Eq. (1), we have $\mathbf{a}_t = \mathbf{\Sigma}_t^{1/2}\epsilon_t$, where $\mathbf{\Sigma}_t^{1/2}$ is the symmetric square-root of the matrix $\mathbf{\Sigma}_t$ and $\{\epsilon_t\}$ is a sequence of independent and identically distributed random vectors with mean zero and identity covariance matrix. Often ϵ_t is assumed to follow a multivariate normal or Student-t distribution. To ensure the positive definiteness of $\mathbf{\Sigma}_t$, several models have been proposed in the literature. For example, consider the simple case of order (1,1). [11] consider the BEKK model $\mathbf{\Sigma}_t = \mathbf{CC}' + \mathbf{A}\mathbf{a}_{t-1}\mathbf{a}_{t-1}'\mathbf{A}' + \mathbf{B}\mathbf{\Sigma}_{t-1}\mathbf{B}'$, where $\mathbf{C}$ is a lower triangular matrix and $\mathbf{A}$ and $\mathbf{B}$ are $k \times k$ matrices. [4] discusses the diagonal model $\mathbf{\Sigma}_t = \mathbf{CC}' + \mathbf{AA}' \otimes (\mathbf{a}_{t-1}\mathbf{a}_{t-1}') + \mathbf{BB}' \otimes \mathbf{\Sigma}_{t-1}$, where $\otimes$ stands for matrix Hadamard product (element-wise product).

When GARCH effects exist, the time series $\mathbf{Z}_t$ is no longer Gaussian. Its innovations become a sequence of uncorrelated, but serially dependent random vectors. It is well-known that such innovations tend to have heavy tails, see [9] and [21], among others. The performance of canonical correlation analysis under such innovations is yet to be investigated. This is the main objective of this paper. Sections 2 & 3 review and introduce the problem considered in the paper. Section 4 establishes the statistics to specify Kronecker indexes for VARMA+GARCH process. Section 5 presents some simulation results, and Section 6 applies the analysis to a real financial time series.

2 Kronecker index and vector ARMA representation

2.1 Vector ARMA model implied by Kronecker index

For simplicity, we assume that $\mu = \mathbf{0}$. Given a time point t, define the past and future vectors $\mathbf{P}_t$ and $\mathbf{F}_t$ of the process $\mathbf{Z}_t$ as $\mathbf{P}_t = (\mathbf{Z}_{t-1}', \mathbf{Z}_{t-2}', \cdots)'$,

$\mathbf{F}_t = (\mathbf{Z}'_t, \mathbf{Z}'_{t+1}, \cdots)'$. The Hankel Matrix of $\mathbf{Z}_t$ is defined as $\mathbf{H} = E(\mathbf{F}_t\mathbf{P}'_t)$. It is obvious that for a VARMA model in Eq. (2) the Hankel matrix $\mathbf{H}$ is of finite rank. In fact, it can be shown that Rank($\mathbf{H}$) is finite if and only if $\mathbf{Z}_t$ has a VARMA model representation, see [12] and [20].

The Kronecker indexes of $\mathbf{Z}_t$ consist of a set of non-negative integers $\{K_i| \quad i = 1, \cdots, k\}$ such that for each i, K_i is the smallest non-negative integer that the $(k \times K_i + i)$th row of $\mathbf{H}$ is either a null vector or is a linear combination of the previous rows of $\mathbf{H}$. It turns out that $\sum_{i=1}^k K_i$ is the rank of $\mathbf{H}$, which is invariant under different VARMA presentations of $\mathbf{Z}_t$. In fact, the set of Kronecker indexes, $\{K_i\}_{i=1}^k$, of a given VARMA process is invariant under various forms of model representation. [20] illustrates how to construct an Echelon VARMA form for $\mathbf{Z}_t$ using the Kronecker indexes $\{K_i\}_{i=1}^k$. For a stationary process $\mathbf{Z}_t$ with specified Kronecker index $\{K_1, \cdots, K_k\}$, let $p = \max\{K_i | i = 1, \cdots, k\}$. Then $\mathbf{Z}_t$ follows a VARMA(p, p) model

$$\mathbf{\Phi}_0\mathbf{Z}_t - \sum_{i=1}^{p} \mathbf{\Phi}_i\mathbf{Z}_{t-i} = \delta + \mathbf{\Phi}_0\mathbf{e}_t - \sum_{j=1}^{p} \mathbf{\Theta}_j\mathbf{e}_{t-j}, \tag{4}$$

where δ is a constant vector, the ith row of $\mathbf{\Phi}_j$ and $\mathbf{\Theta}_j$ are zero for $j > K_i$, and $\mathbf{\Phi}_0$ is a lower triangular matrix with ones on the diagonal. Furthermore, some elements of $\mathbf{\Phi}_i$ can be set to zero based on the Kronecker indexes. A VARMA model in Eq. (4) provides a unique ARMA representation for $\mathbf{Z}_t$, see Theorem 2.5.1 in [12].

2.2 Specification of Kronecker index

If the smallest canonical correlation between the future and past vectors $\mathbf{F}_t$ and $\mathbf{P}_t$ is zero, then $X_t = \mathbf{V}'_f\mathbf{F}_t$ is uncorrelated with $\mathbf{P}_t$, i.e. Cov$(X_t, \mathbf{P}_t)$ $= \mathbf{V}'_f E(\mathbf{F}_t\mathbf{P}'_t) = \mathbf{V}'_f\mathbf{H} = \mathbf{0}$. This leads to a row dependency of the Hankel matrix so that the analysis is directly related to Kronecker index. Testing for zero canonical correlation thus plays an important role in specifying Kronecker indexes. [7] used the traditional χ^2 test to propose a modelling procedure:

Step 1: Select a large lag s so that the vector $\mathbf{P}_t = (\mathbf{Z}'_{t-1}, \cdots, \mathbf{Z}'_{t-s})'$ is a good approximation of the past vector and choose initial future sub-vector $\mathbf{F}^*_t = \{Z_{1t}\}$. If a vector AR approximation is used, then s can be selected by information criteria such as AIC or BIC.

Step 2: Let $\hat{\rho}$ be the smallest sample canonical correlation in modulus between $\mathbf{F}^*_t$ and $\mathbf{P}_t$. Denote the canonical variates by $X_t = \mathbf{V}'_f\mathbf{F}^*_t$ and $Y_t = \mathbf{V}'_p\mathbf{P}_t$, and compute the test statistics

$$S = -n\log(1 - \hat{\rho}^2) \sim \chi^2_{ks-f+1}, \tag{5}$$

where n is the number of observations, f and ks are the dimension of $\mathbf{F}^*_t$ and $\mathbf{P}_t$, respectively.

Step 3: Denote the last element of $\mathbf{F}_t^*$ as $Z_{i,t+h}$. If $H_o : \hat{\rho} = 0$ is not rejected, then the Kronecker index for the ith component Z_{it} of $\mathbf{Z}_t$ is $K_i = h$. In this case, update the future vector $\mathbf{F}_t$ by removing $Z_{i,t+j}$ for $j \geq h$. If all k Kronecker indexes have been found, the procedure is terminated. Otherwise, augment $\mathbf{F}_t^*$ by adding the next available element of the updated $\mathbf{F}_t$ and return to Step 2.

The asymptotic χ^2 distribution of the S-statistic in Eq. (5) of Step 2 is derived under the independence sampling assumption. [18] showed that the canonical correlations cannot be treated as the cross correlation of two white-noise series since the corresponding canonical variates are serially correlated. Suppose $\mathbf{F}_t^* = (Z_{1,t}, \cdots, Z_{i,t+h})'$. The smallest sample canonical correlation $\hat{\rho}$ is the lag-$(h+1)$ sample cross-correlation $\hat{\rho}_{xy}(h+1)$ of the corresponding canonical variates $X_t = \mathbf{V}_f'\mathbf{F}_t^*$ and $Y_t = \mathbf{V}_p'\mathbf{P}_t$ because Y_t is observable at time $t-1$ whereas X_t is observable at time $t+h$. Under $H_0 : \rho_{xy}(m) = 0$, the asymptotic variance of $\hat{\rho}_{xy}(m)$ is, shown in [5],

$$\text{var}[\hat{\rho}_{xy}(m)] \approx n^{-1} \sum_{\nu=-\infty}^{\infty} \{\rho_{xx}(\nu)\rho_{yy}(\nu) + \rho_{xy}(m+\nu)\rho_{yx}(m-\nu)\}. \tag{6}$$

Making use of the result mentioned above, [18] proposed a proper test statistic

$$T = -(n-s)\log(1 - \frac{\hat{\rho}^2}{\hat{d}}) \sim \chi^2_{ks-f+1} \tag{7}$$

where $\hat{d} = 1 + 2\sum_{\nu=1}^{h} \hat{\rho}_{xx}(\nu)\hat{\rho}_{yy}(\nu)$. In Eq. (7), it is understood that $\hat{d} = 1$ if $h = 0$, $\hat{\rho}_{xx}(\nu)$ and $\hat{\rho}_{yy}(\nu)$ are the lag-ν sample autocorrelations of X_t and Y_t, respectively, and n is the sample size. The Bartlett's formula in Eq. (6) is for independent Gaussian innovations $\{a_t\}$. This is not the case when the innovations follow a GARCH(r_1, r_2) model. We shall study in next section properties of sample auto-covariances in the presence of GARCH innovations. All proofs can be found in [14].

3 Sample auto-covariance functions of a linear process

Lemma 3.1. *Suppose $\{a_t\}$ is a stationary GARCH(r_1, r_2) process of Eq. (3) with finite fourth moment and ϵ_t is symmetrically distributed, then $E(a_i a_k a_j a_l) = 0$, $\forall i \leq j \leq k \leq l$ unless $i = j$ and $k = l$ both hold.*

Proposition 3.1. *Suppose $\{a_t\}$ is a GARCH(r_1, r_2) process with $E(a_t^2) = \sigma^2$ and $E(a_t^4) < \infty$ and the process X_t is defined as $X_t = \sum_{i=0}^{\infty} \psi_i a_{t-i}$ with $\sum_i |\psi_i| < \infty$, and $\sum_i i\psi_i^2 < \infty$. Let $\gamma_{xx}(0) = \sigma^2 \sum_{i=0}^{\infty} \psi_i^2$. Then the next inequality holds: $\sum_{t=1}^{\infty} \|E(X_t^2 - \gamma_{xx}(0)|\xi_0)\| < \infty$, where $\xi_0 = \sigma\{\epsilon_0, \epsilon_{-1}, \cdots\}$ and $\|Y\|$ denotes the L^2-norm of a random variable Y.*

Defining the norm of a random matrix as $\|A\| := \sqrt{E(trAA')}$, we can generalize *Prop* 3.1 to a linear process with innovational process that follows a multivariate GARCH model.

Proposition 3.2. *Assume* $\mathbf{a}_t = (a_{1t}, \cdots, a_{mt})'$ *follows a pure diagonal multivariate GARCH model, i.e.* a_{it} *follows a univariate GARCH*(r_1, r_2) *model and is stationary with finite fourth moment for each* $i = 1, \cdots, m$. *Consider the process* $X_t = \sum_{i=0}^{\infty} \mathbf{\Psi}_i' \mathbf{a}_{t-i}$ *where* $\mathbf{\Psi}_i$ *are* m*-dimensional vectors. Assume further that* $\sum_{i=0}^{\infty} \|\mathbf{\Psi}_i\| < \infty$ *and* $\sum_{i=0}^{\infty} i\|\mathbf{\Psi}_i\|^2 < \infty$. *Let* $\xi_0 = \sigma\{\mathbf{a}_0, \mathbf{a}_{-1}, \cdots\}$. *Then the next inequality holds:* $\sum_{t=1}^{\infty} \|E(X_t^2 - \gamma_{xx}(0)|\xi_0)\| < \infty$, *where* $\gamma_{xx}(0) = \sum_{i=0}^{\infty} \mathbf{\Psi}_i' \mathbf{\Sigma} \mathbf{\Psi}_i$ *and* $\mathbf{\Sigma} = E(\mathbf{a}_t \mathbf{a}_t') = diag(\sigma_1^2, \cdots, \sigma_m^2)$.

Observing $X_t Y_{t+h} = \frac{(X_t + Y_{t+h})^2 - (X_t - Y_{t+h})^2}{4}$, we have by the triangle inequality the next corollary.

Corollary 3.1. *Suppose* $X_t = \sum_{i=0}^{\infty} \mathbf{\Psi}_i' \mathbf{a}_{t-i}$ *and* $Y_t = \sum_{i=0}^{\infty} \mathbf{\Phi}_i' \mathbf{a}_{t-i}$ *both satisfy the conditions in Prop 3.2. Let* $\gamma_{xy}(h) = E(X_t Y_{t+h})$, *where* h *is an integer. We have* $\sum_{t=1}^{\infty} \|E(X_t Y_{t+h} - \gamma_{xy}(h)|\xi_0)\| < \infty$.

To generalize the result to the case that $\mathbf{X}_t$ is multivariate, we define $\text{Vec}(\mathbf{A}) = (\mathbf{A}_1', \cdots, \mathbf{A}_n')'$ for a matrix $\mathbf{A}$. We also use a Lemma in [23].

Proposition 3.3. *Let* $\mathbf{X}_t = (X_{1t}, \cdots, X_{kt})' = \sum_{i=0}^{\infty} \mathbf{\Psi}_i \mathbf{a}_{t-i}$, *where* $\mathbf{\Psi}_i$ *are matrices of dimension* $k \times m$ *and* $\mathbf{a}_t$ *is* m*-dimensional and follows a pure diagonal stationary GARCH*(r_1, r_2) *model with finite 4th moment. Further,* $\sum_{i=0}^{\infty} \|\mathbf{\Psi}_i\| < \infty, \sum_{i=0}^{\infty} i\|\mathbf{\Psi}_i\|^2 < \infty$. *Letting* $\mathbf{\Sigma} = E(\mathbf{X}_t \mathbf{X}_{t+h}')$ *where* h *is an integer, we have* $\sum_{t=1}^{\infty} \| Vec(E(\mathbf{X}_t \mathbf{X}_{t+h}'|\xi_0) - \mathbf{\Sigma})\| < \infty$

Proposition 3.4. *Let* $\mathbf{X}_t = (X_{1t}, \cdots, X_{kt})' = \sum_{i=0}^{\infty} \mathbf{\Psi}_i \mathbf{a}_{t-i}$, $\mathbf{Y}_t = (Y_{1t}, \cdots, Y_{lt})' = \sum_{i=0}^{\infty} \mathbf{\Phi}_i \mathbf{a}_{t-i}$, *where* $\mathbf{\Psi}_i$ *and* $\mathbf{\Phi}_i$ *are matrices of dimension* $k \times m$ *and* $l \times m$, *respectively. Suppose both* $\mathbf{X}_t$ *and* $\mathbf{Y}_t$ *satisfy the conditions in Proposition 3.3. Denote* $\mathbf{\Sigma}_{xy}(h) = E(\mathbf{X}_t \mathbf{Y}_{t+h}')$. *Then* $\frac{1}{\sqrt{n}} \sum_{t=1}^{n} Vec(\mathbf{X}_t \mathbf{Y}_{t+h}' - \mathbf{\Sigma}_{xy}(h)) \longrightarrow N(\mathbf{0}, \mathbf{\Sigma})$, *where* h *is any integer and* $\mathbf{\Sigma} \in R^{kl \times kl}$.

Remark 3.1. *For a causal, stationary VARMA*(p, q) *process* $\mathbf{\Phi}(B)(\mathbf{Z}_t - \mu) = \mathbf{\Theta}(B)\mathbf{a}_t$, *its* $MA(\infty)$ *representation* $\mathbf{Z}_t = \mu + \sum_{i=0}^{\infty} \mathbf{\Psi}_i \mathbf{a}_{t-i}$ *satisfies the condition* $\sum_{i=0}^{\infty} \|\mathbf{\Psi}_i\| < \infty, \sum_{i=0}^{\infty} i\|\mathbf{\Psi}_i\|^2 < \infty$ *since* $\|\mathbf{\Psi}_i\| \sim r^i$ *with* $r \in (0, 1)$

being the largest root (in magnitude) of $\mathbf{\Phi}(B^{-1})$*. Consequently, if* $\mathbf{a}_t$ *follows a pure diagonal GARCH model with finite fourth moment, the sample auto-covariance matrix of* $\mathbf{Z}_t$ *has an asymptotic joint normal distribution.*

Theorem 3.1. *Suppose that* $\mathbf{Z}_t$ *is a* k*-dimensional stationary VARMA process of model (2), where the innovation series* $\mathbf{a}_t$ *follows a GARCH*(r_1, r_2) *model with finite 4th moment. Let* $\mathbf{P}_t = (\mathbf{Z}'_{t-1}, \cdots, \mathbf{Z}'_{t-s})'$ *be a past vector with a prespecified* $s > 0$ *that contains all the information needed in predicting the future observation of* $\mathbf{Z}_t$*,* $\mathbf{F}_t = (z_{1,t}, \cdots z_{i,t+h})'$ *be the future subvector of* $\mathbf{Z}_t$ *constructed according to the procedure described in Section 2. Let* $\hat{\rho}$ *be the smallest sample canonical correlation between* $\mathbf{P}_t$ *and* $\mathbf{F}_t$*. Under the null hypothesis that the smallest canonical correlation* ρ *between* $\mathbf{P}_t$ *and* $\mathbf{F}_t$ *is zero but all the other canonical correlations are nonzero, then* $\hat{\rho}^2/var(\hat{\rho})$ *has an asymptotic* χ^2 *distribution with* $ks - f + 1$ *degrees of freedom, where* f *is the dimension of* $\mathbf{F}_t$*.*

4 Asymptotic variance of sample cross correlation

Next we consider the variance of sample cross-correlation coefficient for the case that gives rise to a zero canonical correlation between the past and future vectors of $\mathbf{Z}_t$. To this end, we make use of the Aitken's delta method. Suppose Y_t and X_t are stationary moving-average processes. More specifically, $Y_t = \sum_{i=0}^{h} \phi_i a_{t-i}$ and $X_t = \sum_{i=0}^{\infty} \psi_i a_{t-i}$ with a_t being a GARCH(r_1, r_2) process of Eq. (3). By Lemma 1, $E(a_i a_j a_k a_l) = 0\ \forall i \le j \le k \le l$ unless $i = j$ and $k = l$ both hold. Let $U = \hat{\gamma}_{xx}(0)$, $V = \hat{\gamma}_{yy}(0)$, and $W = \hat{\gamma}_{xy}(q) = \frac{1}{n-q} \sum_{t=1}^{n-q} X_t Y_{t+q}$. Given $q > h$, where h corresponds to a Kronecker index, we have $\gamma_{xy}(q) = \gamma_{yy}(q) = 0$, and on applying the delta method the following result holds:

$$\mathrm{Var}(\hat{\rho}_{xy}(q)) \approx \frac{1}{n} \sum_{|d| \le h} \left[\rho_{xx}(d)\rho_{yy}(d) + \frac{\mathrm{Cum}(X_0, X_d, Y_q, Y_{q+d})}{\gamma_{xx}(0)\gamma_{yy}(0)} \right], \qquad (8)$$

where $\mathrm{Cum}(X_0, X_d, Y_q, Y_{q+d}) = \sum_{i \ge 0} \sum_{k=0}^{h-d} \psi_i \psi_{i+d} \phi_k \phi_{k+d} \mathrm{Cov}(a_0^2, a_{q-k+i}^2)$.

Therefore, the fourth order cumulants of $\{X_t\}$ depend on the auto-covariance function of $\{a_t^2\}$. Compared to $\gamma_{xx}(d)\gamma_{yy}(d)$, $\mathrm{Cum}(X_0, X_d, Y_q, Y_{q+d})$ has a non-negligible impact on $\mathrm{Var}(\hat{\rho}_{xy}(p))$ if $\mathrm{Cov}(a_0^2, a_{q-k+i}^2)/E^2(a_0^2)$ is large. For instance, if a_t is a GARCH(1,1) process, then $\mathrm{Cov}(a_0^2, a_1^2)/\sigma^4 = 2\alpha_1 + \frac{6\alpha_1^2(\alpha_1+\beta_1/3)}{1-2\alpha_1^2-(\alpha_1+\beta_1)^2}$. This ratio is 86 given $\alpha_1 = 0.5$ and $\beta_1 = 0.2$. Considering the 4th order cumulant correction term in $\mathrm{Var}(\hat{\rho})$, one can modify the T statistic proposed by Tsay as

$$
\begin{aligned}
T^* &= -(n-s)\log(1-\frac{\hat{\rho}^2}{\hat{d^*}}) \sim \chi^2_{ks-f+1}, \qquad (9)\\
\hat{d^*} &= \sum_{|d|\le h}\left[\rho_{xx}(d)\rho_{yy}(d) + \frac{\mathrm{Cum}(X_0, X_d, Y_q, Y_{q+d})}{\gamma_{xx}(0)\gamma_{yy}(0)}\right].
\end{aligned}
$$

5 Simulations study

We conduct some simulations to study the finite sample performance of the modified test statistics. We focus on a bivariate ARMA+GARCH(1,1) model chosen to have GARCH parameters similar to those commonly seen in empirical asset returns. The model is

$$
\mathbf{Z}_t - \begin{bmatrix} 0.8 & 0 \\ 0 & 0.3 \end{bmatrix} \mathbf{Z}_{t-1} = \mathbf{a}_t - \begin{bmatrix} -0.8 & 1.3 \\ -0.3 & 0.8 \end{bmatrix} \mathbf{a}_{t-1}, \qquad (10)
$$

where $t = 1, \cdots, n$ and $\mathbf{a}_t = \mathrm{diag}(\sqrt{g_{1t}}, \sqrt{g_{2t}})\epsilon_t$ with $\epsilon_t \sim i.i.d \quad N_2(0, I)$, where g_{it} satisfy the GARCH(1,1) model $g_{it} = 0.5 + 0.2a^2_{i,t-1} + 0.7g_{i,t-1}$ for $i = 1$ and 2. For a given sample size n, each realization was obtained by generating $5n$ observations. To reduce the effect of the starting values $\mathbf{Z}_0$ and $\mathbf{a}_0$, we only use the last n observations. For this model, the two future subvectors which in theory give a zero canonical correlation are $\mathbf{F}_t(1) = (z_{1t}, z_{2t}, z_{1,t+1})'$ and $\mathbf{F}_t(2) = (z_{1t}, z_{2t}, z_{2,t+1})'$. A value of $s = 5$ was selected according to AIC criterion in a preliminary analysis using pure vector AR models. The corresponding past vector is $\mathbf{P}_t = (\mathbf{Z}'_{t-1}, \cdots, \mathbf{Z}'_{t-5})'$.

Let $S(1)$ and $S(2)$ be the test statistics $S = -n\log(1-\hat{\rho}^2)$ of [7] when the future subvectors are $\mathbf{F}_t(1)$ and $\mathbf{F}_t(2)$, respectively. Similarly, let $T(1)$ and $T(2)$ be the corresponding test statistics $T = -(n-s)\log(1-\frac{\hat{\rho}^2}{\hat{d}})$ of [18] and $T^*(1)$ and $T^*(2)$ be the test statistics $T^* = -(n-s)\log(1-\frac{\hat{\rho}^2}{\hat{d^*}})$ proposed in Eq. (9). In particular, we adopt the approach of [2] to estimate the variance of sample cross-covariance $\mathrm{Var}[\hat{\gamma}_{xy}(q)]$ by

$$
n\ \mathrm{Var}[\hat{\gamma}_{xy}(q)] \approx \hat{\sigma}^*(0) + 2\sum_{i=1}^{n-q}(1-i/n)K(ib_n)\hat{\sigma}^*(i),
$$

where $\hat{\sigma}^*(i) = \sum_t X_tY_{t+q}X_{t+i}Y_{t+i+q}/n - \hat{\gamma}^2_{xy}(q)$, $K(x) = I_{|x|\le 1}$, and $b_n = n^{-1/4}$. However, to improve the robustness of the variance estimate in finite samples, we employ a modified estimate of $\hat{\sigma}^*(i)$. The modification is to use a trimmed sequence $\{X_tY_{t+q}\}$ by trimming both the lower and upper 0.2 percentiles of X_tY_{t+q}.

As an alternative, we also applied the stationary bootstrap method of [16] to estimate $\mathrm{Var}(\hat{\rho})$. Each bootstrap step was repeated 1000 times. Let $B(1)$

Statistic	Mean	S.D	**Percentile**			Rej. at $\chi_8^2(0.95)$
			90%	95%	99%	percentage
$S(1)$	10.81	5.81	18.20	21.67	30.30	20.3
$S(2)$	11.63	8.91	20.94	25.94	37.48	22.2
$T(1)$	10.88	6.89	18.26	22.04	32.5	17.3
$T(2)$	9.14	6.66	15.94	19.27	28.66	10.8
χ_8^2	8	4	13.36	15.51	20.10	5.0
$T^*(1)$	8.13	4.29	13.82	16.35	21.60	6.5
$T^*(2)$	7.01	3.93	11.99	14.01	20.11	3.4
$B(1)$	7.72	4.1	13.05	15.32	20.81	4.8
$B(2)$	6.31	3.66	11.03	13.65	18.47	4.0

Table 1: Empirical quantiles of various test statistics for testing zero canonical correlations, based on 2,000 replications with sample size 2,000.

and $B(2)$ be the corresponding test statistics $-(n-s)\log(1-\frac{\hat{\rho}^2}{\hat{d}})$, where $\hat{d}$ is obtained from bootstraps.

Table 1 compares empirical percentiles and the size of various test statistics discussed above for the model in Eq. (10) when the sample sizes is 2000, which is common among financial data. The corresponding quantiles of the asymptotic χ_8^2 are also given in the table. Other sample size is also considered. From the table, we make the following observations. First, the T^* and bootstrap B statistics perform reasonably well when the sample size is sufficiently large. The bootstrap method outperforms the other test statistics. However, it requires intensive computation. For instance, it took several hours to compute the bootstrap tests in Table 1 whereas it only took seconds to compute the other tests. Second, the T statistics underestimate the variance of cross-correlation so that the empirical quantiles exceed their theoretical counterparts. Third, as expected, the S statistics perform poorly for both sample sizes considered. Fourth, the performance of the proposed test statistic T^* indicates that the [2] method to estimate the variance of cross-covariance is reasonable in the presence of GARCH effects provided that robust estimators $\hat{\sigma}^*(i)$ are used.

6 An illustrative example

In this section we apply the proposed test statistics to a 3-dimensional financial time series. The data consist of daily log returns, in percentages, of stocks for Amoco, IBM, and Merck from February 2, 1984 to December 31, 1991 with 2000 observations. The series are shown in Figure 1. It is well-known that daily stock return series tend to have weak dynamic dependence, but strong conditional heteroscedasticity, making them suitable for the proposed test. Our goal here is to provide an illustration of specifying a vector ARMA

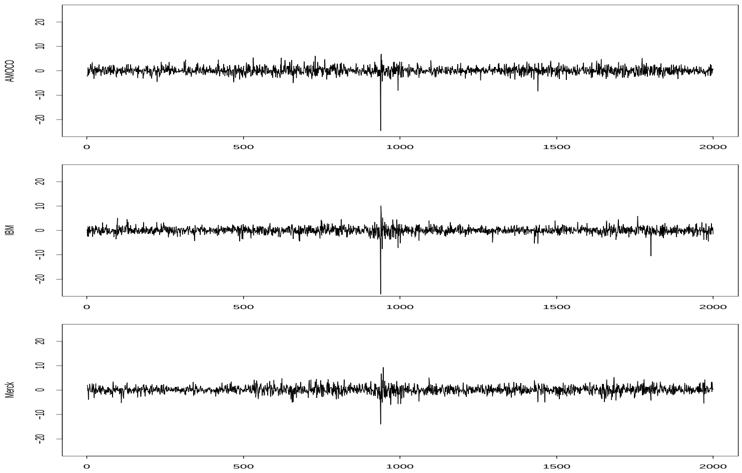

Figure 1: Time series of Amoco, IBM and Merck stocks daily return (2/2/1985–12/31/1991).

model with GARCH innovations rather than a thorough analysis of the term structure of stock returns.

Denote the return series by $\mathbf{Z}_t = (Z_{1t}, Z_{2t}, Z_{3t})'$ for Amoco, IBM, and Merck stock, respectively. Following the order specification procedure of Section 2.2, we apply the proposed test of Eq. (9), denoted by T^*, to the data and summarize the test results in Table 2. We also included the test statistics T of Eq. (7) for comparison purpose. The past vector $\mathbf{P}_t$ is determined by the AIC as $\mathbf{P}_t = (\mathbf{Z}'_{t-1}, \mathbf{Z}'_{t-2})'$. The p-value is based on a χ^2_{ks-f+1} test where $k = 3$, $s = 2$, and $f = \dim(\mathbf{F}^*_t)$.

From Table 2, the proposed test statistic T^* identified $\{1, 1, 1\}$ as the Kronecker indexes for the data, i.e. $K_i = 1$ for all i. On the contrary, if one assumes that there are no GARCH effects and uses the test statistic T, then one would identify $\{1, 1, 2\}$ as the Kronecker indexes. More specifically, the T statistic specifies $K_1 = K_2 = 1$, but finds the smallest canonical correlation between $\mathbf{F}^*_t = (Z_{1,t}, Z_{2,t}, Z_{3,t}, Z_{3,t+1})$ and $\mathbf{P}_t$ to be significant at the usual 5% level. To determine K_3, one need to consider the canonical correlation analysis between $\mathbf{F}^*_t = (Z_{1,t}, Z_{2,t}, Z_{3,t}, Z_{3,t+1}, Z_{3,t+2})'$ and the past vector $\mathbf{P}_t$. The corresponding test statistic is $T = 4.05$, which is insignificant with p-value 0.134 under the asymptotic χ^2_2 distribution. Therefore, without considering GARCH effects, the identified kronecker indexes are $(K_1 = 1, K_2 = 1, K_3 = 2)$, resulting in an ARMA(2,2) model for the data. Consequently, by correctly considering the GARCH effect, the proposed test statistic T^* was able to specify a more parsimonious ARMA(1,1) model for the data. In summary, we entertain a vector ARMA(1,1) model with diagonal GARCH(1,1) innovations for the data. The estimated VARMA-GARCH model is given below:

$$\mathbf{Z}_t - \begin{bmatrix} .0 & 2.0^{***} & .4 \\ .0 & 0.3 & .2^{*} \\ .1 & 0.9^{**} & .1 \end{bmatrix} \mathbf{Z}_{t-1} = \begin{bmatrix} -.1 \\ -.0 \\ .1^{*} \end{bmatrix} + \mathbf{a}_t + \begin{bmatrix} -.1 & 2.1^{***} & .4 \\ .1 & 0.2 & .2^{**} \\ .2^{*} & 0.9^{**} & .1 \end{bmatrix} \mathbf{a}_{t-1} \tag{11}$$

where the superscript *, **, and *** indicate significance at the 10%, 5% and 1% level, respectively, and the volatility $\mathbf{g}_t = E(\mathbf{a}_t^2 | \mathcal{F}_{t-1})$ follows the model

$$\mathbf{g}_t = \begin{bmatrix} 1.59 \\ 0.23 \\ 0.05 \end{bmatrix} + \begin{bmatrix} .28 & 0 & 0 \\ 0 & .14 & 0 \\ 0 & 0 & .06 \end{bmatrix} \mathbf{a}_{t-1}^2 + \begin{bmatrix} .00 & 0 & 0 \\ 0 & .76 & 0 \\ 0 & 0 & .91 \end{bmatrix} \mathbf{g}_{t-1}$$

where all estimates except the (1,1)th element of the coefficient matrix of $\mathbf{g}_{t-1}$ are significant at the 1% level. Model checking shows that the fitted model appears to be adequate in handling serial dependence in the data.

future subvector $\mathbf{F}_t^*$	sm.can.cor	T^*	d.f	p-value	Remark	T
$(Z_{1,t})$	.130	33.96	6	0		33.96
$(Z_{1,t}, Z_{2,t})$	.116	26.97	5	0		26.97
$(Z_{1,t}, Z_{2,t}, Z_{3,t})$	.101	20.68	4	0		20.68
$(Z_{1,t}, Z_{2,t}, Z_{3,t}, Z_{1,t+1})$	.051	5.59	3	.13	$K_1 = 1$	5.95
$(Z_{1,t}, Z_{2,t}, Z_{3,t}, Z_{2,t+1})$	.032	1.52	3	.68	$K_2 = 1$	4.48
$(Z_{1,t}, Z_{2,t}, Z_{3,t}, Z_{3,t+1})$	.055	5.98	3	.11	$K_3 = 1$	11.38

LEARNING STATISTICS BY DOING OR BY DESCRIBING: THE ROLE OF SOFTWARE

Erich Neuwirth

Key words: Statistical computing, statistics education, teaching statistics.

COMPSTAT 2004 section: Teaching statistics.

Abstract: Paper discusses several key questions connected with the teaching, and learning, statistics. Among the problem covered belong: whom to teach, what type of presentation to chose, how and in which extend to use computers . . .

1 Teaching statistics: for whom?

Statistics possibly is the discipline use by most nonspecialists as part of their work. Psychologists, medical doctors, journalists, and people from many more fields they all use statistics, or at least have to be able to interpret statistical data. At election times, newspapers and TV report about opinion polls and most of the public has problems in judging the reliability of forecasts for the election based on samples. So the need of education a rather broad audience for statistics is generally accepted.

When discussing statistics education under these aspects, it is clear that we have to face different audiences with different statistical need and we also have to take into account quite different levels of formal training outside of statistics.

Statistics education may target the following knowledge levels:

- Basic statistical knowledge: understanding simple statistical summaries and graphs, numeracy.
- Basic statistical skills: selecting appropriate simple statistical methods for own analyses, ability to immediately identify misuses of statistics.
- Advanced statistical knowledge: Understanding complex methods, especially multivariate analytical and graphical methods.
- Advanced statistical skills: selecting appropriate complex methods and understanding their role in gaining insights.

We need to distinguish the level of presentation for statistics education

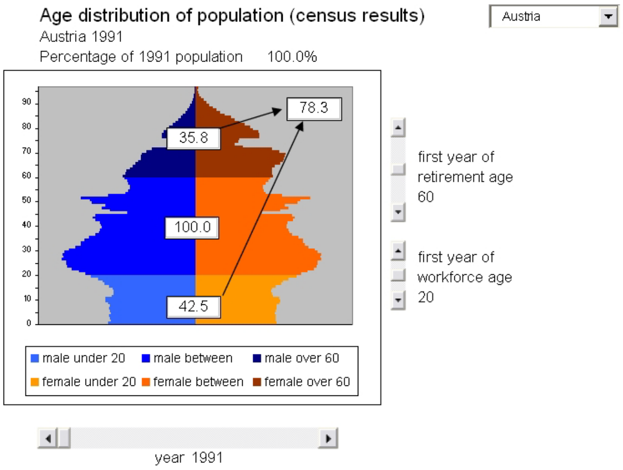
- No formal prerequisites, just data as numbers and graphs.

- Basic mathematical knowledge and skills, simple algebraic formulas admissible as tools for explaining.
- College level mathematical background

Finally, the level of computer expertise of the educatees also plays an important role in designing courses and activities for statistics education.

2 Demographical modelling: a success story

Let us begin with a success story. In Austria, like in many other countries, there is an ongoing discussion about different options of financing the retirement system. At `http://sunsite.univie.ac.at/Projects/demography/` we have published a manipulable statistical model forecasting the population's age structure for Austria for the next 30 years. The model is implemented as an Excel sheet, and it looks like this:



Age distribution of population (census results)
Austria 1991
Percentage of 1991 population 100.0%

Austria

first year of retirement age 60

first year of workforce age 20

year 1991

The most important details in this model are the "sliders"; they allow to change the graph dynamically. The horizontal slider turns the graph into a movie. The graph always displays the population pyramid for a given year; when the slider is moved, the year changes and the change of the age structure becomes dynamically visible.

The other sliders allow to change different model parameters like retirement age, and will immediately display changes in the system resulting from changes in the parameters. The model also allows to use data from different countries (currently we have Austria, Germany, USA, and Japan) to analyze how different populations structures can get.

This model can be used in two ways:

- As a ready made tool for experiments in a given framework, one might say as a demographical microworld.
  This is the “consumer mode” for the model.
- As a project to be developed by the learner. This is the “producer mode” for the model.

A nice story illustrates how the model was used for statistical education in “consumer mode”. The author received an email message from a member of the Austrian parliament, essentially stating that the MP had found the model accidentally when browsing the web. Being involved in discussions about retirement legislative questions he started playing with it and found that he could analyze some consequences of changes in retirement laws easily. The final statement was: “now I understand the problem much better”.

The author regularly teaches a course about computer based demographic modelling for sociology students. In this course, the students are shown the model at the beginning. Then there are two days of intensive computer based modelling, and at the end all the students are able to implement the model themselves. They also are guided towards further investigations. e.g. the influence of changing birth rates on demographical developments. They implement different scenarios and study possible changes with hands on modelling and parameter variation. The students really enjoy this course because the finish with the feeling that they have acquired knowledge and skills allowing them to add statistical modelling to their personal toolkit.

3 Learning statistics for data analysis: how?

The didactic success of the demography model just described is very much tied to information technology. The finished version can be downloaded on the web, the user only needs Microsoft Excel on the computer. So a very widely used tool is the computational infrastructure of the model. This also has an additional important message: serious statistical modelling can be done with software available on almost any desktop computer, quite often there is no immediate need for highly specialized software for models of higher complexity.

When the model is used in producer mode, the statistical and mathematical theory for the model is not too complicated. Mathematically speaking this is a simple linear first order difference equation. It may, however, be described only using basic arithmetic. Since it is implemented in Excel and since the students know Excel already, the important message is that serious modelling can be done with widely available general purpose software. Like in the consumer mode use of the model a case is made for modelling as a mental process and not a function of highly specialized software.

Using spreadsheet programs also has another important didactical aspect. Spreadsheets always display the data, data are not hidden. One of the most important concepts of statistics is the data matrix, also called data frame. In a spreadsheet, the data are always visible and it becomes a very physical experience that doing statistics is operating on data. This fact is much more obscured when a statistical programming language like S, R, SPSS, or SAS is used as the basic tool in statistics courses.

The main difference between the spreadsheet approach and the statistical programming language approach might be characterized as direct manipulation vs. descriptive. The programming language approach is much more formula based, the data are not as omnipresent as in the spreadsheet approach. For introductory statistics courses, this constant reminder "statistics is about data" can be quite helpful. Many students after their first course of non computer based statistics have the impression that statistics is about certain types of formulas, and not so much about data. Programming languages still somewhat support this mindset, whereas the spreadsheet approach really emphasizes the data analysis point of view. More topics about modelling with spreadsheets can be found in [6].

The direct manipulation approach is not solely restricted to spreadsheets. Programs like Fathom (available from Key Curriculum Press) also emphasize the "manipulate the data with the mouse" approach as opposed to the "write a program to manipulate the data" approach.

Spreadsheets are not the answer to all statistical problems. Excel has some flaws concerning statistics. The most inconvenient ones are some inaccuracies with distributions functions and not too high quality of random number generators, inconsistent handling of missing data, and unavailability of some of the most important types of statistical graphs (like histograms with unequal bin widths).

Therefore, it makes sense to use a more advanced statistical toolbox than just a spreadsheet program. This does now, however, imply that the spreadsheet paradigm has to be thrown overboard. The RExcel program (part of the R COM server project accessible at `http://sunsite.univie.ac.at/rcom/` and described in [5]) allows to use practically all the functionality of R from within Excel. This way, the student can still operate on the data in with the direct manipulation method, but use statistical methods not available from the spreadsheet program alone.

This also demonstrates an important message about software in general: Software should adapt to the user's needs. If possible, one should not be forced to switch programs, it is better if a standard package can be enhanced by extending its functionality.

RExcel is not the only statistical extension of Excel. PopTools (available from `http://sunsite.univie.ac.at/Spreadsite/poptools`) also is an example of how additional statistics functions can be integrated into the spreadsheet paradigm.

Statistical graphics is another extremely important concept to be discussed in the context of statistics education. [1] and [9] make a very convincing case for graphical methods. The statistics package R (available from `http://www.r-project.org` comes with many data sets, including data about age, sex, class and survival of the Titanic passengers and crew. Quite a few statistics teachers investigate this data set with mosaic plots (and without any formulas visible for the students). Again, this illustrated the point we already made: statistics should help gaining insights from data, and not be a way of just applying formulas to data. Similarly, trellis plots are a relatively new technique for multivariate analysis by using arrays of graphs arranged according to statistical variables.

So far, we have only discussed software supporting statistical education running on desktop or notebook computers. Additionally, there is a whole range of web sites for statistics education, offering course material and applets for experimenting. `http://wise.cgu.edu/` offers a good overview of such sites.

Some of these sites are just online resources, not offering much more than printable static material to support statistics courses. The more interactive sites follow a philosophy similar to the one exemplified by consumer mode use of our demography example. They offer the students opportunities to analyze data interactively. Projects like the XploRe eBooks (available from `http://www.xplore-stat.de`) combine the printed material approach and the applet approach by directly embedding applets into electronically distributed static course materials.

One of the central problems of teaching statistics mostly as a data analysis course is to find data which are interesting to analyze for students. For this purpose, the WWW is a really powerful resource. The Journal of Statistics Education at `http://www.amstat.org/publications/jse/` has an extensive collection of data especially selected for educational purposes, and StatLib (at `http://lib.stat.cmu.edu`) has a large collection of datasets cited in the statistical literature, especially in textbooks for introductory statistics.

All these datasets have the disadvantage that the students “do not connect” with them. The author therefore since 10 years collects data from his students with a questionnaire and uses these data throughout the statistics courses. The questions are what one would expect: subject area, weight, size, size of parents, grades in some school subjects and so on. The advantage of using this data set is that for each analysis each student sees his or her place in the result, and therefore feels to have learned something about a group he or she belongs to. To the author’s experience the students become quite interested in the final report they have to produce, and sometimes they take the challenge of designing statistical questions which can be analyzed with this data set.

Information technology plays an important role in collecting these data quickly. If the group is small enough, a Palm handheld calculator with questionnaire software (Pendragon forms from Pendragon Software) is used to collect the data in the classroom. At the end of the class period, the handheld is connected to a notebook computer, the data are transferred, and then immediately a first step of the analyze can be performed in front of the students. The message of doing it this way is that collecting data can be set up quite conveniently, and therefore with good planning statistics be used very quickly. For larger classes, a browser based questionnaire is used. As part of this project, students also start asking questions about the privacy of their data and so are exposed to the problems of collecting data through their own experience as part of the course.

All the projects and tools so far mostly have been concerned with analyzing data. An important area in statistics education we have not considered yet is probability. This is the topic of the next section.

4 Learning probability for statistics

As most statistic teachers have experienced, probability is important as one of the foundations of statistics, but it is rather hard to teach if the students are supposed to learn more than just a few formulas. One of the main problems is that students may misunderstand probability as a somewhat strange packaging of combinatorics. Information technology in this case allows us to add something which is not so easy without computers: experiments through Monte Carlo simulation. Chapter 7 in [6] demonstrates the basic techniques of such simulations with spreadsheets. Again, the important message is that this can be done with readily available software.

The danger when using a Monte Carlo approach to teach probability is that students only learn that "computer generated randomness" behaves like probability theory predicts, and do not connect this with "everyday" randomness. Therefore, it is very important to perform experiments using physical randomness with a device like a Galton Board (sometimes called Quincunx) and then build a Monte Carlo simulation for the same phenomenon. Comparing the outcome of "real" randomness and simulated randomness can convince the students that computer simulations are close enough to reality and therefore problems which are more or less unaccessible for real experiments can be studied with Monte Carlo simulations.

A software category we have not discussed at all so far are CAS, Computer Algebra Systems. The most known programs in this category are Mathematica, Maple, MuPAD and Derive. There are special toolkits for doing statistics and probability with CAS, see for example [2] and [8]. The approach there is somewhat different from the spreadsheet approach. The CAS program is used as a specialized programming language, and the experiments are performed by using custom made functions in this programming language.

Monte Carlo Simulations can be considered as computer implementations for the law of large numbers. A difficult topic when dealing with probability is the relation between the law of large numbers and the central limit theorem. Using computers for both Mote Carlo simulations and numerical calculations of probabilities for sums of independent random variables allows to connect numerical-analytical models with simulated randomness and show that probability is able to model randomness reasonably well.

Once the trust in simulations is built, they can be used to empirically verify facts about statistical tests and confidence intervals. Without computers, it is practically impossible to illustrate concepts like the errors of first and second kind of a test and confidence levels of confidence intervals empirically. Monte Carlo simulations once again allow us to study the empirical error rates of simulated tests and compare them with the theoretical values.

Sampling also is a very important concept in statistics. In Monte Carlo simulations, the machinery in the background produces a sequence of numbers. It does not select from a given set, it produces a new number each time it is asked for one. We might say that the random number generator is spitting out an infinite sequence of random numbers. When sampling is investigated, it is very helpful if for experimental activities we can see the whole sample space and then select the sample from this set. Spreadsheets allow us to make this process very visual. From a didactical point of view, it seems very important to clearly model the process of selecting from a given well defined finite set and not blur the lines to the production of random numbers by some unpredictable machinery.

When probability is studied, combinatorics also has to be investigated. The relationship between probability and randomness is the equal probability assumption. This is something that cannot be proved analytically. Therefore, helping to build trust in the assumption is very important for the learner. Monte Carlo experiments can play a key role for that. In this area, computers cannot only be used for simulations, that also can play an important role in better understanding combinatorics.

Just read the following description: Let us build a table. The first column is filled with 1s. The rest of the first row is filled with 0s. All the other cells contain the sum of the number above and the number above and to the left. This is a complete and completely operational description of the binomials.

This description is not only a description, it is the complete instruction to compute the binomials with a spreadsheet. Additionally, it tells that each number in each row migrates down into the next row exactly twice, once vertically and once diagonally. therefore, row sums double from row to row and this description contains the proof of the fact that the row sums of the binomials are the powers of 2.

Expressing this more formally, the binomials can be described by a two term recursion. It turns out that this kind of recursion covers most of the combinatorics problems needed for basic probability models. Therefore, the table approach to combinatorics covers most of the ground needed in an introductory course. Once again, the readily available tool spreadsheet can be used to analyze structures, and to help understand concepts, not just as a more convenient kind of pocket calculator.

5 Some final thoughts

Statistics and probability have their origin in methodology to analyze empirical data and gain insights. So at the beginning of these subjects, there often is an experiment. Without computers, it is very hard to create this experiment based situation as a general setting. Some example highlight are possible, but overall statistics courses without computers are paper and pencil based theory courses (or not too interesting computations courses for very small data sets). With computers, we can analyze real or at least realistic data sets, and we can study probability also with an experimental approach. Therefore, for many learners who are not mostly interested in theory but in methods they can apply in their daily lives, this approach is much more promising than computer free statistics. As a consequence, it might be reasonable to avoid computers as an aid to learning in some specialized areas of statistics. But overall, information technology allows to make statistical concepts and methods both more accessible and more useful for a very wide audience.

EMBEDDING METHODS AND ROBUST STATISTICS FOR DIMENSION REDUCTION

George Ostrouchov and Nagiza F. Samatova

Key words: Dimension reduction, convex hull, FastMap, principal components, multidimensional scaling, robust statistics, Euclidean distance.

COMPSTAT 2004 section: Dimensional reduction.

Abstract: Recently, several non-deterministic distance embedding methods that can be used for fast dimension reduction have been proposed in the machine learning literature. These include FastMap, MetricMap, and SparseMap. Among them, FastMap, implicitly assumes that the objects are points in a p-dimensional Euclidean space. It selects a sequence of $k \leq p$ orthogonal axes defined by distant pairs of points (called pivots) and computes the projection of the points onto the orthogonal axes. We show that FastMap picks all of its pivots from the vertices of the convex hull of the data points in the original implicit Euclidean space. This provides a connection to results in robust statistics, where the convex hull is used as a tool in multivariate outlier detection and in robust estimation methods. The connection sheds a new light on some properties of FastMap and provides an opportunity for a robust class of dimension reduction algorithms that we call RobustMaps, which retain the speed of FastMap and exploit ideas in robust statistics. One simple RobustMap algorithm is shown to outperform principal components on contaminated data both in terms of clean variance captured and in terms of time complexity.

1 Introduction

Dimension reduction starts with n objects as points in a p-dimensional vector space and maps the objects onto n points in a k-dimensional vector space, where $k < p$. A more general situation arises when the point coordinates are not known and only pairwise distances (or a distance function to compute them) are available. This mapping of objects based on their distances only into a k-dimensional vector space is called finite metric space embedding [8]. Several embedding methods and their properties are discussed in [8], including FastMap, MetricMap, and SparseMap. The discussion centers mostly on whether the embeddings are contractive, a property of importance in similarity searching that guarantees no missed items. In this paper, we concentrate on FastMap and its properties that connect the technique to ideas in robust statistics.

FastMap is first introduced in [6] as a fast alternative to Multidimensional Scaling (MDS) [14] and a generalization of Principal Component Analysis (PCA) [9]. Given dimension k and Euclidean distances between n objects, FastMap maps the objects onto n points in k-dimensional Euclidean space. An implicit assumption by FastMap that the objects are points in a p-dimensional Euclidean space ($p \geq k$) is noted in [8]. Because of this assumption, FastMap is usually viewed as a dimension reduction method.

When FastMap begins with Euclidean distances between the n objects, it has time complexity $\mathrm{O}(n)$. If the Euclidean distances must be explicitly computed from a p-dimensional vector representation, FastMap time complexity is $\mathrm{O}(np)$.

We show how FastMap operates within the the implicit or explicit p-dimensional Euclidean space containing the points of a data set. FastMap selects a sequence of $k \leq p$ orthogonal axes defined by distant pairs of points (called pivots) and computes the projections of the points onto the orthogonal axes. We show that FastMap picks all of its pivots from convex hull vertices of the original data set. This provides a connection to results in robust statistics, where the convex hull is used as a tool in multivariate outlier detection and in robust estimation methods. The connection sheds a new light on some properties of FastMap, in particular its sensitivity to outliers, and provides an opportunity for a new class of dimension reduction algorithms that retain the speed of FastMap and exploit ideas in robust statistics.

We begin in Section 2 by defining the convex hull and some of its properties. In Section 3 we describe the FastMap algorithm. The main result, showing that FastMap pivots are pairs of vertices of the convex hull is in Secion 4. Section 5 discusses the implications of this result and finally Section 6 presents an algorithm, RobustMap, that results from these implications. Some further comments and conjectures about connections to QR and QLP factorizations [13] are also made.

2 Convex hull of a data set

Let S be a set of n points in p-dimensional Euclidean space. The convex hull of S, denoted by $C(S)$, is the smallest convex set (a polytope) that contains S [5], [7]. We can visualize a convex hull in two or three dimensions as a rubber band or an elastic bag stretched around the points. In higher dimensions, we must rely on more formal properties of hyperplanes, and the notion of half-space support. Our definitions below are mostly from [5], [7].

Definition 2.1. *A hyperplane is an affine subspace (a translation of a linear subspace) of* $\mathbf{R}^p$ *with dimension* $p-1$.

The set of points

$$h(u,v) = \{x \in \mathbf{R}^p : (u-v)^T(x-v) = 0\}, \text{for } u, v \in \mathbf{R}^p, \tag{1}$$

is a hyperplane perpendicular to the vector $u-v$ and passing through v. The *closed half-space* that is defined by this hyperplane and that contains u is given by

$$H(u, v) = \{x \in \mathbf{R}^p : (u - v)^T (x - v) \geq 0\}, \text{for } u, v \in \mathbf{R}^p, \tag{2}$$

Definition 2.2. *If S intersects $h(u, v)$ and S lies in $H(u, v)$ for some $u, v \in \mathbf{R}^p$, then $h(u, v)$ is a supporting hyperplane of S and $H(u, v)$ is a supporting half-space of S.*

We use Ziegler's [15, section 2.1] definition of a *face* of a polytope and state it in terms of a supporting hyperplane.

Definition 2.3. *A face of a polytope $C(S)$ is any set of the form*

$$C(S) \cap h(u, v),$$

where $h(u, v)$ is a supporting hyperplane of S for some $u, v \in \mathbf{R}^p$. Further, for a p-dimensional polytope, facets are $(p-1)$-dimensional, ridges are $(p-2)$ dimensional, edges are 1-dimensional, and vertices are 0-dimensional.

The above characterization of a vertex as a single point (a 0-dimensional face) of $C(S)$ that lies in the supporting hyperplane, will be used in Section 4 to link FastMap pivots to vertices of the convex hull.

3 FastMap overview

Given the Euclidean distance between any two points (objects) of S, k iterations of FastMap produce a k-dimensional ($k \leq p$) representation of S. Each iteration selects from S a pair of points, called *pivots*, that define an axis and computes coordinates of the S points along this axis. The pairwise distances for S can then be updated to reflect a projection of S onto the subspace (a hyperplane passing through the origin) orthogonal to this axis. The next iteration implicitly operates on the projected S in the subspace. However, these projections are accumulated and jointly performed only for the distances that are needed. In this manner, after k iterations, the S points end up with k coordinates giving their k-dimensional representation.

To provide details of the FastMap algorithm, we first introduce some notation. Let (a_i, b_i) be the pair of pivot elements from S at iteration i. Let $d_i(x, y)$ be the Euclidean distance between points x and y of S after their ith projection onto a pivot-defined hyperplane, so that $d_0(x, y)$ is the initial Euclidean distance. Also, let x_i be the ith coordinate of x in the resulting k-dimensional representation of $x \in S$.

Pivot elements are chosen by the *choose-distant-objects* heuristic shown in Fig. 1. Initially, $i = 0$. After selecting a pivot pair (a_i, b_i), the ith coordinate of each point $x \in S$ is computed as

$$x_i = \frac{d_{i-1}^2(a_i, x) + d_{i-1}^2(a_i, b_i) - d_{i-1}^2(b_i, x)}{2d_{i-1}(a_i, b_i)}. \tag{3}$$

```
Choose-distant-objects ( $S, d_i(,)$ )
  1. Choose an arbitrary object $s \in S$
  2. Let $a_{i+1}$ be the $a \in S$ that maximizes $d_i(a, s)$
  3. Let $b_{i+1}$ be the $b \in S$ that maximizes $d_i(b, s)$
  4. Report $a_{i+1}$ and $b_{i+1}$ as the distant objects.
```

Figure 1: Choose-distant-objects heuristic for iteration i.

This projection is based on the law of cosines and current distances from the two pivot points. The distances are updated whenever needed in *Choose-distant-objects* or in (3). An update for a single iteration is presented in [6] and we extend this in [1] to a combined update

$$d_i^2(x, y) = d_0^2(x, y) - \sum_{j=1}^{i} (x_j - y_j)^2. \tag{4}$$

This is based on the Pythagorean theorem and the sequence of i projections onto hyperplanes perpendicular to pivot axes.

There are k iterations, each requiring $\mathrm{O}(n)$ distance computations of $\mathrm{O}(p)$. The resulting total time complexity is $\mathrm{O}(npk)$. Note that if all the original distances are already available, the total time complexity is $\mathrm{O}(nk^2)$ due to the sum in (4). If k is a small constant compared to n and p, as is usually the case, k is dropped from the above complexity statements giving those we provided in the Introduction.

4 FastMap and vertices of the convex hull

Here we prove the main result of this paper, namely that all pivot points are selected from vertices of the convex hull of the data set. We do this in two steps. First we show that the *Choose-distant-object* heuristic pivot pair is a pair of convex hull vertices within the current working subspace. Then we show that if a point is a vertex in a subspace projection, it is also a vertex in the original p-dimensional space.

The *Choose-distant-objects* heuristic first takes an arbitrary point $b \in S$ and finds $a \in S$, the most distant point from b. Because a is the most distant point in S from b

$$(s - b)^T (s - b) \leq (a - b)^T (a - b), \forall s \in S. \tag{5}$$

Now, for any point $s \in S$ distinct from a, we have

$$\begin{aligned}
0 &< (s-a)^T(s-a) \\
&= (s-b+b-a)^T(s-b+b-a) \\
&= (s-b)^T(s-b) + 2(s-b)^T(b-a) + (b-a)^T(b-a) \\
&\leq 2(s-b)^T(b-a) + 2(b-a)^T(b-a) \qquad \text{by (5)} \\
&= 2(s-b+b-a)^T(b-a) \\
&= 2(s-a)^T(b-a) \qquad (6)
\end{aligned}$$

If we add $s = a$ in (6), we have

$$0 \leq (s-a)^T(b-a), \forall s \in S,$$

which defines a supporting half space $H(a, b)$ for all points in S. Since a is the only point in the supporting hyperplane $h(a, b)$ of S, it must be a single point face of $C(S)$. This, by Definition 2.3, is a vertex of $C(S)$.

Next, the *Choose-distant-objects* heuristic finds the point in S most distant from a. By the same argument this is again a vertex of $C(S)$. We state this as a lemma.

Lemma 4.1. *A single application of the* Choose-distant-objects *heuristic to a set of points S returns a pivot pair of points that are among the vertices of $C(S)$.*

After choosing a pair of vertices, FastMap projects the set S into a subspace orthogonal to the vector defined by the pivot pair (a, b) and repeats the *Choose-Distant-Objects* heuristic in the subspace of dimension $p - 1$. Pivot pairs and projections are computed until suitably many orthogonal vectors are extracted to be used as the principal axes of the lower dimensional representation of S. So far, we have shown that a pivot pair is a pair of convex hull vertices within its current working subspace. Are they all also vertices of $C(S)$ in the original space? The answer is yes, subject to a uniqueness caveat requiring that no pair of points (except the current pivot points) get projected onto the same point. Assuming that the points S are in sufficiently *general position* [15] takes care of this. Because we have a finite set of points, we can perturb them by an arbitrarily small amount to achieve such a general position. We show that a vertex in a subspace projection is a vertex in the original p dimensional space.

Let P_H be a symmetric projection matrix into a subspace $H \subset \mathbf{R}^p$ and let $S_H = \{P_H u : u \in S\}$ be the set of image points of S in this subspace. We also need to assume that S are in sufficiently general position so that all vertices of $C(S_H)$ are projections of distinct points of S.

Lemma 4.2. *If $P_H s$ is a vertex in the convex hull of S_H and S are in general position, then s is a vertex in the convex hull of S.*

Proof Since $P_H s$ is a vertex of $C(S_H)$, by Definition 2.3

$$P_H s = C(S_H) \cap h(u, v),$$

where $h(u, v)$ is a supporting hyperplane of $C(S_H)$ for some $u, v \in H$. Because $P_H s \in h(u, v)$, there is a $u' \in H$ such that $h(u, v) = h(u', P_H s)$. Now, $P_H s$ is the only point of S_H that is in the supporting hyperplane, so that

$$(u' - P_H s)^T (P_H x - P_H s) > 0,$$

for all $P_H x \in S_H$ distinct from $P_H s$. Because S are in general position,

$$(u' - P_H s)^T (P_H x - P_H s) > 0, \forall x \in S \text{ distinct from } s.$$

Then,

$$\begin{aligned}(u' - P_H s)^T [x - (I - P_H)x - s + (I - P_H)s] &> 0\\ (u' - P_H s)^T (x - s) - (u' - P_H s)^T (I - P_H)(x - s) &> 0.\end{aligned}$$

Since $P_H(u' - P_H s) = (u' - P_H s)$ (because $u' \in H$),

$$(u' - P_H s)^T (x - s) > 0, \forall x \in S \text{ distinct from } s.$$

Equality holds for $x = s$, so it is the unique point on this supporting hyperplane of S and thus it is a vertex of the convex hull of S. □

Letting $S_V \subseteq S$ be the vertices of $C(S)$, Lemmas 4.1 and 4.2 lead to the main result:

Theorem 4.1. *FastMap pivot pairs are a subset of the vertices of the convex hull of the data. That is,*

$$a_i, b_i \in S_V, \qquad i = 1, \ldots, k.$$

5 Implications

Convex hull computations in statistics are mostly associated with robust multivariate estimation. Loosely, an estimator of some parameter is said to be robust if it performs well even when the assumed model (implicit or explicit) is not satisfied by the data. For example, when estimating a location parameter, an implicit assumption is that the data are generated by one process that has a location. If more than one process generated the data, a robust estimator would still estimate the location of the dominant process rather than some meaningless location between the processes. The median, for example, is a robust estimator of location while the mean is not. A classic reference on robust estimation is [11].

The concept of *trimming* extremes is often used in reducing dependence on outliers in data [10]. Tukey is attributed with coining the term *peeling* as the multivariate extension of trimming [10], where one peels off the vertices of the convex hull before using the remaining points for estimating a location parameter. This is based on a generalization of the simple practice of removing the maximum and minimum before computing the mean, which dates at least to the early 19th century [10]. Here, with the aim of robustness, the very points on which FastMap depends are discarded! Clearly, FastMap is very sensitive to outliers in the data.

In situations where the data generation system is known to work smoothly, such as machine generated data, outliers may not be of concern. For example, we have recently found that in analyzing climate simulation and astrophysics simulation data, methods that are sensitive to extremes often produce the most compelling results. Here, the extremes are not outliers and may be of most interest. On the other hand, massive data sets are often the result of a long run with several checkpoint restarts where anomalies may occur. For example, in [4], instrument generated Atmospheric Radiation Measurement data [2] contains many instrument restarts that appear as zeros in data with high positive values. Although it is easy to discover these, an automated application of FastMap would be driven by the zero coordinate outliers. Clearly, there are situations where an extremes-sensitive method like FastMap is appropriate or even preferable as well as situations where it will fail.

Outlier sensitivity of FastMap is mentioned in [8] and PCA is presented as more robust. Although PCA is less sensitive to outliers than FastMap, it too is not considered a robust technique. A measure of estimator sensitivity to changes in extreme values of data is the notion of *breakdown point* [3]. Loosely speaking, the breakdown point is the smallest proportion of data that needs to be contaminated to make arbitrarily large changes to the estimator. By this definition, the breakdown point of FastMap is $\frac{1}{n}$, which is asymptotically zero. Principal Components Analysis, the most popular dimension reduction method, also has a breakdown point of $\frac{1}{n}$. In both cases, taking one point arbitrarily far in some direction will rotate the first axis in that direction. Some robust PCA methods begin by computing a robust covariance matrix estimate then proceeding with standard PCA as usual. The classical example of a high breakdown estimator is the median with a .5 breakdown point. That is, half of the data must be moved to make an arbitrarily large change in the median. A multivariate extension of the median is proposed in [12]. This extension uses the notion of half-space support to define the *depth* of a data point so that, ignoring ties, the point with maximal depth is the multivariate median.

The main lesson from robust statistics is that the most distant points are often not the best choice for defining a projection axis. The key to new fast and robust methods is a replacement of the *Choose-distant-object* heuristic by something that considers more than just the maximum distance from a point. One should back-off a little from the maximum, while considering the entire distance distribution. This distribution is already available within the $\mathrm{O}(np)$

complexity. A closer examination, even with more complex algorithms such as clustering, of the distance distribution tail can yield much more robust results, still within the O(np) complexity. In fact, such methods will be more robust than standard PCA. Clearly there are many directions that this methodology can be taken and undoubtedly many such algorithms will be proposed. We provide a simple example in the section that follows.

We would like to note another implication on an algorithm, DFastMap [1], that we recently developed for fast dimension reduction across distributed data sets. Our initial insights that lead to DFastMap produced the main idea for the present paper. Formalizing the convex hull connection to FastMap gives an explanation of why an application of DFastMap to distributed data performs as well as the serial FastMap on a centralized data set. The union of local convex hull vertices necessarily includes all convex hull vertices of the centralized data set. This assertion can be proved using arguments similar to those we used in Section 4. DFastMap centralizes the pivots, arguably a very good subset of the local convex hull vertices (see [1] for more details). This provides a key subset of the combined data convex hull vertices so that little information about extremes is lost when compared to centralizing all the data.

Finally, we also mention an implication on complexity of FastMap and convex hull computations. Because all the FastMap projection axes are computed from points in S_V, the convex hull vertices are sufficient for all distant point searches. Clearly FastMap could be faster if S_V were available. Erickson [5] reports that finding S_V by the "gift-wrapping" algorithm takes O(nf) time, where $f = |S_V|$ is the number of vertices. Since FastMap completes in O(np) time, this is not helpful as $f > p$ for any non-degenerate data sets.

6 A RobustMap algorithm

The FastMap algorithm computes all distances from one object but uses only the maximum, resulting in an outlier-sensitive method. From a statistical viewpoint the distribution of the distances contains information on potential outlier candidates. In essence, we are trimming the extremes of this distance distribution. A complication is that two objects with a similar distance to the reference object can be very far apart in the full p-dimensional space. Selecting a small number of extreme objects and clustering them in the full p-dimensional space, can provide much more information on a robust choice of a distant object. Keeping the selection of a few objects fast and their number small lets us remain within the $O(np)$ time complexity of FastMap.

We provide a simple variant of this idea. Take a constant number, say $r \ll n$, largest distances, cluster the corresponding objects, and choose a central point of the largest cluster as a pivot. This affords protection against a small number, about $r/2$, outliers. Fig. 2 gives the choose-distant-objects heuristic for RobustMap. The parameter r can be some small number that depends on the level of contamination we expect in the data. A second pa-

```
RobustMap: Choose-distant-objects ( $S, d_i(,)$ )
  1. Choose an arbitrary object $s \in S$
  2. Select $r$ largest distances in $d_i(a, s)$
  3. Cluster the $r$ corresponding objects.
  4. Let $a_{i+1}$ be the object nearest the center of the largest cluster.
  5. Similarly, choose $b_{i+1}$ as above, replacing $s$ with $a_{i+1}$.
  6. Report $a_{i+1}$ and $b_{i+1}$ as the distant objects.
```

Figure 2: RobustMap Choose-distant-objects heuristic for iteration i.

rameter controls the number of clusters. Clusters can be considered different at some fixed percentage of the largest distance. Our prototype implementation in R uses single linkage clustering, where a distance of more than 10% of the maximum distance implies a separate cluster.

To test the behavior of RobustMap, we use the Longley data in R and add an observation that blends the origin and the first observation. This is a small data set, but it allows us to move the outlier in and out of the data and quickly explore the behavior of RobustMap, PCA, and FastMap on the contaminated data. To measure the effect of the contamination, we report captured variability within the clean data, while giving the contaminated data to the algorithm. Our reference is PCA on the clean data. Fig. 3 shows typical results and we discuss how the outlier position and non-determinism of RobustMap and FastMap affect the results.

As the outlier moves farther from the data, the FastMap and PCA lines move together but remain well below RobustMap. This is reasonable, as both are highly affected by outliers. The non-determinism of RobustMap and FastMap does not change the order of the methods in Fig. 3 with RobustMap leading and FastMap coming last. Half of a 95% confidence interval around RobustMap would roughly fill the distance between the Reference and RobustMap.

Other, more complex and more robust approaches can consider a multivariate distance distributions from two or more objects. Formal tests may be developed on the basis of distributional assumptions for the objects and derivations of the resulting distance distributions. At the same time, more thorough testing is needed to explore aspects beyond capture of variability. For example, RobustMap projections are different from PCA and can provide alternate data views based on distance distributions.

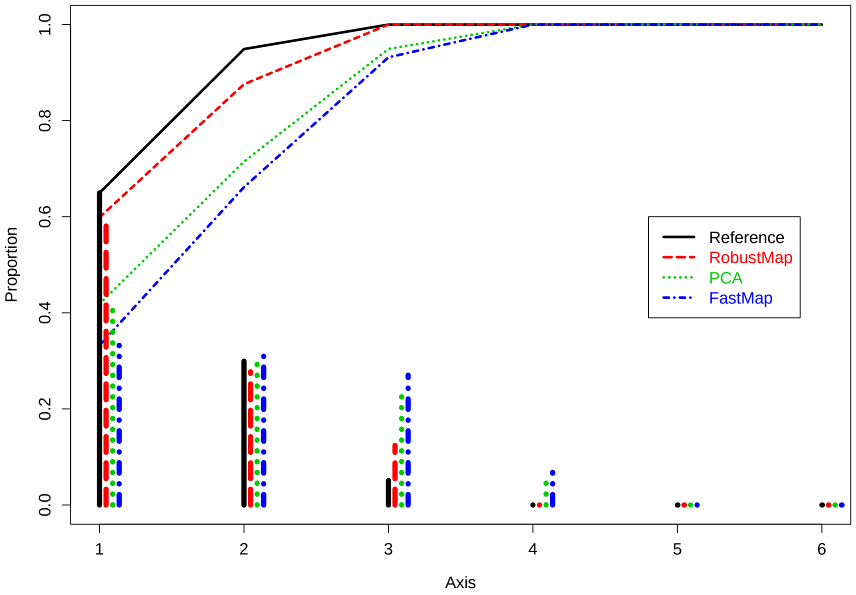

Figure 3: Proportion of clean variability captured by each component axis, when presented with contaminated data. Reference is PCA on clean data only.

We also see some preliminary evidence that these methods are related to pivoting strategies in QR factorization and the recent QLP factorization [13] that provides a fast approximation for the Singular Value Decomposition. Our prototype implementation of RobustMap and FastMap differs from the original [6] by using Householder reflections applied to the rows, somewhat like the QLP factorization. We conjecture that FastMap, RobustMap, and their connection to the convex hull provide a geometric explanation for the success of QLP factorization and may be sources of new pivoting strategies for QR factorization. This is another direction where these methods may provide new insights.

A GENERAL PARTITION CLUSTER ALGORITHM

Daniel Peña, Julio Rodríguez and George C. Tiao

Key words: Predictive distribution, robust estimation, SAR procedure.

COMPSTAT 2004 section: Clustering.

Abstract: A new cluster algorithm based on the SAR procedure proposed by Peña and Tiao [9] is presented. The method splits the data into more homogeneous groups by putting together observations which have the same sensitivity to the deletion of extreme points in the sample. As the sample is always split by this method the second stage is to check if observations outside each group can be recombined one by one into the groups by using the distance implied by the model. The performance of this algorithm is compared to some well known cluster methods.

1 Introduction

Finding groups in data is a key activity in many scientific fields. Gordon [8] is a good general reference. Classical Partition and Hierarchical algorithms have been very useful in many problems but they have some four main limitations. First, the criteria used are not affine equivariant and therefore the results obtained depend on the changes of scale and/or rotation applied to the data. Second, the usual heterogeneity measures based on the Euclidian metric do not work well for highly correlated observations forming elliptical clusters or when the clusters overlap. Third, we have to specify the number of clusters or decide about the criteria for choosing them. Fourth, there is no general procedure to deal with outliers. Some advances have been made to solve these problems, see [4], [5] and [16].

An alternative approach to cluster is to fit mixture models. This idea has been explored both from the classic and Bayesian point of view. Banfield and Raftery [3] and DasGupta and Raftery [6] have proposed a model-based approach to clustering which finds an initial solution by hierarchical clustering and then assumes a mixture of normals model and uses the EM algorithm to estimate the parameters. A clear advantage of fitting normal mixtures is that the implied distance is the Mahalanobis distance, which is affine equivariant. From the Bayesian point of view the parameters of the mixture are estimated by Markov Chain Monte Carlo methods and several procedures have been proposed to allow for an unknown number of components in the mixture, see [12] and [14]. A promising approach to cluster analysis, that can avoid the curse of dimensionality, is projection pursuit, where low-dimensional projections of the multivariate data are used to provide the most interesting views of the full-dimensional data. Peña and Prieto [11] have proposed an algorithm where the data is projected on the directions of maximum heterogeneity defined as those directions in which the kurtosis coefficient of the projected data is maximized or minimized. Then they used the spacings to search for clusters on the univariate variables obtained by these projections.

Finally, Peña and Tiao [9] propose the SAR (split and recombine) procedure for detecting heterogeneity in a sample with respect to a given model. This procedure is general, affine equivariant, does not require to specify a priori the number of clusters and it is well suited for finding the components in a mixture of models. The idea of the procedure is first to split the sample into more homogeneous groups and second recombine the observations one by one in order to form homogeneous clusters. The SAR procedure has two important properties, that are not shared by many of the most often used cluster algorithms, (i) it does not require an initial starting point, (ii) each homogeneous group is obtained independently from the others, so that each group does not compete with the others to incorporate an observation. The first property implies that the algorithm we propose can be used as a first solution for any other cluster algorithm, the second, that the procedure may work well even if the groups are not well separated. This paper analyzes the application of the SAR procedure to cluster analysis and it is organized as follows. Section 2 presents the main ideas of the procedure. Section 3 compares it in a Monte Carlo study to Mclust (Model Based Cluster, [7], k-means, pam (Partition around medoids, [15] and Kpp (Kurtosis projection pursuit, [11].

2 The SAR procedure

Suppose we define a measure $H(x, X)$ of the heterogeneity between an observation, x, and a set of data, X. We are going to use this measure to split the sample iteratively into homogeneous groups and to recombine observations into the groups. We assume that the heterogeneity measure $H(x, X)$ is equivariant, that is invariant to linear transformations, and is coherent with the assumed model. As the true structure of the data is unknown, we start the process by assuming that the data is homogeneous, and have been generated by a normal distribution, $N_p(\boldsymbol{\mu}, \mathbf{V})$. Then we propose a heterogeneity measure based on out of sample prediction as follows. The predictive distribution for a new observation $\mathbf{x}_f$ generated by a normal model using a Jeffrey's prior $p(\boldsymbol{\mu}, \mathbf{V}) \propto |\mathbf{V}|^{-(p+1)/2}$ is (see for instance, [2] $p(\mathbf{x}_f, \mathbf{X}) \propto \left(1 + \frac{Q_f}{n-p}\right)^{-n/2}$, where $Q_f = \frac{n}{n+1}(\mathbf{x}_f - \bar{\mathbf{x}})'\hat{\mathbf{V}}^{-1}(\mathbf{x}_f - \bar{\mathbf{x}})$ and $\bar{\mathbf{x}}$ is the sample mean and $\hat{\mathbf{V}}$ the sample covariance matrix, given by $\hat{\mathbf{V}} = (\mathbf{X} - \mathbf{1}\bar{\mathbf{x}})'(\mathbf{X} - \mathbf{1}\bar{\mathbf{x}})/(n-p)$. Following Peña and Tiao [9] we will use as measure of heterogeneity of a data $\mathbf{x}_i$ with respect to a group $\mathbf{X}_{(i)}$ which does not contain this observation, the standardized predictive value given by

$$H(\mathbf{x}_i, \mathbf{X}_{(i)}) = -2 \ln \left\{ \frac{p(\mathbf{x}_i|\mathbf{X}_{(i)})}{p(\hat{\mathbf{x}}_{i(i)}|\mathbf{X}_{(i)})} \right\} = (n-1) \ln \left\{ 1 + \frac{Q_{i(i)}}{(n-1)-p} \right\}, \quad (1)$$

where $Q_{i(i)} = \frac{n-1}{n}(\mathbf{x}_i - \bar{\mathbf{x}}_{(i)})'\hat{\mathbf{V}}_{(i)}^{-1}(\mathbf{x}_i - \bar{\mathbf{x}}_{(i)})$, and $\hat{\mathbf{V}}_{(i)}$ and $\bar{\mathbf{x}}_{(i)}$ are the covariance matrix and the mean computed using the sample $\mathbf{X}_{(i)}$ without the case i*th*. Note that $H(\mathbf{x}_i, \mathbf{X}_{(i)})$ is a monotonic function of the Mahalanobis distance $Q_{i(i)}$, which is usually used to check the heterogeneity of a point $\mathbf{x}_i$ with respect to the sample $\mathbf{X}_{(i)}$.

The splitting of the sample is made as follows. For each observation, $\mathbf{x}_i$, we define the discriminator of this point as the observation which, when deleted from the sample, makes the point $\mathbf{x}_i$ as heterogeneous as possible with the rest of the data. The discriminator of $\mathbf{x}_i$ is the point $\mathbf{x}_j$ if

$$\mathbf{x}_j = \arg\max_{x_k} H(\mathbf{x}_i, \mathbf{X}_{(ik)}) = \arg\max_{x_k} (\mathbf{x}_i - \bar{\mathbf{x}}_{(ik)})'\hat{\mathbf{V}}_{(ik)}^{-1}(\mathbf{x}_i - \bar{\mathbf{x}}_{(ik)}),$$

where $\mathbf{X}_{(ik)}$ is the sample without the cases i*th* and k*th*.

Each sample point must have a unique discriminator, but several sample points may share the same discriminator. It can be proved (see [10]) that the discriminators are members of the convex hull of the sample. That is, a discriminator must be an extreme point. An intuitive procedure to split the sample into groups is to put together observations with share the same discriminators, as they are affected in the same way to modifications of the sample by deleting some extreme values. It is obvious that if two observations are identical they will have the same discriminator and if they are close they also will have the same discriminator. The number of points in the sample which share the same discriminator is called the order of the discriminator. We consider as special points discriminators of order larger than K, where $K = f(p, n)$ and we will put them in a special group of extreme observations. However, discriminators of order smaller than K are considered as usual points and are assigned to the group defined by all the observations that share a common discriminator. We need to define the minimum size of a set of data to be considered as a group. We will say that we have a group if we could compute the mean and covariance matrix of the group and, therefore, the minimum group size must be $n_0 = p + h$, where $h > 0$, and p is the number of variables. Usually $h = f(p, n)$ and in the examples we have taken $h = \log(n - p)$. In the procedure which follows we have considered as special points to those discriminators of order larger that K, where $K = p + h - 1$. This value seems to work well in the simulations we have made. Based on these considerations the sample is split as follows: 1) Observations which have the same discriminator are put in the same group, the discriminator is only included in the group if it has order smaller than K; 2) Discriminators of order bigger that K are allocated to a specific group of isolated points; 3) if two groups formed by the previous rules have any observation in common the two groups are joined into one group. This three rules split the sample into more homogeneous groups. Each group is now considered as a new sample and the three rules are applied again until splitting further the sample will lead to isolated points because the groups obtained are all of them of size smaller than the minimum group size n_0. A group of data is called basic group if when split will lead to subgroups of size smaller than the minimum size, $p + h$.

When the sample cannot be split further the recombining process is applied starting from any of the basic groups obtained. The recombining process is the one suggested by Peña and Tiao [9]. Each group is enlarged by incorporating observations one by one. For a given group, we begin by testing the observation outside the group which is the closest to the group in terms of the measure $H(y_f, X_g)$, where y_f is the observation outside the group formed by data X_g. If $H(y_f, X_g)$ is smaller than some cut-off value, that is the 99th percentile of the distribution of the statistic $H(y_f, X_g)$, this observation is incorporated into the group and the process of testing the closest observation to the group is repeated for the enlarged group. The enlarging process will continue until either the threshold is crossed or the entire sample is included. A similar idea of recombining points has been used for robust estimation (see for instance, [1]. We may have one of the three possible cases. First, the enlarging of all the basic groups leads to the same group which include all the observations apart from some outliers. Then we have a homogeneous sample with some isolated outliers and the procedure ends. Second, the enlarging of the basic groups leads to a partition of the sample into disjoint groups and we conclude we have some groups in the data and again the procedure ends. Third, we obtain more than a possible solution because the partition obtained is different when starting from different basic groups. Then we have more than one possible solution and the final solutions found are called possible data configurations, PDC. The selection among them is made by a model selection criterion.

3 Monte Carlo results

The properties of the algorithm have been studied in a Monte Carlo experiment, similar to the one used by Peña and Prieto [11] to illustrate the behavior of their cluster procedure. Sets of $10 \times p \times k$ random observations in dimension $p = 2, 4, 8$ have been generated from a mixture of $k = 2, 4$ components of a multivariate distributions. In all data sets the number of observations from each distribution has been determined randomly, but ensuring that each cluster contains a minimum of $p+1$ observations. The mean for each distribution is chosen at random from the multivariate normal distribution $N_p(\mathbf{0}, f\mathbf{I})$. The factor f (see Table 1) is selected to be as small as possible while ensuring that the probability of overlapping between groups is roughly equal to 0.01. We generated data sets in six different scenarios.

a) Mixture of k multivariate normal distributions. In each group the covariance matrix is generated as $\mathbf{S} = \mathbf{UDU}'$, from a random orthogonal matrix $\mathbf{U}$ and a diagonal matrix $\mathbf{D}$ with entries generated from a uniform distribution (a1): $[10^{-3}, 5\sqrt{p}]$, so that the covariance matrices are well conditioned, and (a2): $[10^{-3}, 10\sqrt{p}]$, so that the covariance matrices are ill-conditioned.

b) Mixture of k multivariate uniform distributions with (b1) covariance generated as (a1) and (b2) covariance generated as (a2).

c) Mixture of k multivariate normal distributions generated as indicated in scenario a1), but 10% of the data are outliers (c1): generated by $N_p(\mathbf{0}, f\mathbf{I})$ and (c2): for each cluster in the data, 10% of its observations have been generated as a group of outliers at a distance $4\chi^2_{p,0.99}$ in a group along a random direction, and a single outlier along another random direction.

a1) Covariance matrices well conditioned							
p	k	f	SAR	Kpp	k-means	Mclust	`pam`
2	2	55	**1.65**	7.33	45.35	16.73	34.98

4	2	14	**4.83**	9.90	47.15	12.38	32.11
	4	20	**5.58**	9.39	27.20	6.75	10.76
8	2	12	15.43	13.13	43.29	**12.28**	55.61
	4	18	7.52	12.58	15.81	**3.75**	14.42
Average			**6.05**	8.88	33.95	8.90	24.96
a2) Covariance matrices ill-conditioned							
p	k	f	SAR	Kpp	k-means	Mclust	`pam`
2	2	55	**1.58**	9.38	46.38	14.23	33.95
	4	140	1.00	0.61	25.14	**0.60**	1.83
4	2	14	**0.99**	4.96	48.54	11.64	32.89
	4	20	**1.39**	5.07	30.99	6.55	5.38
8	2	12	**0.64**	5.19	44.83	0.66	50.94
	4	18	**0.87**	6.01	22.92	4.36	11.01
Average			**1.08**	5.20	36.47	6.34	22.66

Table 1: Percentages of mislabeled observations for the SAR, the Kpp, the k-means, the Mclust and the `pam` procedures. Normal observations with: (a1) covariance matrices well conditioned, (a2) covariance matrices ill-conditioned. The best method in each case is indicated in boldface.

To provide better understanding of the behavior of the new procedure, in each table we compare the proposed method with Kpp, k-means, Mclust and the `pam` algorithm. The Mclust algorithm has been run with the function 'EMclust' with models EI, VI, EEE, VVV, EEV and VEV and number of cluster between 1 to 8 and the final configuration is selected by the BIC (see [7], for a description of different models used in the function 'EMclust'). The rule to select the number of clusters in the algorithm `pam` is the maximum of the silhouette statistic for $k = 1, \ldots, 8$ and in k-means the stopping rule used is the one proposed by Calinski and Harabasz.

Table 1 gives the average percentage of observations which have been labeled incorrectly in scenarios a1) and a2), obtained from 200 replications for each value in the same data sets in all procedures. In scenario a1) the SAR procedure has the best performance, and Kpp and Mclust are second having a similar behavior. In the scenario a2) when the covariance matrix is ill-conditioned, the SAR procedure is again the best followed by Kpp and Mclust. This result is quite consistent as the SAR procedure is the best in eight out of the twelve comparison included in the two scenarios of Table 1 and in the four cases in which it is not the best it is not far from the best one. The k-means and `pam` show a poor result.

b1) Covariance matrices well conditioned							
p	k	f	SAR	Kpp	k-means	Mclust	`pam`
2	2	55	**0.45**	11.53	51.40	21.08	44.75
	4	140	**0.58**	0.38	29.25	0.84	1.16
4	2	14	**0.85**	4.81	51.71	12.48	51.41
	4	20	**1.58**	4.33	33.15	9.11	7.68
8	2	12	6.24	**5.45**	41.83	7.38	60.80
	4	18	**2.33**	4.93	20.07	5.58	16.93
Average			**2.00**	5.24	37.90	9.41	30.46
b2) Covariance matrices ill-conditioned							
p	k	f	SAR	Kpp	k-means	Mclust	`pam`
2	2	55	**1.55**	11.78	48.65	20.53	41.95
	4	140	**0.56**	0.99	34.30	1.75	2.06
4	2	14	**0.79**	4.06	53.23	6.00	46.45
	4	20	**0.38**	3.13	34.39	7.54	7.28
8	2	12	0.34	5.76	45.96	**0.00**	62.13
	4	18	**0.46**	4.21	27.32	4.74	12.61
Average			**0.68**	4.99	40.64	6.76	28.75

Table 2: Percentages of mislabeled observations for the SAR, the Kpp, the k-means, the Mclust and the `pam` procedures. Uniform observations with: (b1) covariance matrices well conditioned, (b2) covariance matrices ill-conditioned.

Table 2 shows the outcome for scenarios b1) and b2) where we analyze the same structure that in scenarios a1) and a2) but now using mixtures of uniform distributions. Table 2 shows the percentages of mislabeled observations for both scenarios b1) and b2). The behavior of the SAR procedure is again the best as an average and the best in ten of the twelve cases. The second best behavior corresponds to Kpp, that is better than Mclust in eleven out of the twelve cases.

c1) Non concentrated contaminations							
p	k	f	SAR	Kpp	k-means	Mclust	`pam`
2	2	55	1.25	**0.68**	3.00	6.47	0.69
2	4	140	**0.83**	1.30	12.31	3.50	2.85
4	2	14	8.58	9.46	14.55	**6.71**	7.21
4	4	20	5.66	11.89	22.64	**5.27**	6.13
8	2	12	12.64	14.48	16.88	**12.58**	16.46
8	4	18	9.47	16.67	44.08	6.78	**4.59**
Average			6.40	9.08	18.91	6.89	**6.32**
c2) Concentrated contaminations							
p	k	f	SAR	Kpp	k-means	Mclust	`pam`
2	2	55	**0.98**	4.03	26.25	12.61	17.50
2	4	140	**0.40**	0.65	12.88	0.49	2.04
4	2	14	**3.58**	6.29	35.46	17.90	28.46
4	4	20	**3.21**	10.01	17.69	15.47	7.50
8	2	12	15.03	**13.41**	38.66	23.42	53.08
8	4	18	8.15	13.73	17.72	**6.93**	14.71
Average			**5.22**	8.02	24.78	12.80	20.55

Table 3: Percentages of mislabeled observations for the SAR, the Kpp, the k-means, the Mclust and the `pam` procedures. Normal observations with 10% the outliers: (c1) non concentrated contaminations, (c2) concentrated contaminations.

A final simulation study has been conducted (see Table 3) to determine the behavior of the methods in the presence of outliers. Scenarios c1) and c2) contain 10% of data contaminated by first, a non concentrate contamination, and second, a concentrated contamination defined in scenario c). The criterion to obtain the mislabeled observation is based only in the 90% of observations not contaminated. Table 3 shows the percentage of mislabeled observations for the scenarios c1) and c2). The maximum number of clusters k have been increase to ten in the algorithms k-means, Mclust and `pam` so that the concentrated contamination can be considered as isolated clusters. In the scenario c1) the best methods, as an average, are, with very small difference, the `pam` algorithm and the SAR procedure. However, for concentrated contamination, scenario c2), the SAR procedure is again clearly the best followed by Kpp. As a summary of this Monte Carlo study we may conclude that the SAR procedure has the smallest error classification rate in

22 out of the 36 situations considered and the best average number of mislabeled observations in 5 scenarios out of the six considered. The only scenario in which the SAR is not the best is in scenario c1) but the difference with respect to the best method, `pam`, is very small: misclassification percentage of 6.4% versus 6.32% for pam. The Kpp is the second best in five out of the six scenarios. Ordering the methods for average classification errors in all the scenarios from better to worse, the order would be: SAR, Kpp, Mclust, `pam` and k-means.

ITERATIVE DENOISING FOR CROSS-CORPUS DISCOVERY

Carey E. Priebe, David J. Marchette, Youngser Park, Edward J. Wegman, Jeffrey L. Solka, Diego A. Socolinsky, Damianos Karakos, Ken W. Church, Roland Guglielmi, Ronald R. Coifman, Dekang Lin, Dennis M. Healy, Marc Q. Jacobs, Anna Tsao

Key words: Text document processing, statistical pattern recognition, dimensionality reduction.

COMPSTAT 2004 section: Dimensional reduction, Classification.

Abstract: We consider the problem of statistical pattern recognition in a heterogeneous, high-dimensional setting. In particular, we consider the search for meaningful cross-category associations in a heterogeneous text document corpus. Our approach involves "iterative denoising" — that is, iteratively extracting (corpus-dependent) features and partitioning the document collection into sub-corpora. We present an anecdote wherein this methodology discovers a meaningful cross-category association in a heterogeneous collection of scientific documents.

1 Introduction

The "integrated sensing and processing decision trees" introduced in [9] proceed according to the following philosophy. Assume that there is a heterogeneous collection of entities $\mathcal{X} = x_1, \cdots, x_n$ which can, in principle, be measured (sensed) in a large number of ways. Because the sensor cannot make all measurements simultaneously — either due to physical sensor constraints or because of the high intrinsic dimension of the complete feature collection — only a subset of the possible measurements is to be made at any one time.

Thus, for the entire entity collection $\mathcal{X}$ a first set of measurements is made. Based on the features obtained, $\mathcal{X}$ is partitioned into $\{\mathcal{X}_1, \cdots, \mathcal{X}_{J_1}\}$, each $\mathcal{X}_{j_1}$ being (presumably) more homogeneous than the original entity collection $\mathcal{X}$. Then, for each partition cell $\mathcal{X}_{j_1}$ a new set of measurements is considered. This process continues, generating branches consisting of "iteratively denoised" entity collections $\{\mathcal{X}_{j_1 1}, \cdots, \mathcal{X}_{j_1 J_2}\}$, $\{\mathcal{X}_{j_1 j_2 1}, \cdots, \mathcal{X}_{j_1 j_2 J_3}\}$, and so forth, until a collection (say, $\mathcal{X}_{j_1 j_2 j_3}$) is deemed sufficiently coherent for inference to proceed. Such collections are the leaves of the tree.

2 Iterative denoising for cross-corpus discovery

The example application we consider herein is that of discovering meaningful associations in a heterogeneous text document corpus. See, for example, [1] for a survey of text mining.

2.1 Feature extraction & dimensionality reduction

Let C be a collection of text documents. The corpus-dependent feature extraction of Lin & Pantel [6], [8] can be described as

$$\mathcal{L}_C(\cdot) : \mathcal{D}\text{ocument}\mathcal{S}\text{pace} \to [\mathcal{M}\text{utual}\mathcal{I}\text{nformation}\mathcal{F}\text{eature}]^{d_{\mathcal{L}}(C)}.$$

Both the features themselves and the number of features $d_{\mathcal{L}}(C)$ depend on the corpus C. Thus $\mathcal{L}_C(C)$ is a $|C| \times d_{\mathcal{L}}(C)$ *mutual information feature matrix*. Each of the features is associated with a word (after stemming and removal of stopper words), as follows. For document x in corpus C, and associated word w, the mutual information between x and w is given by

$$m_{x,w} = \log\left(\frac{f_{x,w}}{\sum_{\xi} f_{\xi,w} \sum_{\omega} f_{x,\omega}}\right).$$

Here $f_{x,w} = c_{x,w}/N$ where $c_{x,w}$ is the number of times word w appears in document x and N is the total number of words in the corpus C. This information is discounted to reduce the impact of infrequent words via

$$\tilde{m}_{x,w} = m_{x,w} \cdot \frac{c_{x,w}}{1 + c_{x,w}} \cdot \frac{\min(\sum_{\xi} c_{\xi,w}, \sum_{\omega} c_{x,\omega})}{1 + \min(\sum_{\xi} c_{\xi,w}, \sum_{\omega} c_{x,\omega})}.$$

The *mutual information feature vector*, then, for document x in corpus C, is given by

$$e_x = \mathcal{L}_C(x) = [\tilde{m}_{x,w_1}, \cdots, \tilde{m}_{x,w_{d_{\mathcal{L}}(C)}}].$$

Given two documents $x, y \in C$, the distance (we use the term loosely; it is in fact a pseudo-dissimilarity) employed, ρ, is given by

$$\rho(x, y) = 1 - (e_x \cdot e_y)/(||e_x||_2||e_y||_2) \in [0, 2].$$

Thus

$$\rho \circ \mathcal{L}_C(C)$$

is a $|C| \times |C|$ *interpoint distance matrix*. All subsequent processing will be based on these interpoint distances, as discussed in [7]. However, the features, and hence the interpoint distances themselves, are *corpus dependent* and so, as the iterative denoising tree is built, based on the evolving partitioning, these distances change.

Multidimensional scaling [2] is used to embed the interpoint distance matrix $\rho \circ \mathcal{L}_C(C)$ into a Euclidean space $\mathbb{R}^{d_{mds}(C)}$. Notice first that, if the feature vectors were Euclidean — that is, if we were using an actual distance in the $d_{\mathcal{L}}(C)$-dimensional space — then the features could be represented *with no distortion* in $\mathbb{R}^{d_{\mathcal{L}}(C)-1}$. Alas, they are not, and cannot be. So

$$mds \circ \rho \circ \mathcal{L}_C(C)$$

is a $|C| \times d_{mds}(C)$ *Euclidean feature matrix* representing the corpus C. The choice of $d_{mds}(C)$ represents a distortion/dimensionality tradeoff.

Finally, the Euclidean representation $mds \circ \rho \circ \mathcal{L}_C(C)$ produced by multidimensional scaling is reduced, via principal component analysis [5], to a lower dimensional space for subsequent processing. Again we face a model selection choice of dimensionality. The combination feature extraction/dimensionality reduction we propose, then, is given by

$$pca \circ mds \circ \rho \circ \mathcal{L}_C(C),$$

yielding a $|C| \times d_{pca}(C)$ *LSI feature matrix* which can be seen as akin to a (generalized) latent semantic indexing (LSI) [4].

2.2 Science news corpus

A heterogeneous corpus of text documents obtained from the Science News web site is used in this example. The Science News (SN) corpus C consists of $|C| = 1047$ documents in eight classes. Table 1 provides a breakdown of the corpus by number of documents per class. Our goal is two find two documents in different classes which have a meaningful association.

Class	**Number of Documents**
Anthropology	54
Astronomy	121
Behavioral Sciences	72
Earth Sciences	137
Life Sciences	205
Math & CS	60
Medicine	280
Physics	118

Table 1: Science News corpus.

For this Science News corpus C, feature extraction via $\mathcal{L}_C(C)$ yields a feature dimension $d_{\mathcal{L}}(C) = 10906$. That is, there are 10906 distinct meaningful words in the corpus, and the Lin & Pantel feature extraction produces a 1047×10906 feature matrix.

Multidimensional scaling (Figure 1, left panel) on the 1047×1047 interpoint distance matrix $\rho \circ \mathcal{L}_C(C)$ yields $d_{mds}(C) = 898$. (Numerical issues in the multidimensional scaling algorithm make 898 the largest dimension into which the interpoint distance matrix can be embedded. So, while Figure 1

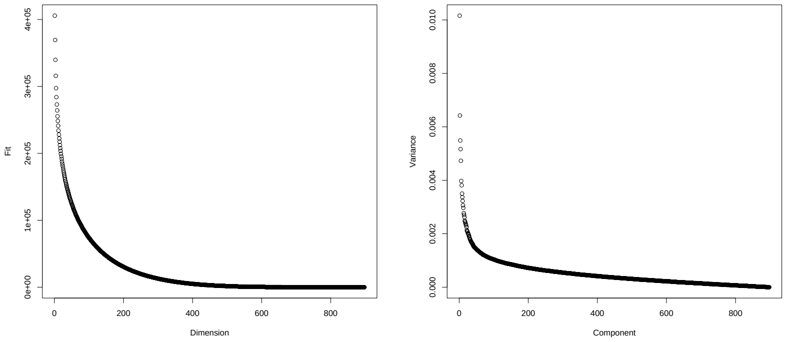

Figure 1: Multidimensional scaling (left panel) for the original 1047 10906-dimensional SN feature vectors. The largest numerically stable multidimensional scaling embedding is $d_{mds}(C) = 898$. (This left curve suggests that perhaps 200, and certainly 400 dimensions is sufficient to adequately fit the documents into Euclidean space.) Principal components (right panel) for the 898-dimensional Euclidean embedding of the original 1047 10906-dimensional SN feature vectors. (The "elbow" of this scree plot occurs, perhaps, in the range of 10-50 principal components.)

suggests that perhaps 200, and certainly 400 dimensions is sufficient to adequately fit the documents into Euclidean space, we avoid the first model selection quandary by choosing the largest numerically stable multidimensional scaling embedding.)

A subsequent principal component analysis of the 898-dimensional Euclidean features $mds \circ \rho \circ \mathcal{L}_C(C)$ yields the scree plot presented in Figure 1, right panel. This scree plot suggests that a latent semantic index dimension of perhaps 10-50 is appropriate for the SN corpus.

Figure 2 displays the projection of the data set onto the first two principal components of

$$pca \circ mds \circ \rho \circ \mathcal{L}_C(C) \tag{1}$$

for the Science News corpus. Notice that this plot suggests that the combination feature extraction/dimensionality reduction we have employed (eq. 1) has captured well some of the information concerning the eight classes, despite the fact that we are viewing just two dimensions (as opposed to, say, the 10-50 dimensions suggested by the scree plot in Figure 1). To wit: there are two groups extending from and distinguishable from the main body of documents. These two groups are dominated by medicine (the upper left arm) and astronomy (the upper right arm). Additionally, some physics documents are present in the astronomy arm and some life sciences and behavioral sciences documents are present in the medicine arm. That physics should have some similarity with astronomy, and that life sciences and behavioral sciences should have some similarity with medicine, agrees with intuition.

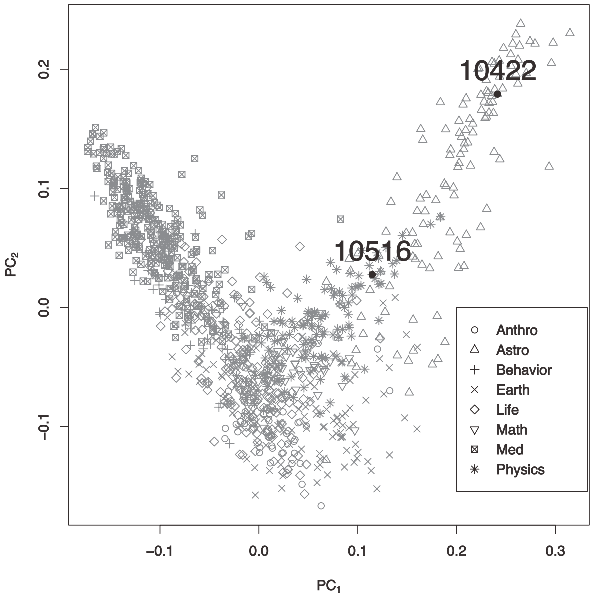

Figure 2: The first two principal components of $pca \circ mds \circ \rho \circ \mathcal{L}_C(C)$ for the Science News corpus. The eight symbols represent the eight classes; the three clusters generated via hierarchical clustering correspond roughly to the main body and the two arms. Notice that there are two groups extending from and distinguishable from the main body of documents. These two groups are dominated by medicine (the upper left arm) and astronomy (the upper right arm). The documents selected as our anecdotal "meaningful association" are indicated throughout by the solid dots and document number.

2.3 Example result

Recall that the SN corpus C has $|C| = 1047$ with class label vector

$$v = [54, 121, 72, 137, 205, 60, 280, 118].$$

The iterative denoising tree for cross-corpus discovery is illustrated on the SN corpus in Figure 3. This figure provides a coarse depiction of one path, from root to leaf, of the tree; a row-by-row description thereof follows.

Row 1: At the root, we have

$$pca \circ mds \circ \rho \circ \mathcal{L}_C(C).$$

Recall that these 1047 documents yield a feature dimension $d_{\mathcal{L}}(C) = 10906$ and an mds dimension $d_{mds}(C) = 898$. We display the first two principal components; thus the root (row 1) in Figure 3 is presented in detail in Figure 2.

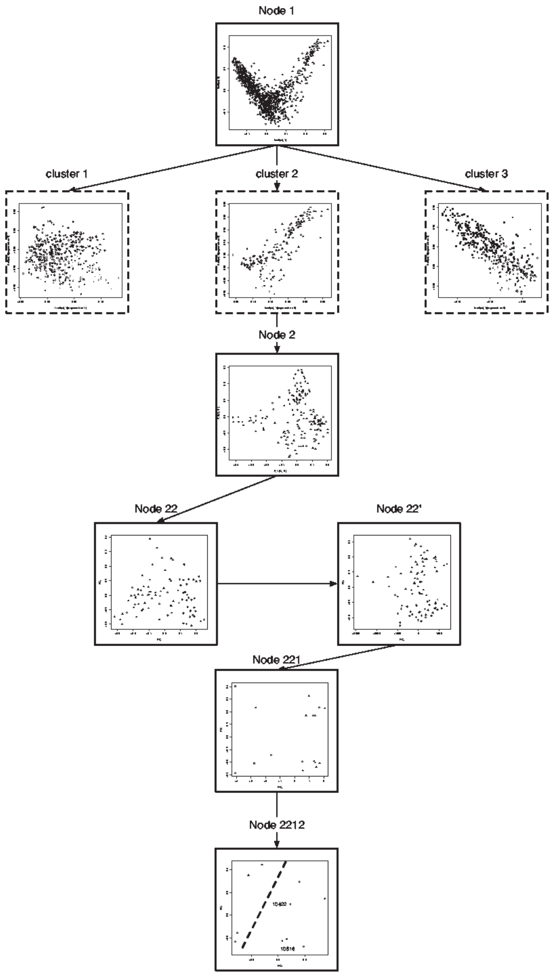

Figure 3: One path in an iterative denoising tree for the SN corpus.

Row 2: In the same space as for Row 1, we have simply split out three clusters obtained via hierarchical clustering, for display convenience.

(We choose in this manuscript to avoid model selection details; e.g., the choice of three vs. two clusters at the root. In general, we recommend that this issue be avoided by generating a *binary* tree unless user intervention is possible. In this example, the root begs for three clusters — a core and two arms.)

To illustrate an anecdotal meaningful cross-corpus discovery, we will follow cluster 2, C_2, which contains 166 documents. This subset of the original corpus is *denoised* in the sense that it is primarily physics and astronomy. The class label vector is

$$v_2 = [2, 113, 0, 10, 4, 0, 1, 36].$$

Thus, C_2 contains nearly all (113 of 121) of the astronomy documents, nearly one third (36 of 118) of the physics documents, and but a smattering from the other classes. So while the original feature extraction was done in the context of a corpus containing medicine, behavioral sciences, and mathematics documents, these topics are not a part of the context for the feature extraction for C_2 and this feature extraction can therefore focus on features germane to physics and astronomy.

Row 3: Here we display

$$pca \circ mds \circ \rho \circ \mathcal{L}_{C_2}(C_2).$$

(See Figure 4 for more detail.) These 166 documents yield a feature dimension $d_{\mathcal{L}}(C_2) = 3037$ and an mds dimension $d_{mds}(C_2) = 162$. Since $\mathcal{L}$ involves *corpus-dependent* feature extraction, this display is different than the "cluster 2" display in Row 2. This difference is due to denoising. The indicated partition represents the clusters generated via hierarchical clustering. Notice that one of the clusters (C_{22}, lower right, containing 91 documents) contains approximately half of C_2's astronomy documents (52 of 113) and nearly all of C_2's physics documents (35 of 36). In continuing pursuit of our anecdotal meaningful cross-corpus discovery, we follow C_{22}.

Row 4: The class label vector for C_{22} is

$$v_{22} = [0, 52, 0, 1, 2, 0, 1, 35].$$

The left display in Row 4 (see Figure 5 for more detail) depicts

$$pca \circ mds \circ \rho \circ \mathcal{L}_{C_{22}}(C_{22}).$$

These 91 documents yield a feature dimension $d_{\mathcal{L}}(C_{22}) = 1981$ and an mds dimension $d_{mds}(C_{22}) = 89$. Again, recall that the feature extraction is corpus-dependent. Now consider altering the geometry via the document subset

$$S_{22} = \{10500, 10651\} \subset C_{22}.$$

(These documents were chosen arbitrarily, for the purposes of illustration: they consist of a Physics document about neutrinos and an Astronomy document about black holes.) In the display, the two black squares represent S_{22}.

The right display in Row 4 (see Figure 6 for more detail) depicts the altered geometry after consideration of S_{22}. That is, here we have added

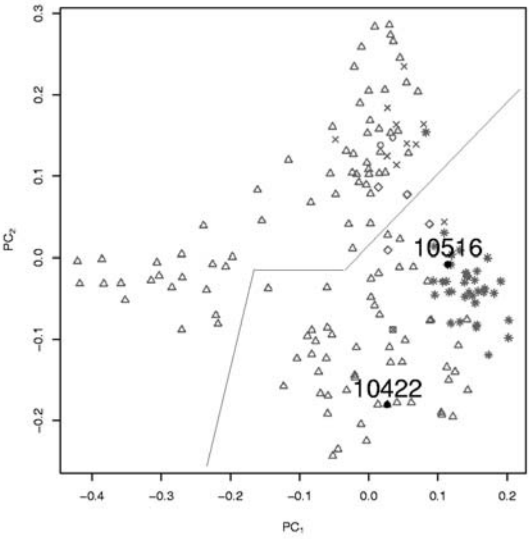

Figure 4: Node N_2 in the iterative denoising tree for the SN corpus.

a new (90th) feature $K_c d(\cdot, S_{22})$ to the 89 multidimensional scaling features, and are displaying

$$pca \circ [(mds \circ \rho \circ \mathcal{L}_{C_{22}}(C_{22}))\,; K_c d(\cdot, S_{22})]\,.$$

In the display, the two black squares again represent S_{22}. The distance-to-subset used for the additional "tunnelling" feature (see, for instance, [3]) $d(\cdot, S_{22})$, is the minimum Euclidean distance to an element of the subset in the LSI-space defined by the selected principal components; in this case, the scree plot suggests $d_{pca}(C'_{22}) = 20$. The coefficient K_c used for the tunnelling feature is obtained by scaling the values $d(\cdot, S_{22})$ so that the variance for the tunnelling feature $K_c d(\cdot, S_{22})$ is some pre-specified positive multiple c of the maximum multidimensional scaling feature variance. We use $c = 10000$ in this example so that this new feature dominates the multidimensional scaling features in the subsequent principal component analysis. (Note that the scale presented in N'_{22} in Figure 6 is such that the ordinate has no impact on the subsequent clustering; the abscissa dominates.) Rather than use the automatic clustering (depicted), we illustrate user intervention via manual clustering based on a vertical line (recall that the abscissa dominates) at 700 in N'_{22}. We follow the rightmost cluster obtained thusly, C_{221}.

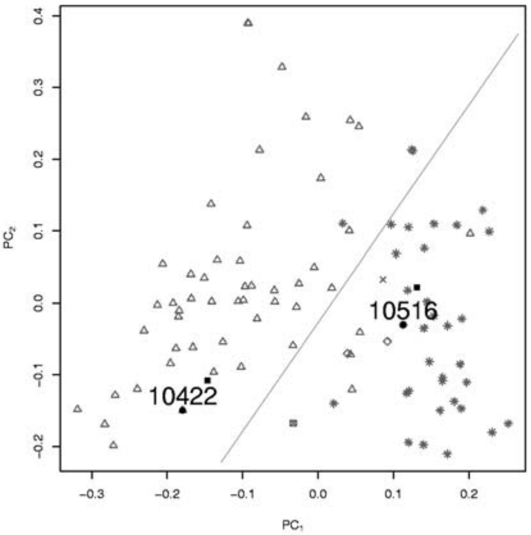

Figure 5: Node N_{22} in the iterative denoising tree for the SN corpus.

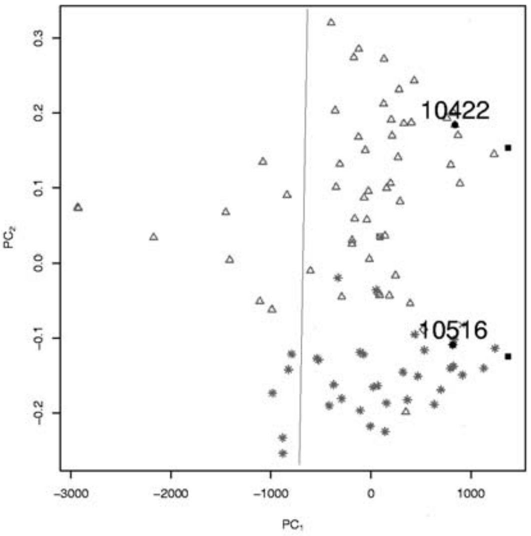

Figure 6: Node N'_{22} in the iterative denoising tree for the SN corpus.

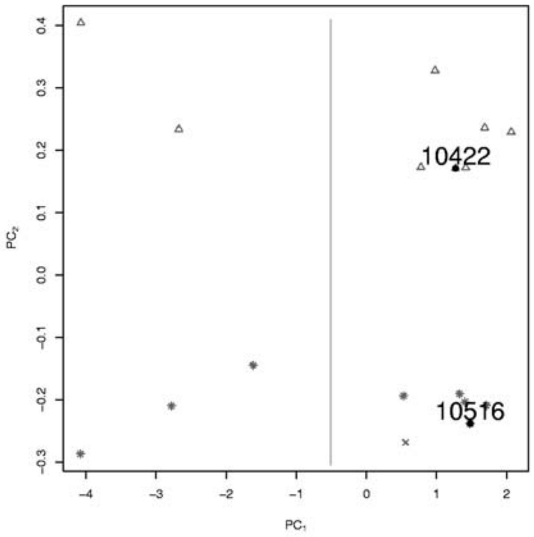

Figure 7: Node N_{221} in the iterative denoising tree for the SN corpus.

Row 5: The document collection C_{221} is, again, almost entirely astronomy and physics, with

$$|C_{221}| = 17$$

and

$$v_{221} = [0, 8, 0, 1, 0, 0, 0, 8].$$

These 17 documents yield a feature dimension $d_{\mathcal{L}}(C_{221}) = 367$ and an mds dimension $d_{mds} = 16$. After recalculating the features for C_{221}, we display

$$pca \circ [(mds \circ \rho \circ \mathcal{L}_{C_{221}}(C_{221}))\,; K_{c'}d(\cdot, S_{22})]\,.$$

(See Figure 7 for more detail.) (A value of $c' = 100$ is used here; the impact of the tunnelling feature is lessened.)

Row 6: Here we consider one of the two clusters, C_{2212}, from N_{221} via

$$pca \circ [(mds \circ \rho \circ \mathcal{L}_{C_{2212}}(C_{2212}))\,; K_{c'}d(\cdot, S_{22})]\,.$$

$$|C_{2212}| = 12$$

and

$$v_{2212} = [0, 6, 0, 1, 0, 0, 0, 5].$$

These 12 documents yield a feature dimension $d_{\mathcal{L}}(C_{2212}) = 215$ and an mds dimension $d_{mds} = 11$. This, in turn, clusters into C_{22121} and C_{22122}.

Let us finally consider C_{22121}. This leaf contains eight documents, with class label vector

$$v_{22121} = [0, 4, 0, 0, 0, 0, 0, 4].$$

Pairs of documents from different classes which fall to the same leaf of the iterative denoising tree are candidate associations. Thus this example yields 16 candidate associations, at least one of which (astronomy #10422 = "X-Ray Universe: Quasar's jet goes the distance" by R. Cowen, Science News Online, Feb. 16, 2002 & physics #10516 = "Glimpses inside a tiny, flashing bubble" by I. Peterson, Science News Online, Oct. 5, 1996) is plausibly a *meaningful* association.

3 Conclusion

We have presented an anecdote — not an experiment! — suggesting that an iterative denoising methodology can be a useful tool in discovering meaningful cross-corpus associations. Corpus-dependent feature extraction is an essential part of the methodology, providing features which are iteratively fine-tuned to ever more homogeneous subsets of documents as one progresses down the tree. The specific approaches to feature extraction, dimensionality reduction, and partitioning may be profitably altered within the framework of the general methodology. The adaptive geometry provided by employing distance-to-subset "tunnelling" features allows the user to alter the details of tree growth. Experimental design to allow for statistical evaluation of the performance of the methodology provides some interesting hurdles, and will be reported elsewhere.

Finally, we note that the methodology described is not specific to text document processing, and may have application in many disparate discovery scenarios. The fundamental idea, as in [9], is to address the problem of there being more measurements that can be made than should be made at any one time.

COMPSTAT'2004 Symposium

FROM DATA TO DIFFERENTIAL EQUATIONS

Jim O. Ramsay

Key words: Functional data analysis, differential equation, smoothing, nonparametric regression, lupus.

COMPSTAT 2004 section: Functional data analysis, Spatial statistics.

Abstract: Differential equations are the natural way to model systems with functional inputs and functional outputs. They allow us to study the system's dynamics in the sense of explicitly modelling how the output changes in response to sudden changes in input. For example, engineers developing control systems for industrial processes routinely use DIFE's as modelling tools.

A new method is described for going directly from noisy discrete data, not necessarily sampled at equally spaced times, to a system of differential equations of arbitrary orders, linear or nonlinear, that describes the data. The method involves a generalization of nonparametric curve estimation in which the penalty functional rather than the smoothing functions is estimated.

Examples are drawn from chemical engineering and medicine.

1 Introduction: Three main themes

Differential equations (here shortened to DIFE's) make explicit the relation between one or more derivatives and the function itself. For example, the general first order equation for function $x(t)$,

$$Dx = f(t, x),$$

defines a dependency of the first derivative Dx on the function x as well as, possibly, other direct dependencies on argument t.

The talk for which this paper is a summary aims to make three general points:

- DIFE's are powerful tools for modeling data. Indeed, they are already routinely used in the chemical, physical and biological sciences as well as in engineering. They are important primarily because they model the *dynamics* of an observed process; that is, rates of change are modeled along the observed function. This is especially important in input/output systems where how the system responds to an abrupt change in input can be as important as the long-term change that results.
- We have new methods for fitting differential equations or dynamic models to raw noisy data that appear to be substantially more effective than

existing techniques. These methods are based on developments in *functional data analysis* [1], [2], a collection of methods for the analysis of curves and images as data.

- Some important applications are outlined to show the potential for these developments in chemical engineering and medicine. In chemical engineering, there are many possibilities for the use of these techniques in process control applications. In medicine, the methods are applied to some data on lupus, where the dynamics of the disease are the central issue for developing effective treatments.

2 Why consider differential equation models?

The behavior of a derivative is often of more interest than the function itself. The classic example is mechanics, where Newton's second law for position $x(t)$ as a function of mass m, $x(t) = mD^2x(t)$, as well as it's descendent, $e = mc^2$, shows that energy exchange takes place at the level of acceleration, not position. How rapidly a system responds rather than its final level of response is often what matters.

Since a DIFE links the behavior of a derivative to the behavior of the function, it implies that derivatives will exhibit the same smoothness and regularity that characterizes the function. Consequently, a DIFE is can be an important method for computing stable estimates of derivatives.

Natural scientists often deliver theory to biologists and engineers in the form of DIFE's. Moreover, many other fields, such as pharmacokinetics and industrial process control, routinely use DIFE's as models for real-life systems. DIFE's are especially important when feedback systems must be developed to control the behavior of systems.

Although linear differential equations are much easier to work with then nonlinear systems, nonlinear DIFE's are often compact and elegant models for systems exhibiting exceedingly complex behavior, especially in the biosciences. Indeed, chaotic systems and systems exhibiting catastrophic changes are usually modelled with nonlinear dynamics.

It is the business of statistics to model random variation. We usually model random behavior in functions by assuming a fixed underlying process with superimposed noisy variation. But a DIFE allows a much richer range of ways in which stochastic behavior can be introduced:

- random coefficient functions
- random forcing functions
- random initial, boundary and other constraints
- system time t unfolding at a random rate

3 A simple input/output system

We begin by looking at a first order linear DIFE for a single output function $x(t)$ and a single input function $u(t)$, although our ultimate goal is to link multiple outputs to multiple inputs.

Figure 1 is an example: The fluid level in a tray within a distillation column of an oil refinery is shown as a function of the flow of a fluid into the tray. We must explain two things: By how much does the fluid level ultimate change in response to the change in input flow indicated, and how rapidly does this change take place?

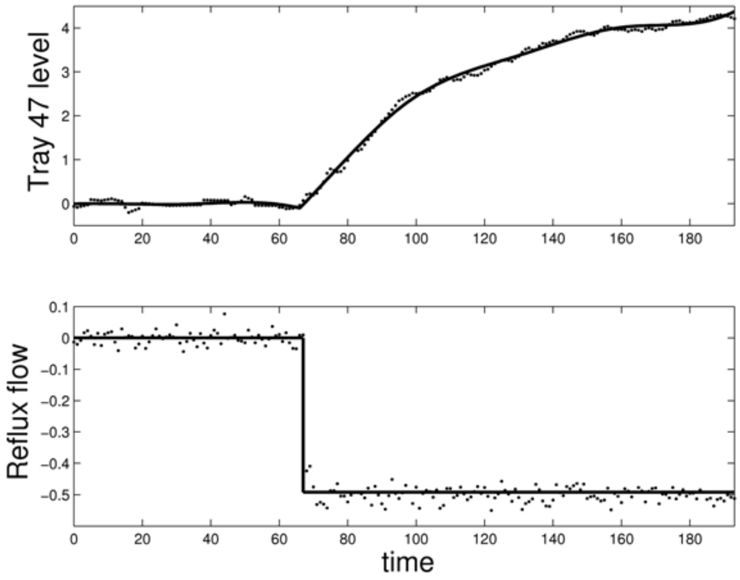

Figure 1: The upper panel shows the level of material in a tray of a distillation column in an oil refinery, and the lower level shows the flow of material being distilled into the tray. The points are measured values, and the solid lines are smooths of the data using regression splines.

The DIFE has the general form

$$Dx(t) = -\beta(t)x(t) + \alpha(t)u(t) \tag{1}$$

The *homogeneous* part of the equation

$$Dx(t) = -\beta(t)x(t)$$

describes the *endogenous* or internal dynamics of the system. the *forcing function u* is an exogenous functional independent variable that perturbs these internal dynamics. The functions α and β are the coefficient functions that define the DIFE. The system is linear in these coefficient functions, and also in the input and output functions.

One way to understand the separate roles of α and β is to study a simpler *constant coefficient* model with an input that steps from 0 to 1 at time 1 and for which $x(0) = 1$. The solution to the equation in this case is

$$\begin{aligned} x(t) &= e^{-\beta t}, 0 \le t \le 1, \\ &= e^{-\beta t}[1 - (\alpha/\beta)e^{-\beta(t-1)}], 1 \le t. \end{aligned}$$

We see that β controls the rate of change and that the ultimate level or *gain* is α/β. We can compare α to the volume control on a radio playing a song carried by radio signal u; the bigger α, the louder the sound. The bass/treble control, on the other hand, corresponds to β; the larger β, the higher the frequency of what we hear.

4 Fitting a differential equation to data

The basic idea is to use *profiled least squares* to estimate unknown parameters, such as α and β in the above example. We do this by replacing the smoothing function x used to smooth a sequence of noisy functional observations $y_j, i = 1, \ldots, n$ by the equations defining the fit to the data conditional on a roughness penalty defined by a differential operator L. Then we optimize the fit with respect to only the unknown parameters; the fitted values $x(t_j)$ are computed as byproduct of the process, but do not themselves require additional parameters.

Focussing for simplicity on the first order linear equation (1), and defining the coefficient functions to be constants, we define the linear differential operator $L_{\alpha,\beta}$ to be

$$L_{\alpha,\beta}x(t) = -\beta x(t) + Dx(t) - \alpha u(t)$$

Function x is a solution to (1) if and only if $L_{\alpha,\beta}x = 0$.

Now define the penalized least squares fitting criterion as

$$\texttt{PENSSE}(y|\lambda, \alpha, \beta) = \sum_j [y_j - x(t_j)]^2 + \lambda \int [L_{\alpha,\beta}x]^2. \tag{2}$$

If x has the basis function expansion $x(t) = \mathbf{c}'\boldsymbol{\phi}(t)$, where $\boldsymbol{\phi}(t)$ is a functional vector of basis functions of length K, then criterion (2) is minimized with respect to coefficient vector $\mathbf{c}$ by

$$\mathbf{c}(\alpha, \beta) = [\boldsymbol{\Phi}'\boldsymbol{\Phi} + \lambda\mathbf{R}(\alpha, \beta)]^{-1}[\boldsymbol{\Phi}'\mathbf{y} + \lambda\mathbf{s}(\alpha, \beta)] \tag{3}$$

where

- $\boldsymbol{\Phi}$ is the n by K matrix of basis function values $\phi_k(t_j)$

- λ is a smoothing parameter
- $\mathbf{y}$ is the vector of noisy observations to be smoothed
- penalty matrix $\mathbf{R}(\alpha, \beta)$ is

$$\mathbf{R}(\alpha, \beta) = \int (L_{\alpha,\beta}\boldsymbol{\phi})(L_{\alpha,\beta}\boldsymbol{\phi})'$$

- penalty vector $\mathbf{s}(\alpha, \beta)$ is

$$\mathbf{s}(\alpha, \beta) = \int (L_{\alpha,\beta}\boldsymbol{\phi})u$$

Substituting (3) into (2), we may now minimize the un–penalized profiled error sum of squares

$$\texttt{PROFSSE}(y|\lambda, \alpha, \beta) = \sum_j [y_j - x(t_j|\alpha, \beta)]^2 \tag{4}$$

with respect to parameters α and β. Our experience is that the smoothing parameter λ can usually be selected by minimizing the generalized cross-validation (GCV) criterion.

This process may be extended to equations of an arbitrary order, nonlinear equations, and systems of equations.

5 Two simulated data examples

5.1 Twenty tilted sinusoids

How well can we recover derivatives using this process? Consider a tilted sinusoid

$$x_i(t) = c_{i1} + c_{i2}t + c_{i3}\sin(6\pi t) + c_{i4}\cos(6\pi t)$$

that is annihilated by the operator

$$Lx_i = (6\pi)^2 D^2 x + D^4 x$$

We generated $N = 20$ of these by randomly generating coefficients from $N(0, 1)$ and adding noise to x_i from the same distribution.

As a point of comparison, when we smoothed with $L = D^4$, best results were obtained with $\lambda = 10^{-10}$ and the integrated root-mean-squared errors for the function and the first two derivatives were 0.32, 9.3and 315.6, respectively.

When we estimated all four constant coefficients for the order four linear differential operator L, best results were obtained for $\lambda = 10^{-5}$ and the integrated root-mean-squared errors for the function and the first two derivatives were 0.18, 2.8 and 49.3, respectively. These represent improvements in precision of estimation by factors of 1.8, 3.3 and 6.4, respectively. We estimated β_2 to be 353.6, whereas the right value was 355.3.

The most dramatic improvement in derivative estimation occurred at the boundaries. Estimating the linear differential operator virtually eliminated the usual instability of derivative estimates in these regions because these estimates are linked by the DIFE to the behavior of the function values, which are only mildly more unstable at the boundaries than within the interior. But even in the interior, for example, the precisions of the estimates of D^1x and D^2x were at least doubled.

5.2 A single forced harmonic

How well does the method do when applied to a single functional observation? A second order equation with coefficients $\beta_0 = 4.04$ and $\beta_1 = 0.4$ was forced by a step function u that was zero up to $t = 2\pi$ and one after, and multiplied by coefficient $\alpha = -2.0$. Noise sampled from $N(0, 0.04)$ was added. One hundred trials were conducted, and in each λ was chosen by minimizing GCV.

The mean estimates of coefficients β_0, β_1 and α were $4.041 \pm 0.007, 0.397 \pm 0.005$ and -1.998 ± 0.0009, respectively, indicating no detectable bias.

6 The oil refinery data

After some experimentation with first and second order models, and with constant and varying coefficient models, the clear conclusion was that the constant coefficient model $Dx = -0.02x - 0.19u$ was preferred. The standard error for β was estimated be 0.0004 by both the bootstrapping and the delta methods. The corresponding estimates for the standard error of α were 0.0024 and 0.0025, respectively.

Figure 2 shows the data for the tray level along with the fit to the data implied by the differential equation.

7 The lupus data

7.1 The disease

Systemic lupus erythematosus (SLE), or simply “lupus”, is an auto–immune disease in the same family as rheumatoid arthritis. The body’s immune system attacks itself, producing a wide spectrum of symptoms and affecting many organs. These attacks, called *flares*, occur suddenly and unpredictably, last for varying periods, and then disappear, sometimes for long periods. “Erythematosus” means reddening, referring to a characteristic skin rash by which it was first identified.

The disease is incurable. Around 9 times as many women as men get the disease, and blacks and some Asian groups more susceptible. Incidence

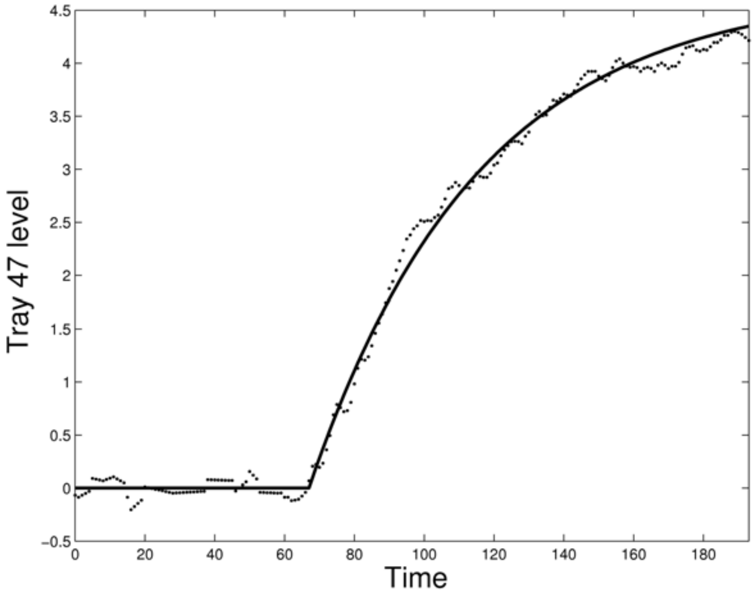

Figure 2: The fit to the data defined by the differential equation is shown as a solid line, and the data as points.

ranges from 3 to 400 per 100,000. Lupus can appear at any age, and the earlier it appears, the more severe it tends to be. Lupus is on the increase, and in some places is now more common than rheumatoid arthritis. Genetic, environmental, and hormonal factors are all involved. Exposures to chemicals and ultra-violet light are suspected triggers for flares.

Symptoms range from mild to severe, and can cause permanent damage or be fatal. A rash on the face and chest, pain and swelling in the joints and fatigue are common and early signs of a flare. The kidneys are often affected, with swelling and loss of function, and end–stage renal failure is a real risk. The heart, arteries, lungs, eyes and central nervous system may also be involved; and the psychological effects of lupus are receiving more and more attention. A typical flare goes from just noticeable to acute in the order of ten days or less.

The variation in the nature and severity of symptoms combined with the unpredictability of flares makes treating this disease a huge challenge. Mild symptoms are treated with anti–inflammatory drugs (aspirin, etc.), and more severe symptoms require the use of corticosteroids, usually *prednisone*. The response time to an increase in prednisone dose is usually of the order of a few days. However, corticosteroids are toxic if taken over long periods at high doses, with common side effects being weight gain, sleeplessness and osteoporosis. Sudden decreases in dose can trigger a new flare; consequently, high dose levels must be tapered down gradually.

Patients are assessed at regular intervals. Although lupus symptoms are multidimensional, long term treatment requires some overall measure of disease severity. A number of symptom severity scales have been proposed, and the SLEDAI scale is now widely used. SLEDAI is a check list of 24 symptoms, each given a numerical weight ranging from 1 for fever to 8 for seizures.

A flare has been defined by an international committee as a SLEDAI score increase of 3 or more to a level of 8 or higher. During flares SLEDAI scores of 25 to 30 are common.

A joint McGill/University of Toronto team headed by Dr. Paul Fortin has complete histories for about 300 patients spanning, in many cases, around 20 years. This is one of the largest and highest quality set of patient records in the world.

Figure 3 shows the data for a single patient over a three-year period. Notice the strong flare that coincides with the reduction in prednisone dose just after the seventh year.

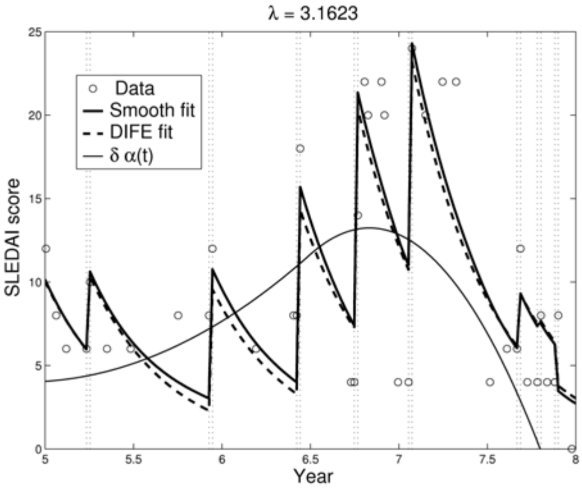

Figure 3: The data for a single patient over a three-year period. Heavy lines join times and values of SLEDAI measurements. A flare is indicated by a solid heavy line joining the first SLEDAI measurement within the flare to the previous measurement extended to a time 0.02 years back. The light solid line joins times and values at which prednisone doses were fixed.

7.2 The statistical challenges

We require a model for:

- flare timings (a point process)
- flare intensities (a marked point process)
- flare durations (a marked interval process)
- flare dynamics: rate of onset and rate of recovery
- how flare characteristics depend on prednisone level and
- prednisone dynamics or rate of change
- individual differences in all of the above

7.3 Data issues

The SLEDAI scale score has limited reliability. The dates at which these scores are assessed are themselves haphazard. Some data may be actually missing, eg: does SLEDAI = 0 always mean "no symptoms"?

We can, however, work closely with the physicians who work with these patients to identify flare characteristics, including flare onset times, flare durations, and to answer some questions. For example, a SLEDAI score may not change, but the fact that prednisone was increased at that point suggests that the disease has nonetheless become acute. We can also return to patient records to retrieve other information as required.

7.4 A simple model for flare dynamics

Let $u(t)$ be an indicator function for when lupus is in its active state and a flare is taking place.

- $u(t)$ takes only values 0 and 1.
- The times t_i at which $u(t)$ becomes positive can be estimated directly from the data, and therefore assumed known.
- The duration of an active state will be δ, and may vary from flare to flare.

We might propose to model symptom level $s(t)$ as a first order differential equation:

$$Ds(t) = -\beta s(t) + \alpha(t)u(t) \tag{5}$$

This, however, is too simple in an important way. It predicts that the rate of increase in symptom level is equal to its rate decrease when $u(t)$ returns to zero. In fact, however, symptoms rise far more rapidly than they decay.

We can imagine that the disease also affects the body's capacity to respond to the disease itself, as well as it's capacity to recover. That is, β is also affected by the disease, and therefore must be replaced by the function $\beta(t)$. When the patient is healthy between flares, $\beta(t)$ is high, leading to rapid response to the onset of the disease. When the patient is experiencing a flare, $\beta(t)$ is near zero, implying a slow recovery.

We tried this differential equation for $\beta(t)$

$$D\beta(t) = -\gamma\beta(t) + \theta[1 - u(t)]$$

When $u(t)$ switches on, $\beta(t)$ decays to zero, and $Ds(t)$ tends to equal $\alpha u(t)$; that is, $s(t)$ increases linearly while $u(t) = 1$. When $u(t)$ switches off, $\beta(t)$ returns to the level of its gain, θ/γ, and $s(t)$ tends to decay exponentially with rate equal to $\beta(t)$'s gain.

This gives us the general shape of a lupus flare. The increase in symptoms is essentially linear because $\beta(t)$ decays rapidly to 0 inside a flare; when $\beta(t) \approx 0$, the gain becomes $\alpha\delta$. But after a flare, when $u(t)$ returns to zero, β returns to its healthy level, and there is an exponential decrease in symptoms.

Actually, preliminary results indicated large values for rate parameter γ, implying that $\beta(t)$ moved extremely rapidly between virtually zero and its maximum value, defined by θ. We decided to simplify the differential equation for $\beta(t)$ to

$$D\beta(t) = \theta[1 - u(t)]$$

This implies linear increase within a flare episode, and exponential decrease afterwards with a rate constant θ.

7.5 The data analysis

Order 4 B-spline basis functions, with a knot at every data point, and three coincident knots at the times of onset and offset of flares were used to represent symptom function $s(t)$. Coincident knots allow the first derivative to be discontinuous at flare boundaries, as required by the model. Coefficient $\alpha(t)$ was made nonconstant, and represented as a basis function expansion in terms of four order 3 B-splines.

Figure 4 shows the fitting function s, the solution to the differential equation and coefficient function α for smoothing parameter $\lambda = 10^{-0.5}$. For this value of λ, s fits the data quite well everywhere, and certainly adequately given the reliability of the SLEDAI score. But the solution of the differential equation climbs with each successive flare because the estimated rate constant $\theta = 0.61$ is too small to allow enough decay in symptoms between flares.

Figure 5 shows these results for the higher smoothing parameter $\lambda = 10^{0.5}$. Now we see that the fit $s(t)$ and the solution to the differential equation are very close. The estimate of θ is now 2.24, and this rate constant is sufficient

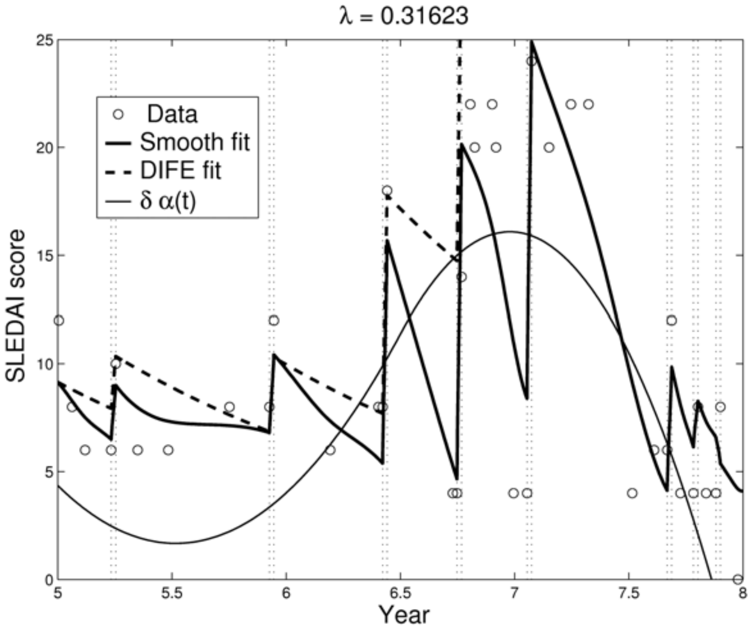

Figure 4: Results for the analysis of the data in Figure 3 using a smoothing parameter $\lambda = 10^{-0.5}$. The circles are SLEDAI measurements. The heavy solid line is the fit to the data $s(t)$ that minimizes criterion (4) and the dashed line is the solution to the differential equation (5). The light solid line plots the value of $\delta\alpha(t)$.

for the recovery from a flare before the next flare begins. What we lose, however, is the capacity to fit lower values of SLEDAI; the range of variation within a flare is too limited to permit this.

On the whole, however, these fits are quite satisfactory and capture well the main dynamic features of this segment of a lupus record.

SIMPLE SIMULATIONS FOR ROBUST TESTS OF MULTIPLE OUTLIERS IN REGRESSION

Marco Riani and Anthony Atkinson

Key words: Forward search, large data sets, simultaneous inference, trimmed estimators..

COMPSTAT 2004 section: Robustness.

Abstract: The null distribution of the likelihood ratio test for outliers in regression depends on the distributional properties of trimmed samples. Approximations to the distribution of the statistic that are simple to simulate are described and applied to three examples.

1 Introduction

Tests of outliers in regression need estimates of both the parameters of the linear model and of the error variance σ^2. If the outliers are included in the set used for estimation, inconsistent estimates of the parameters will be obtained and the existence and the effect of the outliers will be masked. We therefore consider procedures in which the observations are divided into two groups: those believed to be 'good' and the outliers. The good observations are used to provide estimates of the parameters to be used in the test for outliers.

Let there provisionally be m good observations out of n. We are interested in the null distribution of the outlier test. We therefore need to perform our calculations as though there were no outliers. If we were interested in the simplest case when, instead of regression, the focus is the location parameter of a random sample from a symmetrical distribution, we would base our estimates on the m central observations, trimming the remaining $m - n$. The properties of our estimators would then be those coming from this trimmed sample of n observations, rather than from m observations taken at random from the parent population. We use this insight to provide excellent approximations to the distribution of the outlier test in regression.

The literature on the detection of outliers in regression is vast. The test we study here is the likelihood ratio test, that is the test based on the prediction residuals used, for example, by Hadi and Simonoff [13], for the detection of multiple outliers. Two useful surveys of methods for multiple outliers in regression are Beckman and Cook [9] and Barnett and Lewis [8]. An important point is that, if several outliers are present, single deletion methods (for example, Cook and Weisberg [12], Atkinson [1]) may fail. Hawkins [14] argues for exclusion of all possibly outlying observations, which are then tested sequentially for reinclusion. This corresponds to our description in which m observations are used for estimation.

The drawback to Hawkins's procedure is that it is unclear how many observations should be deleted, and, because of masking, which ones, before reinclusion and testing begin. However, the forward search is an objective procedure of this type: it starts from a small, robustly chosen, subset of the data and fits subsets of increasing size. Each newly introduced observation can be tested for outlyingness before it is included in the fitted subset.

The use of the forward search in regression is described in Atkinson and Riani [4] where, as in Atkinson [2], the emphasis is on informative plots and their interpretation. The extension to multivariate data is described by Atkinson [3], with a book length treatment in Atkinson, Riani and Cerioli [7]. Although the forward search is a powerful general method for the detection of multiple outliers and unidentified clusters, the references do not describe inferential procedures based on the quantities plotted. Atkinson and Riani [6] use the forward search as a means of generating a series of outlier tests with decreasing amounts of trimming; m increases from slightly more than the number of parameters to n. The values of the statistics are assessed by simulation and by analytical approximations to the robust tests. The interest in the present paper is in the application of the tests. We use both simulations of forward searches and two simple simulated approximations to the distribution to analyse three sets of data. As a result we are able to combine the power of the forward search with precise statistical procedures.

The paper is organised as follows: in §2 we briefly review the forward search and robust estimation; both depend on estimators from trimmed samples. In §3 we write the outlier test explicitly in terms of such samples and show how simulations using samples from trimmed distributions can be used to approximate the distribution of the statistic. Examples in §4 show how well our approximation works. The final section briefly describes further work.

2 Least squares and outlier detection

2.1 Least squares

In the regression model

$$y = X\beta + \epsilon, \tag{1}$$

y is the $n \times 1$ vector of responses, X is an $n \times p$ full-rank matrix of known constants, with ith row x_i^T, and β is a vector of p unknown parameters. The normal theory assumptions are that the errors ϵ_i are i.i.d. $N(0, \sigma^2)$.

With $\hat{\beta}$ the least squares estimator of β the vector of least squares residuals is

$$e = y - \hat{y} = y - X\hat{\beta} = (I - H)y, \tag{2}$$

where $H = X(X^TX)^{-1}X^T$ is the 'hat' matrix, with diagonal elements h_i and off-diagonal elements h_{ij}. The mean square estimator of σ^2 can be written

$$s^2 = e^Te/(n-p) = \sum_{i=1}^{n} e_i^2/(n-p). \tag{3}$$

We define the standardized residuals

$$q_i = e_i/\sqrt{(1-h_i)} = (y_i - \hat{y}_i)/\sqrt{(1-h_i)}. \tag{4}$$

Like the errors ϵ_i, the q_i are distributed $N(0, \sigma^2)$, although they are not independent.

The likelihood ratio test for agreement of a new observation y_{new} observed at x_{new} with the sample of n observations providing $\hat{\beta}$ and s^2 is the prediction residual

$$d_i^* = \frac{y_{\text{new}} - x_{\text{new}}^T\hat{\beta}}{s\sqrt{\{1 + x_{\text{new}}^T(X^TX)^{-1}x_{\text{new}}\}}}, \tag{5}$$

which, when the observation y_{new} comes from the same population as the other observations, has a t distribution on $n-p$ degrees of freedom.

2.2 The forward search

Let $\mathcal{M}$ be the set of all subsets of size m of the n observations. The forward search fits subsets of observations of size m to the data, with $m_0 \le m \le n$. We discuss the starting point of the search in §2.3.

Let $S_*^{(m)} \in \mathcal{M}$ be the optimum subset of size m. Least squares applied to this subset yields parameter estimates $\hat{\beta}(m^*)$ and $s^2(m^*)$, the mean square estimate of σ^2 on $m-p$ degrees of freedom. Residuals can be calculated for all observations including those not in $S_*^{(m)}$. The n resulting standardized residuals can from (4) be written as

$$q_i(m^*) = \frac{y_i - x_i^T\hat{\beta}(m^*)}{\sqrt{\{1 - h_i(m^*)\}}}. \tag{6}$$

The notation $h_i(m^*)$ serves as a reminder that the leverage of each observation depends on $S_*^{(m)}$. The search moves forward with the subset $S_*^{(m+1)}$ consisting of the observations with the $m+1$ smallest absolute values of the e_i, that is the numerator of $q_i(m^*)$.

In order to simulate the distribution of the outlier test of §2.4 we need a simple way of simulating variables with the same distribution as the $q_i(m^*)$. When $m = n$ these residuals are those in (4) and the distribution is $N(0, \sigma^2)$. But with $m < n$ the estimates of the parameters are based on only those observations giving the central m residuals: $\hat{\beta}(m^*)$ and $s^2(m^*)$ are calculated from truncated samples.

2.3 Robust estimation and the start of the search

The search starts from a subset of p observations $S_*^{(p)}$ that is chosen to provide a very robust estimator of the regression parameters. For example, if Least Median of Squares (LMS, Rousseeuw [16]) is used, the subset of p observations is found minimizing the scale estimate

$$\sigma^2(h) = e^2_{[h]}(p^*), \tag{7}$$

where $e^2_{[k]}(p^*)$ is the kth ordered squared residual and h is the integer part of $(n+p+1)/2$ and corresponds to 'half' the observations when allowance is made for fitting. Typically the search either examines all subsets of size p, if this is not too large, or several thousand subsets are examined at random. These starting methods destroy masking; any remaining outliers are then removed in the initial steps of the search. Consequently, the search is insensitive to the exact starting procedure. What is important for our present purpose is that the search again uses parameter estimates based on a central part of the sample.

2.4 Testing for outliers

Let the observation "nearest" to those constituting $S_*^{(m)}$ be $i_{\min}$ where

$$q_{\text{imin}}(m^*) = \min |q_i(m^*)| \quad \text{for} \quad i \notin S_*^{(m)}, \tag{8}$$

the observation with the minimum prediction residual among those not in $S_*^{(m)}$. If observation $i_{\min}$ is an outlier, so will be all other observations not in $S_*^{(m)}$.

To test whether observation $i_{\min}$ is an outlier we use the predictive residual (5). The test for agreement of the observed and predicted values is

$$|d_{\text{imin}}| = \left| \frac{y_{\text{imin}} - x^T_{\text{imin}}\hat{\beta}(m^*)}{s(m^*)\sqrt{\{1 + h_{\text{imin}}(m^*)\}}} \right|. \tag{9}$$

It is the distribution of this statistic that is the subject of this paper. In (5), when all observations were used in fitting and a new observation was being tested, the distribution was t_{n-p}. Now the estimates $\beta(m^*)$ and $s(m^*)$ are based on the central part of the distribution. Even under the null hypothesis that the sample contains no outliers, the distribution is no longer t.

3 Simulating the distribution

The empirical distribution of the series of test statistics can be found by repeated simulations of forward searches. In this section we describe this method and then describe two alternative simulation-based methods. The first replaces the series of simulations and forward searches with independent simulations for each value of m. The second uses a series of orderings of simulated data, but avoids the forward search.

Both of these methods are for the statistics calculated for simple samples. In §3.4 we introduce a correction for the dependence of the distribution of the statistics on p.

3.1 The empirical distribution

In order to find the distribution of the test statistic during the forward search the most straightforward method is to simulate samples of all n observations and repeat the forward search a number of times. In order to capture any special features of the hat matrix, the matrix of explanatory variables is that of the data under study. Observations are simulated using the fitted values at the end of the search, that is $x_i^T\hat{\beta}(n)$, and the estimated standard deviation $s(n)$.

3.2 Method 1: Truncated samples

We are interested in approximations to the null distribution of (9) for given m which can easily be found. The statistic is a function of the m residuals $q_i(m^*) \in S_*^{(m)}$ and of $q_{\text{imin}}(m^*)$. In the absence of outliers, these will be the observations with the $m+1$ smallest values of $|q_i(m^*)|$. Since the $q_i(m^*)$ are residuals, their distribution does not depend on the parameters β of the linear model. They have also been standardised to have constant variance, which is then estimated. To find the required distribution we therefore simulate from a truncated normal distribution and calculate the value of the outlier test for such samples. The steps are:

Step 1. Obtain a random sample of $m+1$ observations U_i from the uniform distribution on $[0.5-(m+1)/2n, 0.5+(m+1)/2n]$.

Step 2. Use the inversion method to obtain a sample of $m+1$ from the truncated normal distribution:

$$z_i = \Phi^{-1}(U_i), \tag{10}$$

where Φ is the standard normal c.d.f.

Step 3. Find the most outlying observation:

$$z_{\text{imin}} = \max |z_i| \quad i = 1, \dots, m+1. \tag{11}$$

Then $S_z^{(m)} = \{z_i\}, i \neq i_{\text{min}} = 1, \dots, m+1$.

Step 4. Estimate the parameters. Let $\bar{z}(m)$ be the mean of the m observations in $S_z^{(m)}$ and $s_z^2(m)$ be the mean square estimate of the variance.

Step 5. Calculate the simulated value of the outlier test in (9):

$$d_{\text{imin}}^z = \frac{z_{\text{imin}} - \bar{z}(m)}{s_z(m)\sqrt{\{(m+1)/m\}}}. \tag{12}$$

The simulation of the truncated normal distribution using the inversion method in Steps 1 and 2 is straightforward in S-Plus or R.

3.3 Method 2: Ordered observations

In the forward search the n observations are ordered for each value of n. In the absence of outliers we might expect that this order would not change much during the search. As a second method of approximating the distribution of the statistics, we simulate sets of n observations from the normal distribution, correct for the mean and order the absolute values of the observations. For our calculations for each value of m we use the m smallest absolute residuals to estimate the parameters. The procedure is repeated several times, typically 1,000, to give the empirical distribution of the statistics.

3.4 Adjustment for regression

In both Method 1 and Method 2 we estimate the sample mean, rather than a regression model, so $h_{\mathrm{imin}}(m) = 1/m$. Simulations show that the resulting upper percentage points of the distribution are too small when we are analysing regression data. Good agreement is obtained by using the adjusted statistic

$$|d_{\mathrm{imin}}| = \left| \sqrt{\frac{m+\theta p}{m}} \frac{y_{\mathrm{imin}} - x_{\mathrm{imin}}^T \hat{\beta}(m^*)}{s(m^*)\sqrt{\{1 + h_{\mathrm{imin}}(m^*)\}}} \right|, \qquad (13)$$

with $\theta = 0.7$. As m increases, the effect of the correction becomes less.

4 Examples

4.1 Hawkins's data

This set of simulated data was analysed by Atkinson and Riani [4], §3.1. There are 128 observations and nine explanatory variables. The data were intended by Hawkins to be misleading for standard regression methods. Figure 1 shows a forward plot of the minimum deletion residual among observations not in the subset, that is the outlier test statistic (13), together with two sets of simulated percentage points of the distribution, both based on 1,000 simulations. We first consider these simulation envelopes.

The envelopes plotted with continuous lines in the figure are the 1, 2.5, 5, 50, 95, 97.5 and 99% points of the empirical distribution of the outlier test during forward searches simulated without outliers. The dotted lines are from our second approximate simulation method in which random samples of observations are ordered once. Agreement between the two envelopes is excellent during the second half of the search; agreement between the two sets of upper envelopes is also good during the first half of the search for $m > 20$. The envelopes are of a kind we shall see in all simulations. Initially they are very broad, corresponding to distributions with high trimming and

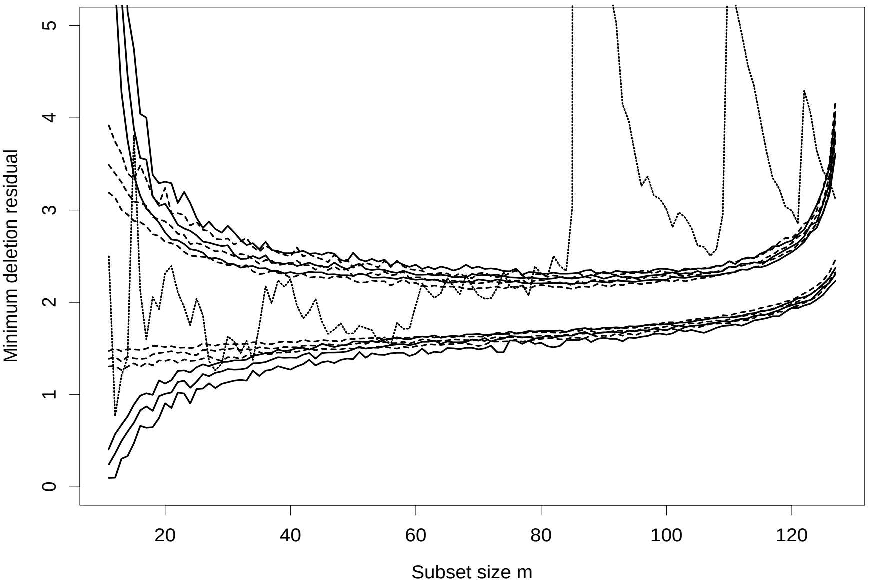

Figure 1: Hawkins's Data: forward plot of minimum deletion residuals (the outlier test). The four groups of observations are clearly separated by the three large peaks signalling the first observation from each new group immediately before it enters the subset. The dotted lines are envelopes simulated by Method 2.

few degrees of freedom for the estimation of error. In the central part of the search the band is virtually horizontal and gradually narrows. Towards the end of the search there is rapid increase as we test the few largest residuals.

The continuous line showing the plot of the outlier test in the figure reveals all the features that Hawkins put in the data. There are 86 observations with very small variance. The plot shows a huge jump in the value of the statistic when the first observation of the next group enters. This process is repeated two more times, clearly identifying the four separate groups of data that are present, the decline after each peak being due to the effect of masking. The forward plot of this test statistic is the same as that in the lower panel of Figure 3.6 of Atkinson and Riani [4]; the new confidence bands calibrate inferences about the significance of the peaks.

The envelopes rise rapidly at the end of the search and we can see that the outlier test finishes up being non-significant. Thus Hawkins has succeeded in constructing a data set with many outliers all of which are masked. The curve of the statistic starts to rise just before $m = 86$. If we take only the first 86 observations and provide simulation envelopes for them, the envelopes rise at the end as the envelopes do here from m around 125. The last few observations do not then lie outside the simulation bands for this reduced set of data.

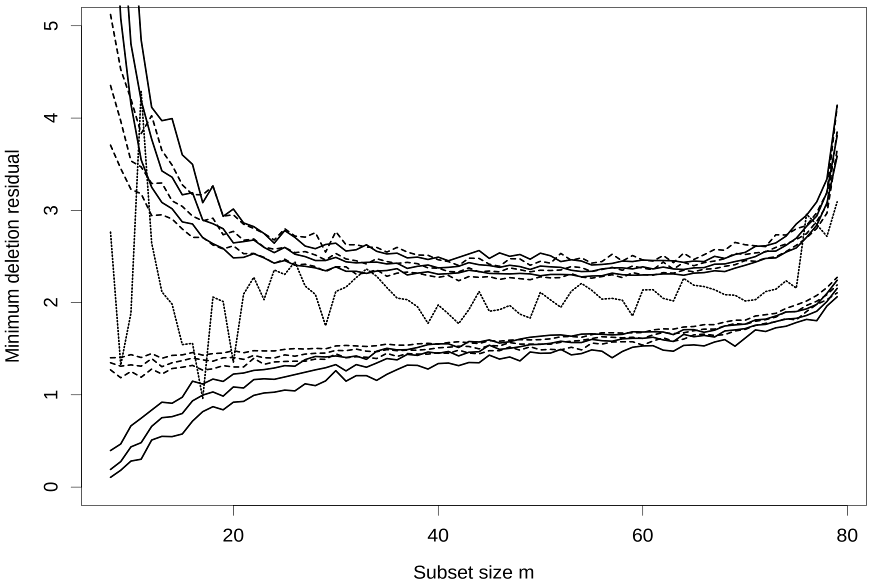

Figure 2: Ozone Data: forward plot of minimum deletion residuals (the outlier test). There are some mild outliers towards the end of the search and some evidence of masking. The dotted lines are envelopes simulated by Method 1.

4.2 Ozone data

Hawkins's data are a synthetic example in which there are many outliers. We now consider two examples of real data.

The first is the ozone data from Breiman and Freedman [10] which give readings of ozone concentration on 300 consecutive days. The results for the first 80 days were extensively analysed by Atkinson and Riani [4], §3.4. Here we follow their analysis.

As a result of the use of the forward search combined with response transformation the final model found by Atkinson and Riani had a logged response with five of Breiman and Freedman's original variables augmented by a linear trend in time. Figure 2 shows a forward plot of the outlier test for this model together with simulation envelopes from the forward search (continuous lines) and the approximate envelopes from the first method, of sampling from a truncated distribution. The agreement between the two sets of envelopes is again good, particularly for the upper envelope.

The evidence from this plot is much less dramatic than that of Figure 1. Apart from the very beginning of the search, the plot lies near or within the bounds for all values of m up to the introduction of the 76th observation. Thereafter there seem to be four mild outliers, a conclusion in line with the forward plot of residuals in Figure 3.37 of Atkinson and Riani [4]. At

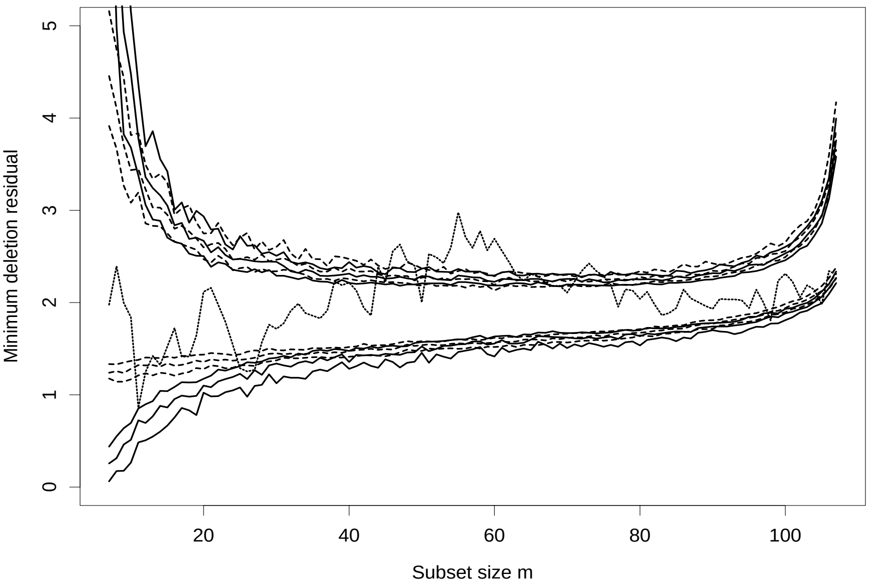

Figure 3: Surgical Unit Data: forward plot of minimum deletion residuals (the outlier test). The appreciable maximum of the statistic in the centre of the search suggest there may be two equal sized groups of observations that differ in some systematic way. The dotted lines are envelopes simulated by Method 1.

$m = 76$ this plot shows four appreciable residuals, three negative and one positive: these lie apart from the general cloud of residuals throughout the whole search. The plot also shows some evidence of masking, the residuals decreasing somewhat in magnitude at the end of the search. The effect of masking is also evident in Figure 2, where the test statistic lies within the simulation envelopes for the last two steps of the search. Although the masking here is not as misleading about the structure of the data as that in Figure 1, there are again outliers whose presence would be overlooked by an analysis based on all the data, or on single deletion diagnostics.

4.3 Surgical unit data

Neter, Kutner, Nachtsheim and Wasserman [15] introduce, on p.334, data on the survival time of 54 patients undergoing liver surgery, together with four explanatory variables that may be used to predict survival time. Their preferred model regresses y on three of the explanatory variables, x_4 being excluded. On p.437 another 54 observations are introduced to check the model fitted to the first 54. Their Table 10.9 compares parameter estimates from the two sets for the preferred regression model. The conclusion is that there is no systematic difference between the two sets and that the same model is acceptable for all the data.

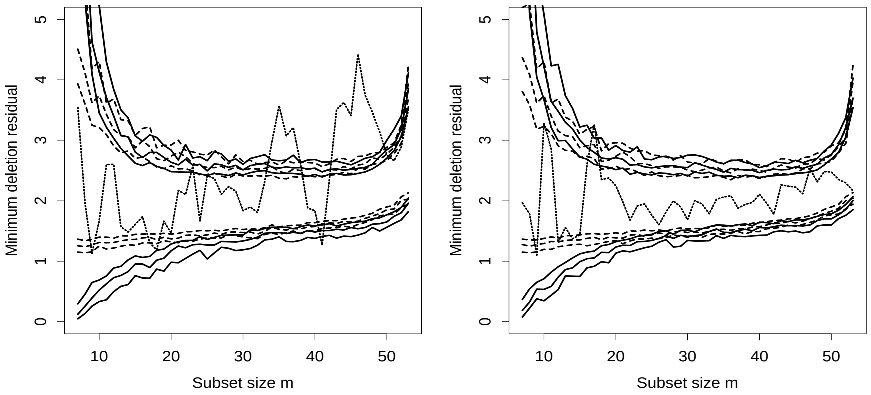

Figure 4: Surgical Unit Data: forward plot of minimum deletion residuals (the outlier test) for the first and second 54 observations. There is strong evidence that here are three groups amongst the first 54 observations. The dotted lines are envelopes simulated by Method 1.

Atkinson and Riani [5] analysed the combined set of all 108 observations using the forward search to assess the influence of individual observations on the estimated regression coefficients. They also conclude that a logged response and a linear model in $x_1 - x_3$ adequately describes the data. Because we will shortly be augmenting the set of explanatory variables, we work with all four original variables.

Figure 3 is a forward plot of the test for outliers for all 108 observations, together with simulation envelope and the approximation found by our first method. This surprising plot seems to show evidence of two groups - the extreme value of the statistic, well outside the boundaries is at the entre of the search, after which there is a gradual decline in the values. At the end of the search the statistic is nudging the lower envelope, a stronger version of the effect of masking noticed in the two previous figures.

Since the maximum value of the statistic is at $m = 55$, we examine those units that enter after this value, to see whether they might belong to a second cluster. Detailed analysis of the results of the forward search show that, after $m = 57$ nearly all the patients entering have unit numbers greater than 54 and so come from the group of confirmatory observations.

This figure suggests the group of confirmatory observations may be different from the original 54 units. Accordingly, we introduce a dummy variable for the two sets and repeat the analysis. This variable is highly significant, with a t value of -7.83 at the end of the search. However, the resulting forward plot still has a slight peak in the centre, although this is much reduced from that in Figure 3. Some remaining structure is indicated.

To take the analysis further we consider the two groups separately. Figure 4 gives the forward plots of the test for outliers. The plot for the second group of observations in the right-hand panel, suggests that the group is homogeneous. However, that in the left-hand panel strongly indicates that the first group contains at least one identifiable subgroup that needs to be disentangled before further analysis is undertaken. A next stage in the analysis would be to extend the scatterplot matrix of the data in Figure 8.3 of Neter et al. [15] to include different plotting symbols for the tentative groups.

5 Discussion

The previous examples are comparatively small and the many plots from the forward search can easily be interpreted. However, as the number of units increases, plots for individual units, such as forward plots of residuals, can become messy and uninformative due to overplotting. Atkinson and Riani [6] analyse 500 observations on the behaviour of customers with loyalty cards from a supermarket chain in Northern Italy. Despite the larger number of observations the forward plot of the test for outliers is as easily interpreted as those in this paper and shows an unsuspected group of 30 very different customers.

There are two further general methodological matters that deserve comment. The first is that the envelopes presented in this paper were all found by simulation. An alternative, investigated by Atkinson and Riani [6], is to calculate the percentage points directly using analytical results on order statistics and the variance of truncated normal distributions. The other point is that, however the envelopes are calculated, the probability statements refer to pointwise exceedance of the bands. To find, for example, the probability of at least one transgression of a specified envelope somewhere during a particular region of the search, for example the second half, requires calculation of the simultaneous probability of transgression at any of the stages of the search within that region. Computationally feasible methods are described by Buja and Rolke [11].

THE ST@TNET PROJECT FOR TEACHING STATISTICS

Gilbert Saporta and Marc Bourdeau

Key words: Teaching, statistics, information society.

COMPSTAT 2004 section: Teaching statistics.

Abstract: This paper describes the design and development of St@tNet, an Internet environment for the teaching of basic Applied Statistics. St@tNet has been developed by a consortium of French-speaking universities. After some general considerations on education for the Information Society, and more specifically for the teaching of Statistics, we will present our product in its present state of development.

1 Means and ends

The title of this session is about teaching Statistics for the Information Society. Well, the Information Society began with the invention of the printing press with moveable type, and that has profoundly modified the formal education process. In essence, it has permitted widespread knowledge dissemination. For a few centuries things have stayed more or less the same, until the invention of mass media. Starting with the radio, then television, it became apparent that the world had once more profoundly changed. Their consequences in the formal and informal education processes were no doubt far-reaching, but now that we have entered the computer age, we have passed into speed *Warp Five* to speak StarTrek lingo; in the last few years the Internet development has brought about a genuine revolution in education thinking, actually a totally new *zeitgeist*.

Neil Postman [1931-2003], one of the keener observers of the evolution of education, and of society in general, has fully explored the consequences of this information revolution [4], [5]. He reports, and it is a common observation, that the situation of teachers and professors has become precarious: they are worried, even anxious, about their role and their immediate future in the Information Society.

Topping all this, governing bodies in many of the developed countries have nowadays become obstinate in drastically reducing budgets, with the elusive hope that the new technologies will give rise to an unprecedented increase in productivity: lesser means, greater expectations... Illusion, reality, who can tell? And what is the end of education finally?

At first sight then, it might appear that the new Information technologies (ITs) could lead to the end of the profession: at this journey's end, all the transmission of knowledge would originate from a few specialized quarters far away from students, pedagogical encounters would be virtual with the Internet being the sole communication channel. Universities and colleges would supply themselves for knowledge transmission and certification from those virtual hyper-classrooms.

ITs could secure huge savings for education boards, but could entail the disappearance of most teachers and professors.

From an overview of some recent and very successful pedagogical experiments in Québec universities using ITs, one can suspect that things will not be that simple [1]. The same situation, it is easy to confirm, is prevalent the world over. Actually, getting an education is a form a travelling. And quality travelling often imply personal guides, at least human encounters, not just guidebooks and TV documentaries though they can be illuminating and irreplaceable. In our experience, all the pedagogies devised with the ITs in mind have always implied more personal contacts with students, less mass dispensing of knowledge[1]

With the Internet, we have perhaps entered an era of renaissance of the true pedagogical relation, not the opposite. As we will explain, this has far reaching implications for teachers and students reciprocal relations.

1.1 Teaching statistics in the information age

Concerning Statistics and Data analysis, there is no gloom and doom scenario in view: there is a huge increase of informations that have to be processed. As John Wilder Tukey [1915-2000] has so correctly noted “The best thing about being a Statistician is that you get to play in everybody’s backyard.”

Better tools of analysis are badly needed, and, since there is already a widespread availability of data sources and an increased appetite for synthetic information, an important increase in Statistics literacy is urgently needed for an ever increasing number of people. Think, among other things, of the amount of information stored and available in national Statistics Offices the world over. All newspapers and mass media are now replete with reports of polls, of official statistics on the economy and society in general. Think also of the huge amount of business informations stored in Data Warehouses that come with an abundance of *Data Mining* softwares recently marketed. Making sense out of this “chaos” [8] is a huge undertaking. We are heading towards a knowledge-based society where statisticians will be ever more in demand.

We report here on the education material for the teaching of Statistics produced in our universities. See Saporta [6] for an overview of some of the web facilities for the teaching of Statistics[2]. See also the remarkable paper by Velleman & Moore for the ins and outs for the use of ITs in the teaching of Statistics [9].

2 The St@tNet project

The St@tNet project is developed at the *Conservatoire National des Arts et Métiers* (Cnam), a major public institution for continuous education and an integral part of the French Ministry of Education, Research and Technology. The Cnam was founded in 1794 to "enlighten ignorance that does not yet know, and poverty which cannot afford knowledge." More than 70 000 adult students attend its courses each year in numerous fields, two-thirds of them have already had two years of 'higher' education, one third are women.

Courses are given mainly in the evenings and in Saturday classes for credits leading towards a degree, as well as through in-service training during working hours, and, finally, through distance-learning. The Cnam links a network of 150 towns and is organized around a 'main' complex in Paris, 22 regional centers, plus some centers in overseas territories. One can begin a program anywhere in the network and continue in any other center. Graduate studies leading to Masters and PhDs are available in many disciplines.

St@tNet follows a series of previous developments of teaching materials for introductory Statistics that date back to the early nineties. Previous courses were available on diskettes and CD-roms [7]. The actual web-course version was financed by the *Agence Universitaire de la Francophonie* (*AUF*) and the French *Ministère de l'Éducation Nationale*. It is operational since 2002, and can be obtained also on a CD-rom version.

St@tNet is the only web resource proposed at the Cnam for distance learning for the much needed Introductory Statistics. It is freely accessible[3]. Indeed, having been financed by public funds, and for the advancement of public learning in conformity with its founding principles that go back to the Enlightenment Age, the decision of the free access of St@tNet was finally agreed upon after fierce debates, but registering at a cost of 250 euros is mandatory for certification purposes and the use of usual facilities: tutorship (one tutor per 25 students), an Internet access on a virtual teaching environment (VTE), an e-mail, etc. This fee comprises the CD-rom that avoids most of the Internet costs and waiting times, especially in distant locations. St@tNet is now also implemented on the virtual campuses of the *Agence Universitaire de la Francophonie* where it is one of the two most popular resources for self-education. Starting in the Fall of 2004, the Cnam will organize a certification system for the AUF courses. St@tNet is a complementary resource for the *École Militaire*, it is also recommended by the French association of mathematics teachers as an aid to school teachers who have to adapt themselves to new curricula that include elements of Probability and Statistics.

With its network of institutions, the Cnam is an ideal ground for the development of pedagogy and teaching material using ITs. Modern teaching of Applied Statistics requires the use of specialized software, and should be

[3] `http://www.agro-montpellier.fr/cnam-lr/statnet/`.

data based, centered on case studies for more advanced material and hands-on training. Applied Statistics is indeed much more than a set of mathematical formulae: its learning implies the development of "statistical thinking", requires the understanding of difficult concepts such as variation, randomness, laws of chance — a difficult oxymoron at first glance —, probable errors, risks, etc. Animations and various graphical tools provide efficient means of learning.

Depending on the level, one can think of various designs for the Internet environments and interactions. Up to now, there are two stages planned in the St@tNet project, the first one is fully operational, the second in development, but with partial versions tested in ordinary classrooms.

For the first stage, at the very basic level of statistical knowledge, St@tNet has opted for a complete Html environment. The advantage of this choice is that interactions of the students with the environment are quite easy to realize: this course is by no means a paper-course translated into Html, as one can still see quite often, but a full-fledged Html environment with frequent short interactions inserted by design into the course.

For higher levels of knowledge, where short interactions are much less needed, St@tNet has opted for a downloadable Latex-Pdf text, with full hyper-referencing possibilities, and many of the hyper-references are internal.

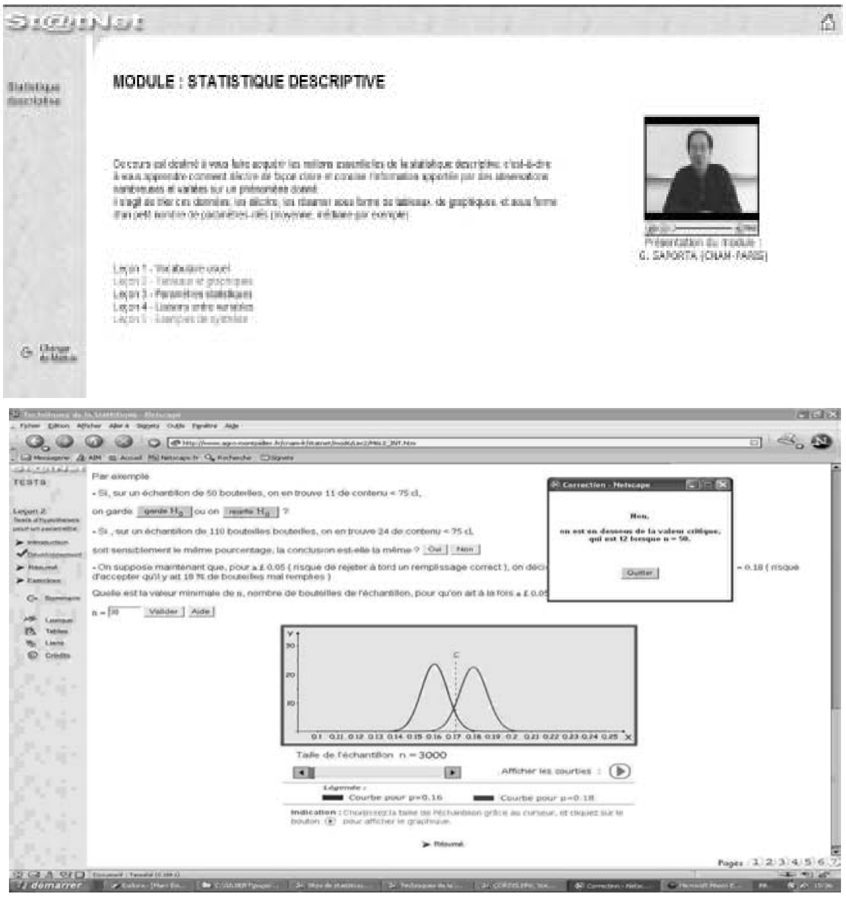
2.1 First stage: the basics

The first stage of the project, the one for the really basic knowledge, is now fully operational. It consists of six modules: data description, probability, random variables, sampling and estimation, tests, basic linear regression. Each of the modules is introduced by a video file (Figure 1, upper part) and is composed of lessons, all of which are of the same structure: Introduction, development, synopsis, exercices. A glossary of terms is accessible within each lesson, as well as all the necessary Statistical Tables and Internet links.

Once in a module, and after viewing its presentation video, the user can pick a *lesson* of his choice: indeed, the learning progression is not designed with a linear structure in mind. Most of our students detest such a progression that do not correspond to their needs.

The lower part of Figure 1 shows part of a page of the *Développement* (development) section of *Leçon* 1 (Lesson 1) of the module *Tests* (tests), with the shown pop-up window that is produced when a wrong answer is given by the reader. Upon a wrong answer, the reader can either correct his answer or get the right one with a short explanation.

Similarly to what is represented in this last Figure, lessons are interspersed with questions to the reader to check if the elements of learning have been correctly assimilated, as well as with some Flash animations and some hyperlinks to Java applets. All lessons end with a page of summary (Figure 2), and a few more elaborate exercices, again with answers given directly on the page, with pop-ups for feedback. A pop-up Glossary, the same for all lessons is hyper-referenced, and, finally, a page of links is available, with some of them referring to external Java applets useful for the learning.



MODULE : STATISTIQUE DESCRIPTIVE

Ce cours est destiné à vous faire acquérir les notions essentielles de la statistique descriptive, c'est-à-dire à vous apprendre comment décrire de façon claire et concise l'information apportée par des observations nombreuses et variées sur un phénomène donné.
Il s'agit de trier ces données, les décrire, les résumer sous forme de tableaux, de graphiques, et sous forme d'un petit nombre de paramètres-clés (moyenne, médiane par exemple).

Leçon 1 - Vocabulaire usuel
Leçon 2 - Tableaux et graphiques
Leçon 3 - Paramètres statistiques
Leçon 4 - Liaisons entre variables
Leçon 5 - Exemples de synthèse

Présentation du module :
G. SAPORTA (CNAM-PARIS)

Par exemple

- Si, sur un échantillon de 50 bouteilles, on en trouve 11 de contenu < 75 cl,

on garde [garde H_0] ou on [rejette H_0] ?

- Si , sur un échantillon de 110 bouteilles bouteilles, on en trouve 24 de contenu < 75 cl,

soit sensiblement le même pourcentage, la conclusion est-elle la même ? [Oui] [Non]

- On suppose maintenant que, pour a £ 0.05 (risque de rejeter à tord un remplissage correct), on déci = 0.18 (risque d'accepter qu'il y ait 18 % de bouteilles mal remplies)

Quelle est la valeur minimale de n, nombre de bouteilles de l'échantillon, pour qu'on ait à la fois a £ 0.05

n = 30 [Valider] [Aide]

Correction - Netscape

Non,
on est en dessous de la valeur critique, qui est 12 lorsque n = 50.

[Quitter]

Taille de l'échantillon n = 3000

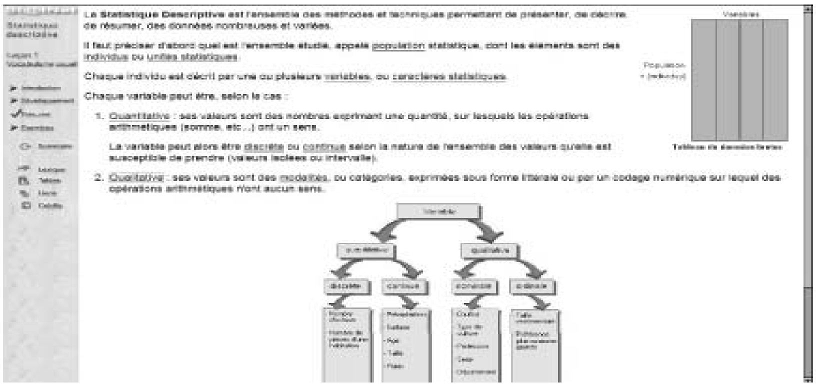
Résumé

Pages : 1 2 3 4 5 6 7

Figure 1: Upper: The entry for the module *Statistiques descriptives* (Descriptive statistics), with its introductory video. Lower: Part of the development section for Lesson 1 of the module *Tests* (Tests), with a pop-up window obtained with a wrong answer.

A new audience has been reached by this approach, and the rate of retention and success is better than for traditional courses. This last point might be the consequence of the type of students (a "sampling bias" !) interested in such an environment.



La **Statistique Descriptive** est l'ensemble des méthodes et techniques permettant de présenter, de décrire, de résumer, des données nombreuses et variées.

Il faut préciser d'abord quel est l'ensemble étudié, appelé population statistique, dont les éléments sont des individus ou unités statistiques.

Chaque individu est décrit par une ou plusieurs variables, ou caractères statistiques.

Chaque variable peut être, selon le cas :

1. Quantitative : ses valeurs sont des nombres exprimant une quantité, sur lesquels les opérations arithmétiques (somme, etc...) ont un sens.

   La variable peut alors être discrète ou continue selon la nature de l'ensemble des valeurs qu'elle est susceptible de prendre (valeurs isolées ou intervalle).

2. Qualitative : ses valeurs sont des modalités, ou catégories, exprimées sous forme littérale ou par un codage numérique sur lequel des opérations arithmétiques n'ont aucun sens.

Figure 2: The summary page from Lesson 1 of the module *Statistiques descriptives* (Descriptive Statistics).)

2.2 Second stage: applied linear models

After the first stage of the project was carried out, and after a decision was made to embark on a large project concerning applied linear models, consisting of the standard curriculum completed by methodologies for categorical data, like the logistic and log-linear models, reflection was given as to what format would be appropriate for more advanced learning.

The advanced learner of a given discipline, especially at the Cnam, has very different needs than the learner of the elements. More often than not, a first course in Probability-Statistics is mandatory. A second course is taken by those who feel a greater relevance of the material taught to their actual work. Hence a truer motivation. In any case, to get the attention of a student, any student, one has to pay heed to its needs, to speak his language.

In Applied Statistics, the actual practice requires the continuous use of a Statistics software on real data – real as opposed to simulated, with all the complexities then of reality –, and an important part of the work consists of careful questioning from the analyst and writing of the facts found during the process.

All this points to a pedagogy that rests principally on case studies, probably the natural points of entry to the curriculum for many students in the engineering and management sciences to whom this course is destined. Theory, the mathematical derivations – and they show a complexity far beyond that found in the elements –, are seen as answers to specific questioning on their part. Thus bigger and more mathematical chunks of material in more advanced studies, instead of the tidbits of the elements.

Another important point in our view of things, there should be a constant preoccupation from the designers of Internet courses, all courses for that matter, to instill into the students the art of questioning. We refer here also to Postman in his last essay ([4] p.161 *seq*): "(...) question-asking is the most significant intellectual skill available to human beings," and it is extremely strange that, especially in the Sciences whether hard or applied, it is not taught in schools!

Finally, and this also harks back to Postman in all his books on Education, we have written historical notes on all the principal aspects on the origin of the need of statistical models for reality. It is a fact that with History notes there is a sort of holographic phenomenon: even when one starts from hard sciences' bits of knowledge, exploring how things came to be, where ideas came from and how we came by them, provides, if propelled by a sense of questioning, an insight on the whole of societies, on all of Human nature. This constitutes an essential part for any formation. Education after all is not only about information, but first and foremost about the formation or casting of minds, young ones in particular.

In summary, due to the mathematical sophistication of this material there is a need for textbook typography, as well as, as usual, a need for a complete system of inner referencing and outer or hyper-referencing facilities. This leaves nowadays almost no choice: such a course must be written in Latex-Pdf typeset. The Pdf-files are virus-proof, they can be readily printed on paper with textbook color quality, their use on computer screens is very confortable, moreover providing some annotating facilities, and, finally, inner links and hyperlinks are manipulated with extreme ease.

This second stage of St@tNet is not, as yet, fully operational, but a demo-version ia available, and parts of the material, especially some case studies, were tested with great success in standard classrooms[4]. In the following pages we present some of its highlights.

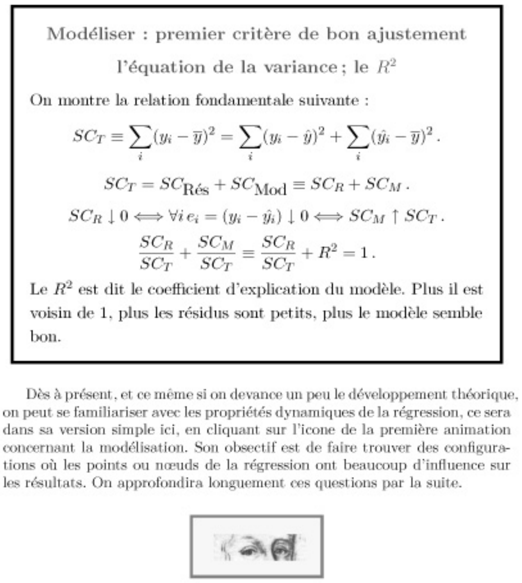
In Figure 3, we can see part of ordinary page of the course file. At the bottom of the page an icon referring to a Flash animation, an image of which appears on Figure 4.

The reader can flip back and forth from any page giving internal links to an equation, a table, a figure. He can also, if he subscribes to an Internet server, readily access a certain number of hyper-links to whatever sites deemed interesting by the authors. These pages will be added automatically at the end of the pdf-file file which can be saved with the added information. The Adobe-reader provides also various facilities to annotate the file pages.

Like in the first stage of St@tNet, many Flash animations are also included in the text. They constitute a remarkable tool to ease the learning. The development of a Flash animation is fairly easy, they are space efficient, and the Flash plug-in is very light and widespread. Furthermore, these animations are upward compatible, and can be readily updated.

Each one of our animations comes with a certain number of controllable buttons one of which is an audio file. In the example (Figure 4), the nodes of

[4] `http://www.mgi.polymtl.ca/marc.bourdeau/InfAgeTeaching` .



Modéliser : premier critère de bon ajustement

l'équation de la variance ; le R^2

On montre la relation fondamentale suivante :

$$SC_T \equiv \sum_i (y_i - \overline{y})^2 = \sum_i (y_i - \hat{y})^2 + \sum_i (\hat{y}_i - \overline{y})^2 .$$

$$SC_T = SC_{\text{Rés}} + SC_{\text{Mod}} \equiv SC_R + SC_M .$$

$$SC_R \downarrow 0 \Longleftrightarrow \forall i\, e_i = (y_i - \hat{y}_i) \downarrow 0 \Longleftrightarrow SC_M \uparrow SC_T .$$

$$\frac{SC_R}{SC_T} + \frac{SC_M}{SC_T} \equiv \frac{SC_R}{SC_T} + R^2 = 1 .$$

Le R^2 est dit le coefficient d'explication du modèle. Plus il est voisin de 1, plus les résidus sont petits, plus le modèle semble bon.

Dès à présent, et ce même si on devance un peu le développement théorique, on peut se familiariser avec les propriétés dynamiques de la régression, ce sera dans sa version simple ici, en cliquant sur l'icone de la première animation concernant la modélisation. Son obsectif est de faire trouver des configurations où les points ou nœuds de la régression ont beaucoup d'influence sur les résultats. On approfondira longuement ces questions par la suite.

Figure 3: Part of a typical page in stage two, with the icon referring to a Flash animation.

Data

Figure 5: A typical page of a case study, with an icon to import the data.

In Figure 5, we show a typical page of a case study. Remember: case studies are the backbone of our pedagogy. A case study is usually several pages long and is built along a certain questioning on a data set that is usually quite complicated. Its flow is very progressive, and generally requires a few dozen hours of work with the writing of a roughly 20 page report.

This task imperatively implies team work. And true collaboration is necessary: a case study is not composed of a certain number of unrelated problems, like the standard homeworks found in most curricula, but has a synthetic character where each part responds or resonates with other ones. There is a wide landscape built in every case study, several chapters of Statistics are brought to bear. This precludes the "usual" split up of the work... The work required is similar to actual data analysis required by engineers and scientists, and ordinary work for that matter.

In a standard classroom, students often have a natural peer group and team formation is quite easy – though there are more optimal ways for this selection –, but for distance learning things are not that easy. However, in most organizations nowadays, the new ITs (chats, forums, etc.) already allow team virtual meeting and working that take up a very large, if not the larger part of the work process!

Students tend to use all the modern hyper-communicating computer facilities that are usually available on all recent computers, as well as within the VTEs in use in most universities. In most North American universities students are in constant Internet contact with their peer-groups, almost day and night, sending each other files of their works, of their thoughts, comments on the courses, etc. And Internet real time voice communication facilities are rapidly spreading. Writing, however, thanks to the Internet, has regained much luster: writing constitutes indeed an essential tool for the unveiling of one's real thoughts. Team work is constant. On a less bright side, homeworks and exams tend to be freely accessible to all...

Professors must adapt to this situation. The Internet has and will profoundly change the learning world. Thus ITs can compensate the isolation of students of the past in distance learning, as they have already done so in the traditional classroom. But our type of pedagogy implies a much greater contact not only horizontally, from students to students as we just noted, but also vertically. For professors of Statistics, it is not the transmission of bits of knowledge that will constitute their main task, it is the statistical cast of mind itself that will be more and more the focal point of teaching. And statistical thinking, like all casts of mind, is best transferred through apprenticeship.

3 Conclusion

The Information Age offers mind-boggling perspectives and cannot but have a profound impact on the pedagogy of whatever discipline there is, but first and foremost for those that present a technical character, and Statistics is one of them. All the presentations in this session will no doubt show the diversity of options.

The end of the journey for teachers? At first sight, it might appear that all these new facilities lead to the disappearance of teachers and professors. But many very successful pedagogical experiments have shown that human pedagogical guides are more necessary than ever, and that ITs provide an indispensable structure for more interactions between them and the students. Il would not be surprising that the new pedagogical paradigm would be that of apprentices and masters. In all the pedagogical experiences we have seen, not only in Statistics, not only our own, there is a greater need than ever for human personal transmission. The role of professors becomes more and more that of a *personne ressource*, a guide so to speak, and less and less that of a knowledge dispenser. Pure knowledge transmission is not the principal role of professors anymore: this has now been more or less automated thanks to the new ITs. Transmission is required now at a much higher cognitive level. And written words for their precision, as well as oral contacts, play — ITs in the background again! — a crucial role. On the Internet, all courses tend to become tutorials! And this is the expensive form of teaching... That may explain why the pedagogical interaction has become so much more demanding than ever.

We do not imply however that teaching becomes a student driven process for the development of curricula and material. But a clear result of our experience with teaching case-based Statistics courses to engineers with an active pedagogy approach, amply confirms Parr's [3] and Moore's [2] experiences: we obtain a much more efficient knowledge transmission, as well as a more positive attitude towards the discipline, than what we observed through years of teaching with the traditional approach.

On the other hand, many governments nowadays tend easily to believe that education and other public services are not of primary importance and cost too much. For reasons of globalization and so forth, they preside over decreasing public spending. The Internet Age can readily provide very low quality and very low cost formative material – garbage-in, garbage-out –, as well as higher than ever quality education. The latter being the kind needed in an increasingly complex world. But the wheel of Fortune spins faster than ever, and, it has always been the case, the outcomes are not totally random: the better educated no doubt will reap the profits.

The question of what's in store for pedagogues in the future will in any case be with us for some time.

What about St@tNet's journey? The conception, development and implementation of St@tNet required considerable resources, human as well as financial. The end product could constitute a complete curriculum in French for Applied Statistics.

The first stage was conceived with a playful spirit in mind, to which the elementary concepts of Probability and Statistics lend themselves fairly easily. But putting it into service required a considerable amount of work, so much more than the writing of a standard chalk and blackboard course, or of a set of telegraphic computer slides. The second stage is much more difficult to conceive if one does not care for a standard run of the mill product, but strives after something more pedagogically efficient. The deeper one goes into the discipline, the more difficult the task.

The question is not whether or not there will be a need for St@tNet or its successors in the future, but what form they will take, and what resources will it be necessary to put into action? A knowledge-based society will indeed bring no dearth of work for statisticians and teachers of the discipline (cf. the 6th European research program FP6). However, at the same time that technology's pace shows no sign of slowing down and that the demand is growing rapidly, the human and financial resources might become more difficult to muster... International cooperation and sharing of the new IT products catering to the needs of students of Statistics as well as greater imagination and dedication on the part of teachers of Statistics will no doubt be necessary.

AN AUTOMATIC THRESHOLDING APPROACH TO GENE EXPRESSION ANALYSIS

Michael G. Schimek and Wolfgang Schmidt

Key words: Empirical Bayes, microarray, multiple testing, R, sparse sequence, statistical computing, threshold.

COMPSTAT 2004 section: Bayesian methods.

Abstract: The statistical problems of gene expression analysis based on the two popular array readout methods, cDNA and Affymetrix, are addressed. As an alternative to multiple frequentist statistical testing the empirical Bayes methodology is introduced. An empirical Bayes thresholding approach is described and its relevance for microarray data analysis is shown. Finally two data sets, one of cDNA-type and the other of Affymetrix-type, are analyzed with the new automatic and computationally efficient thresholding technique.

1 Introduction

In recent years the new technology of microarrays has made it feasible to measure expression of thousands of genes to identify changes between different biological states. Statisticians are requested to design methods which help to quantify the relevance of these experimentally obtained changes.

In such biological experiments (for an introduction see [12]) we are confronted with the problem of high-dimensionality because of thousands of genes involved and at the same time with small sample sizes (due to limited availability of cases and for reasons of cost). This makes it a statistically and computationally demanding task. The complexity of the diseases, the poor understanding of the underlying biology and the imperfection of the measurements (many different sources of noise) are additional problems.

There are two dominating DNA array readout methods, cDNA ([3], p. 17ff, [12]) and Affymetrix GeneChips ([2], [12]). In the first the data are read from a fluorescent signal and in the last the data are recorded from a radioactive signal. The statistical method described in this paper can be applied in both instances.

At first we portray popular techniques for gene expression analysis. Then the idea of empirical Bayes methods is introduced and an empirical Bayes thresholding (EBT) approach is described in some detail. Its practical relevance is demonstrated for colon data from one of our laboratories (cDNA) and for the so-called Golub data set (Affymetrix) from [8].

2 Fold change and classical inference methods

Let us assume that for each of n genes $(i = 1, \ldots, n)$ we have measurements over J experimental conditions $(j = 1, \ldots, J)$ on K slides (arrays) per experiment $(k = 1, \ldots, K)$. These measurements may be intensity readings from a spotted cDNA or probe-level intensity signals from an Affymetrix oligonucleotide system. The expression data are either log-ratios of intensities or log-intensities.

For each gene the fundamental question is whether the level of expression is substantially different between two $(J = 2)$ or more $(J > 2)$ situations. One approach commonly used in early publications (e.g. [13]) - always limited to control versus treatment designs - has been a simple fold approach. This means that a gene is labeled significantly changed if its average expression level varies by more than a constant factor, typically two, between the two experimental conditions, the so-called "twofold rule". This ad hoc approach has one severe disadvantage: a factor of two does not mean the same in different regions of the spectrum of intensities, especially when extreme values are concerned.

The standard statistical approach taken is significance testing which implies that fold change is replaced by significance. The null hypothesis for each gene is that the data we observe have some common distributional parameter among the conditions, usually the mean of the expression levels. For each gene we calculate a statistic that is a function of the data. For instance a t-test statistic is applied (despite an unrealistic distributional assumption). Yet there is not much gain compared to the fold approach because the difference between two logarithmic expression levels is the logarithm of their ratio.

Which errors are committed at each particular gene when testing for differential expression? Apart from the type I error (false positive) and the type II error (false negative) there is the complication of testing multiple hypotheses simultaneously. Each gene has individual type I and II errors and it is nothing but clear how to measure the overall error rates. In the recent literature several compound error measures have been suggested, such as the false discovery rate ([4]) and the positive false discovery rate ([14]). However their calculation is not straight forward and the selection of a test statistic in this situation is far from trivial.

Suppose n genes $(i = 1, \ldots, n)$ have been measured over two experimental conditions $(j = 1, 2)$ on K_1 arrays of condition 1 and K_2 arrays of condition 2 and $K_1 + K_2 = K$. Let $\bar{x}_{i1}$ and $\bar{x}_{i2}$ be the mean gene expression for gene i under conditions 1 and 2, and let s_i be the pooled standard deviation for gene i,

$$s_i = \sqrt{\left(\frac{1}{K_1} + \frac{1}{K_2}\right) \frac{\sum_{k_1=1}^{K_1} (x_{ik_1} - \bar{x}_{i1})^2 + \sum_{k_2=1}^{K_2} (x_{ik_2} - \bar{x}_{i2})^2}{K - 2}}.$$

As pointed out already a test statistic for assessing differential gene expression is the standard t-test

$$t_i = \frac{\bar{x}_{i2} - \bar{x}_{i1}}{s_i}.$$

Alternatively a rank-sum statistic can be adopted. Suppose r_{ik} be the rank of the kth expression level within gene i. Then the rank-sum statistic for gene i is

$$r_i = \sum_{k_1=1}^{K_1} r_{ik_1}.$$

An extreme r_i value in either direction would indicate a difference in gene expression. The t-statistic as introduced above tests for difference in the mean whereas the rank statistic tests for difference in distribution.

Under the assumption of only two experimental conditions and no correlation between measurements it is possible to derive the null distribution: either permutation ([17]) or bootstrap ([6]) techniques can be applied. In both cases the computational demand is quite high.

If the null distribution is calculated individually for each gene, this has two disadvantages. The first is what is known as granularity problem: the null distribution has a resolution on the order of the number of permutations. With n genes and m permutations the resolution is on the order of $1/m$ for individual null distributions, but $1/(nm)$ for a pooled null distribution. For instance, if we test 3000 genes with 100 permutations, then we can expect to reject 30 at a time. The second problem is that we are not in the position to construct better rejection regions. With individual null distributions, each gene is treated as a different experiment. For each "experiment" we have m observations from the null distribution and one from the original measurements. It is not possible to compare the null distribution to the observed statistic to derive more powerful, asymmetric rejection regions ([15], p. 277f). This means loss of power.

In the SAM ("Significance Analysis of Microarray") method ([16]) another approach has been taken: there the test statistics are pooled and considered to follow a mixture distribution. As a consequence, many observations from the mixture of the null and affected distributions, as well as from the pure null distribution are available, leading to improved rejection regions. The pitfall of using different distributions for the estimation of the overall error rate (due to pooling of the null statistics) is sufficiently controlled in SAM according to its authors. In SAM expression is evaluated by a combination of test and thresholding steps for the purpose of non-symmetric rejection regions. This approach improves the decision process when the numbers of overexpressed and underexpressed genes are substantially different (usually the case in practice). The cutoff for test significance is tuned via a user-specified parameter connected to the false discovery rate (the number of false positives is limited this way). Hence SAM is not an automatic approach.

3 Empirical Bayes methods

Empirical Bayes methods have been around in statistics for thirty years, beginning with [5]. One cannot say that they have enjoyed much attention so far. Why are they attractive for gene expression analysis? Empirical Bayes methods are well-suited for high-dimensional decision problems. In contrast to techniques as discussed above, where inference is performed separately for different genes, in empirical Bayes information among genes is shared. In most microarray experiments involving thousands of genes but only a small number of microarrays, the amount of information per gene is quite low. The idea is to combine related inference problems which means that the evaluation of the expression level of one gene is influenced by the overall expression levels. Here advantage is taken of the quantification of the variability characterizing the bulk of genes (still assuming independent measurements).

The general framework of empirical Bayes methods is quite flexible. Probability distributions are specified in several layers that account for multiple sources of variation. Then based on a mixture model posterior probabilities are computed. This allows comparison among multiple conditions.

Empirical Bayes methods have been applied for the first time to gene expression analysis in [11] and [7]. In these papers the concepts of fold change respectively significance with respect to the frequentist false discovery rate are generalized. In the next section we consider an empirical Bayes thresholding approach that does not require a concept of fold change or significance.

3.1 A fully automatic thresholding approach

Here we describe an empirical Bayes approach for the estimation of possibly sparse sequences observed with white noise (modest correlation is tolerable). A sparse sequence consists of a relatively small number of informative measurements (in which the signal component is dominating) and a very large number of noisy zero measurements. This is the typical situation found in image processing. Gene expression profiling can be seen along the same lines.

Johnstone and Silverman (2004) have proposed a method that can handle such sparse sequences by means of thresholding without any users-specified parameters apart from distributional assumptions ([10]). It is called empirical Bayes thresholding (EBT). As will be seen later on, the choice of the threshold is the most critical aspect, both in terms of signal extraction and computational burden.

In empirical Bayes threshold models the object of interest is a sequence of parameters θ_i on each of which we have a single observation X_i subject to some noise ϵ_i, such that

$$X_i = \theta_i + \epsilon_i.$$

For the estimation of the θ_is additional assumptions are required. In [10] the θ_is are assumed to be medians and that the observation $X = (X_1, \ldots, X_n)$ satisfies

$$X_i = \mu_i + \epsilon_i,$$

where the ϵ_is are $N(0, \sigma^2)$ random variables, not too highly correlated. Further let $\mu = (\mu_1, \mu_2, \ldots, \mu_n)$ be a vector of medians (means are also feasible but not of interest in this paper).

Obviously the μ_is will not be exactly zero in most applications. The p-norm of μ, $\|\mu\|_p = (\sum |\mu_i|^p)^{1/p}$ allows for a more subtle characterization of sparsity of μ (assuming small p). In other words, the quantification of sparsity corresponds to bounds on the p-norm of μ for $p > 0$. Consider the sum of squares of a vector with $\|\mu\|_p = 1$ for some small p. If only one of the components of μ is nonzero, then the energy will be 1. If on the other hand, all of the components are equal, then the energy will be $n^{1-2/p}$ and is tending to zero as $n \to \infty$ if $p < 2$, tending rapidly to zero if p is near zero. Consider the case of p small. Then the only way for a signal in an l_p ball with small p to have large energy (sum of squares) is to consist of a few large components, as opposed to many small components of roughly equal magnitude. Among all signals with a given energy, the sparse ones are those with small l_p norm.

Some measure of sparsity is needed because sparsity of a signal is not solely a matter of the proportion of μ_i that are zero or near zero, but also of subtle ways in which the energy of the signal μ is distributed among the various components. For our purposes it is sufficient that the number of indices i for which μ_i is nonzero is bounded. In engineering such a parameter μ is called a "nearly black signal". For some η this is

$$l_0\,[\eta] = \left\{ \mu : \frac{1}{n} \sum_{i=1}^{n} I\,[\mu_i \neq 0] \leq \eta \right\}, \tag{1}$$

where I denotes an indicator function. Assuming the signal is sparse in the sense of belonging to an l_p norm ball of small radius η, we have

$$l_p\,[\eta] = \left\{ \mu : \frac{1}{n} \sum_{i=1}^{n} |\mu_i|^p \leq \eta^p \right\}. \tag{2}$$

For (1) and (2) it is possible to derive minimax squared error properties. It can be shown that EBT adapts automatically to the degree and character of sparsity of the signal with the minimax rate (i.e. the optimum rate for such signals; for details see [10]). It is worth mentioning that the minimax properties are the same as in the false discovery rate approach in [1].

Suppose the errors ϵ_i are independent. Within the Bayesian context sparsity is equivalent to suitable prior distributions for the θ_is we are interested in. The notion that many or most of the θ_is are near zero is captured by assuming that the elements θ_i have independent prior distributions each given by the mixture

$$f_{prior}(\theta) = (1 - \omega)\delta_0(\theta) + \omega\gamma(\theta). \tag{3}$$

The nonzero part of the prior, γ, is assumed to be a fixed unimodal symmetric density. γ is traditionally assumed to be a normal density, Here ([10]) it is recommend to use a heavier-tailed prior. For the mixing prior in (3) it is favorable to use for γ the Laplace density with scale parameter $a > 0$

$$\gamma_a(u) = \frac{1}{2} a \exp(-a\,|u|)$$

or the mixture density

$$(\mu|\Theta = \theta) \sim N(0, \theta^{-1} - 1) \text{ with } \Theta \sim \text{ Beta}\,(\alpha, 1)\,.$$

The mixture density for μ has tails that decay as $\mu^{-2\alpha-1}$. For $\alpha = \frac{1}{2}$ the tails have the same weight as those of the Cauchy distribution.

In both cases the posterior distribution of μ given an observed X, and the marginal distribution of X, are tractable. This makes it feasible to adopt marginal maximum likelihood for the ω selection as well as to estimate μ by the posterior median.

Further assumptions required for the nonzero part of the prior γ are (i) a fixed unimodal symmetric density, (ii) tails to be exponential or heavier, and (iii) a mild regularity condition.

The key feature of this empirical Bayes approach is the threshold. If the absolute value of a particular X_i exceeds some threshold t then it is taken to correspond to a nonzero μ_i, estimated simply by X_i itself. Otherwise the coefficient μ_i is estimated zero. The problem is, that the threshold t (or rather t_is) needs to be tuned to the sparsity of the signal. If a threshold appropriate for dense singnals is applied to a sparse signal, or vice versa, the result is of no use at all. Hence a good threshold selection method needs (i) to be adaptive between sparse and dense signals, (ii) to be stable to small changes in the data, and (iii) to be tractable to compute. The approach in [10] comprises all these properties.

Let us now discuss the choice of the mixing weight ω, or equivalently, of the threshold $t(\omega)$. Assume that the X_i are independent. For any value of the weight ω consider the posterior distribution of μ given $X = x$ under the assumption that $X \sim N(\mu, \sigma^2)$. Let $\mu(x;\omega)$ be the median of this distribution. For fixed $\omega < 1$, $\mu(x;\omega)$ is a monotonic function of x with the following threshold property

$$\exists t(\omega) > 0 \text{ such that } \mu(x;\omega) = 0 \Leftrightarrow |x| \leq t(\omega).$$

Let $g = \gamma * \phi$ denote the convolution of the density γ with the standard normal density ϕ. The marginal density of the observations X_i is then

$$(1 - \omega)\phi(x) - \omega g(x).$$

The marginal maximum likelihood estimator $\tilde{\omega}$ of ω is defined as the maximizer of the marginal log-likelihood

$$l(\omega) = \sum_{i=1}^{n} log \left\{(1 - \omega)\,\phi\,(X_i) + \omega g\,(X_i)\right\},$$

subject to the constraint on ω that the threshold satisfies $t(\omega) \leq \sqrt{2\log n}$ (the threshold takes values from 0 to $\sqrt{2\log n}$).

What is the posterior probability that μ is nonzero? Let us define

$$\beta(x) = \frac{g(x)}{\phi(x)} - 1. \tag{4}$$

Then the posterior probability $\omega_{post}(x) = P(\mu \neq 0|X = x)$ will satisfy

$$\omega_{post}(x) = \frac{\omega g(x)}{\omega g(x) + (1-\omega)\phi(x)} = \frac{1+\beta(x)}{\omega^{-1} + \beta(x)}$$

As a result it can be found using function (4) alone.

To find the posterior median $\hat{\mu}(x;\omega)$ of μ given $X = x > 0$, we need the cumulative distribution

$$\tilde{F}_1(\mu|x) = \int_{\mu}^{\infty} f_1(u|x)du,$$

where f_1 is a density. If $x > 0$, we can find $\hat{\mu}(x;\omega)$ via the following properties:

$$\begin{array}{ll} \widehat{\mu}(x;\omega) = 0 & \text{if } \omega_{post}\tilde{F}_1(0|x) < \frac{1}{2} \\ \tilde{F}_1(\widehat{\mu}(x;\omega)|x) = (2\omega_{post}(x))^{-1} & \text{otherwise.} \end{array}$$

For $\omega_{post}(x) \leq \frac{1}{2}$ the median is necessarily zero (no need to evaluate $\tilde{F}_1(0|x)$). For $x < 0$ the antisymmetric property $\hat{\mu}(-x,\omega) = -\hat{\mu}(x,\omega)$ can be used.

The Bayes factor threshold is related to the posterior median. It is a value $\tau(\omega)$ such that $P(\mu > 0|X = \tau(\omega)) = 0.5$. This is to say that $\tau(\omega)$ is the largest value of the sequence for which the estimated μ will be zero, if the estimate is obtained from the posterior median.

How can we find the estimate $\tilde{\omega}$ of ω or the scale parameter a of the Laplace density? Maximization of the marginal maximum likelihood l gives the solution. Let us define the score function $S(\omega) = l'(\omega)$. Because of smoothness and monotonicity of $S(\omega)$ it is possible to find the estimates by a binary search, or an even faster algorithm. The obtained values are then plugged back into the prior and the parameters μ_i are evaluated via these estimates, either by using the posterior median itself, or by using some other threshold rule with the same threshold $t(\omega)$.

The threshold is obtained from the posterior median $\hat{\mu}$, mainly by use of the following properties:

(i) shrinkage rule: $0 \leq \widehat{\mu} \leq x$ for $x \geq 0$

(ii) threshold rule: there exists $t(x) > 0$ such that $\widehat{\mu}(x) = 0$ if and only if $|x| \leq t(\omega)$

(iii) bounded shrinkage: there exists a constant b such that for all ω and x $|\widehat{\mu}(x;\omega) - x| \leq t(x) + b$.

This approach is quite unique in combining features of excellent theoretical properties and efficient computation. According to [10] the results

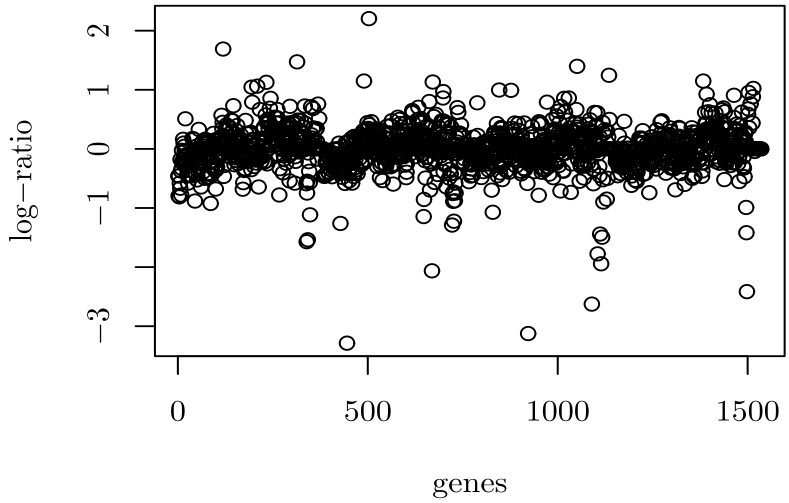

Figure 1: Colon data after preprocessing.

proven for white noise errors still hold for modestly correlated errors, at least in an approximate sense. This generalization is important for microarray applications because some of the measurements are usually replicates. The EBT approach was implemented in the R language ([9]) by Iain M. Johnstone and Bernard W. Silverman. The master function of the EBT algorithm is *ebayesthresh*(). This function as well as the others required to analyze sparse sequences can be downloaded freely for academic purposes from `http://www.stats.ox.ac.uk/∼silverma/ebayesthresh/`. Relevant documentation is found there too. After having been sourced to R, the EBT algorithm can be used as any other function in R.

4 Two examples

Our first example uses cDNA measurements and our second example is based on Affymetrix measurements. In both techniques we have many different sources of noise such as variation in hybridization time, variation in reagent concentrations, leak of external light during chip reading, inhomogeneities in chip preparation, variations in laser intensity during chip reading, trace contamination with cross-hybridizing oligonucleotides, etc. EBT is an ideal method to handle a decision problem under sparsity due to substantial noise.

4.1 The colon data set

The data are of cDNA-type from a colon carcinoma experiment which encompasses a set of 13 colon carcinoma patients. None of these patients was treated neoadjuvant. The invasionfront of the tumors was investi-

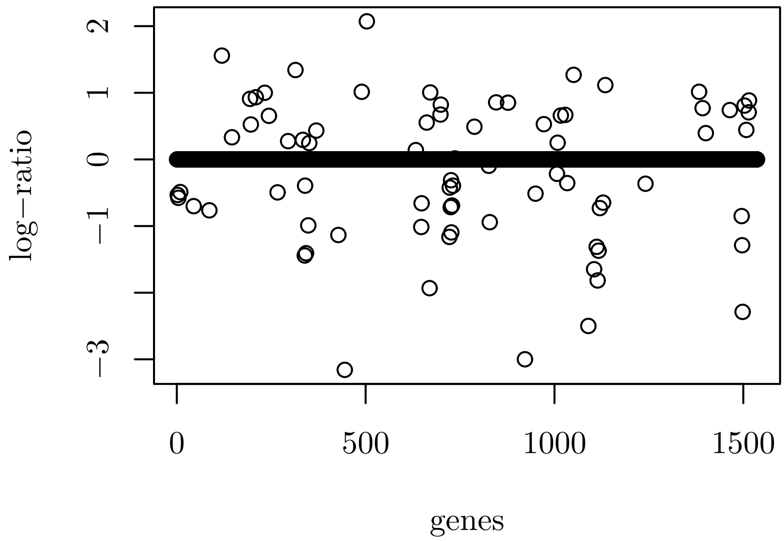

Figure 2: EBT result for colon data.

gated and hybridization was made against a pool of 4 probes of normal colon tissue. Standard protocol was used and quality control ensured by the Institute of Pathology, Medical University of Graz. The experiments contain $n = 1536$ different genes, among them some replicates. The cDNA chips where then scanned with microarray image analysis software Imagene from BioDiscovery producing two text files. These files where then imported into R ([9]) using the object-oriented microarray analysis library *com.braju.sma* (can be obtained from the University of California at Berkeley, `http://www.maths.lth.se/help/R/com.braju.sma/`) The following preprocessing steps were applied: (i) background subtraction, (ii) transformation into $M = \log_2 (Red/Green)$ (M is further referred to as *log-ratio*), (iii) normalizing within slide using scaled print-tip method, (iv) few values which were not detected on a subset of slides, hence NAs, were set to zero in order to allow further processing, and (v) the experiments where merged using the median. The data after preprocessing are displayed in Fig. 1.

The EBT algorithm was applied using following parameters: $prior =$ "*laplace*" and $a = NA$, so that the scale parameter a is estimated by marginal maximum likelihood. $bayesfac = T$ means that whenever a threshold is explicitly calculated, the Bayes factor threshold will be used. Having $sdev = NA$, the standard deviation is estimated via the median absolute deviation from zero ($mad(x, center = 0)$). Finally, with $threshrule =$ "*median*" the posterior median is chosen.

Fig. 2 shows the genes from the colon data that are informative after administering the EBT algorithm. Finally we obtained $n_1 = 37$ overexpressed and $n_2 = 39$ underexpressed genes. These could be verified by pathologists.

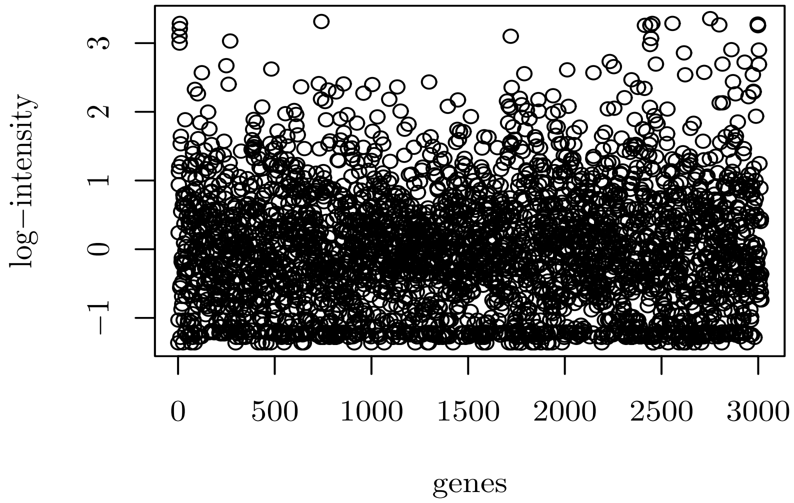

Figure 3: Subclass ALL of Golub data after preprocessing.

4.2 The Golub data set

The Golub data set ([8]) is well-known and has been re-analyzed by many authors. The data originate from a gene expression study with patients suffering from two types of acute leukemia. Here we consider only a subset of it (i.e. the learning set) with data from 27 acute lymphoblastic leukemia (ALL) patients and 11 acute myeloid leukemia (AML) patients. The intensities were measured using Affymetrix high-density oligonucleotide chips. The data comprise the expression of $n = 6817$ human genes and can be obtained from the Web site `http://www-genome.wi.mit.edu/mpr/data_set_ALL_AML.html`.

The following preprocessing steps were administered using R functions: (i) thresholding of the expressions (floor of 100 and ceiling of 16000), (ii) filtering by excluding genes with expressions $max/min \leq 5$ or$(max - min) \leq 500$, (iii) a base 10 logarithmic transformation, (iv) scaling the matrix using the R command *scale* from the package *base*, which is a generic function whose default method centers and/or scales the columns of a numeric matrix, and (v) merging the experiments by subclass ALL or AML respectively. Due to the preprocessing an accumulation at a minimum value was observed that had to be eliminated in order to comply with the requirements of the EBT algorithm. This bottom line was eliminated by removing the respective gene during the processing step. It is re-inserted at the preceding index location of the result matrix with a value of zero after the transformation. This filtering omits 35 genes for the merged ALL data and 117 genes for the merged AML data. For the subclass ALL the preprocessed data are displayed in Fig. 3.

Applying the EBT algorithm with the same parameters as specified for

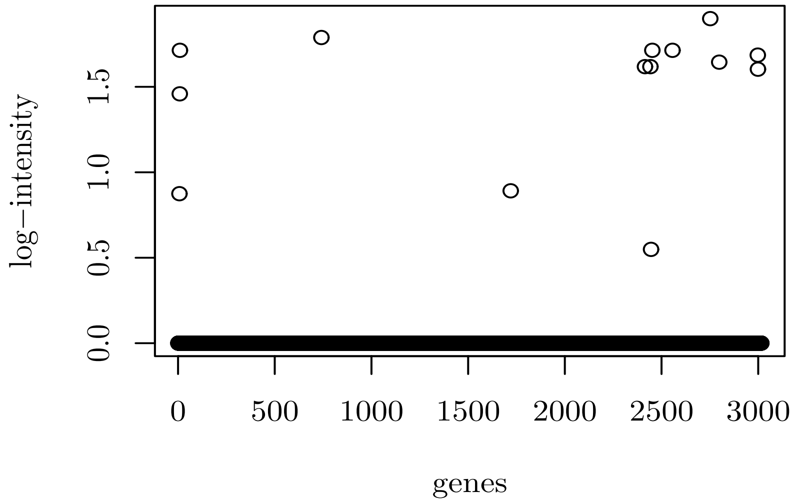

Figure 4: EBT result for subclass ALL of Golub data.

the above colon data cDNA experiment, 2 genes are detected for ALL, 1 gene is detected for AML and 12 genes are expressed in both subclasses (for a plot of the all together 14 overexpressed genes of the ALL subclass see Fig. 4). This is a substantial reduction in the number of informative genes. Whether the identified genes that are overexpressed in one subclass while not in the other (i.e. having a zero estimate) – obviously of discriminative power – are of high biological relevance needs to be answered by future leukemia research and is not a statistical matter.

KERNEL METHODS FOR MANIFOLD ESTIMATION

Bernhard Schölkopf

Key words: Kernel methods, support vector machines, quantile estimation.

COMPSTAT 2004 section: Neural networks and machine learning.

Abstract: We describe methods for estimating manifolds in high-dimensional spacs. They work by mapping the data into a reproducing kernel Hilbert space and then determining regions in terms of hyperplanes.

1 Kernel algorithms for pattern recognition

Suppose we are given empirical data

$$(x_1, y_1), \ldots, (x_m, y_m) \in \mathcal{X} \times \{\pm 1\}. \tag{1}$$

Here, the domain $\mathcal{X}$ is some nonempty set that the inputs x_i are taken from; the $y_i \in \mathcal{Y}$ are called *targets*. Here and below, $i, j = 1, \ldots, m$.

We have made no assumptions on the domain $\mathcal{X}$ other than it being a set. In order to study the problem of learning, we need additional structure. In learning, we want to be able to *generalize* to unseen data points. In the case of pattern recognition, given some new input $x \in \mathcal{X}$, we want to predict the corresponding $y \in \{\pm 1\}$. Loosely speaking, we want to choose y such that (x, y) is *similar* to the training examples. To this end, we need similarity measures in $\mathcal{X}$ and in $\{\pm 1\}$. The latter is easier, as two target values can only be identical or different.[1] For the former, we require a similarity measure

$$k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}, \qquad (x, x') \mapsto k(x, x') \tag{2}$$

with the property that there exists a map Φ into a Hilbert space $\mathcal{H}$ such that for all $x, x' \in \mathcal{X}$,

$$k(x, x') = \langle \Phi(x), \Phi(x') \rangle . \tag{3}$$

Such a function k is called a *positive definite kernel* [1], [10], [8], $\mathcal{H}$ is the *reproducing kernel Hilbert space (RKHS)* associated with it, and Φ is called its *feature map*. A popular example, in the case where $\mathcal{X}$ is a normed space, is the Gaussian

$$k(x, x') = \exp\left(-\frac{\|x - x'\|^2}{2\,\sigma^2}\right), \tag{4}$$

where $\sigma > 0$.

[1] In the case where the outputs are taken from a general set $\mathcal{Y}$, the situation is more complex, cf. [11].

The advantage of using a positive definite kernel as a similarity measure is that it allows us to construct algorithms in Hilbert spaces. For instance, consider the following simple classification algorithm, where $\mathcal{Y} = \{\pm 1\}$. The idea is to compute the means of the two classes in the RKHS, $\mathbf{c}_1 = \frac{1}{m_1}\sum_{\{i:y_i=+1\}}\Phi(x_i)$, and $\mathbf{c}_2 = \frac{1}{m_2}\sum_{\{i:y_i=-1\}}\Phi(x_i)$, where m_1 and m_2 are the number of examples with positive and negative target values, respectively. We then assign a new point $\Phi(x)$ to the class whose mean is closer to it. This can be shown [8] to lead to

$$y = \operatorname{sgn}\left(\langle\Phi(x),\mathbf{c}_1\rangle - \langle\Phi(x),\mathbf{c}_2\rangle + b\right) \tag{5}$$

with $b = \frac{1}{2}\left(\|\mathbf{c}_2\|^2 - \|\mathbf{c}_1\|^2\right)$. Rewritten in terms of k, this reads

$$y = \operatorname{sgn}\left(\frac{1}{m_1}\sum_{\{i:y_i=+1\}} k(x,x_i) - \frac{1}{m_2}\sum_{\{i:y_i=-1\}} k(x,x_i) + b\right) \tag{6}$$

and $b = \frac{1}{2}\left(\frac{1}{m_2^2}\sum_{\{(i,j):y_i=y_j=-1\}} k(x_i,x_j) - \frac{1}{m_1^2}\sum_{\{(i,j):y_i=y_j=+1\}} k(x_i,x_j)\right)$.

Let us consider one well-known special case of this type of classifier. Assume that the class means have the same distance to the origin (hence $b = 0$), and that k can be viewed as a density, i.e., it is positive and has integral 1 (assuming the integral exists), $\int_X k(x,x')dx = 1$ for all $x' \in \mathcal{X}$. Then (6) corresponds to the Bayes decision boundary separating the two classes, subject to the assumption that the two classes are equally likely and were generated from two probability distributions that are correctly estimated by the Parzen windows estimators of the two classes,

$$p_1(x) := \frac{1}{m_1}\sum_{\{i:y_i=+1\}} k(x,x_i), \qquad p_2(x) := \frac{1}{m_2}\sum_{\{i:y_i=-1\}} k(x,x_i). \tag{7}$$

The classifier (6) is quite close to the *Support Vector Machine (SVM)* that has recently attracted much attention [10], [8]. It is linear in the RKHS (see (5)), while in the input domain, it is represented by a kernel expansion (6). It is example-based in the sense that the kernels are centered on the training examples, i.e., one of the two arguments of the kernels is always a training example. This is a general property of kernel methods, due to the Representer Theorem [5], [8]. The main point where SVMs deviate from (6) is in the selection of the examples that the kernels are centered on, and in the weight that is put on the individual kernels in the decision function. The SVM decision boundary takes the form

$$y = \operatorname{sgn}\left(\sum_{i=1}^{m}\lambda_i k(x,x_i) + b\right), \tag{8}$$

where the coefficients λ_i and b are computed by solving a convex quadratic programming problem such that the margin of separation of the classes in the RKHS is maximized. It turns out that for many problems this leads to sparse solutions, i.e., often many of the λ_i take the value 0. The x_i with nonzero λ_i are usually called *Support Vectors*.

Using methods from statistical learning theory [10], one can bound the generalization error of SVMs. In a nutshell, statistical learning theory shows that it is imperative that one uses a class of functions whose *capacity* (e.g., measured by the VC dimension) is matched to the size of the training set. In SVMs, the capacity measure used is the size of the margin, which is inversely proportional to the RKHS norm of the SVM parameter vector.

The SV algorithm has been generalized to problems such as regression estimation [10], mappings between general sets of objects [11], and single class problems. As the latter algorithm is closely related to the one to be proposed in the present paper, we will describe it in the next section.

2 Single-class SVMs

Let us assume we are given unlabelled data $x_1, \ldots, x_m \in \mathcal{X}$ generated i.i.d. according to some underlying distribution P. We would like to estimate quantiles C of P using kernel expansions as $C \approx \{x \in \mathcal{X} | f(x) \in I\}$. Here, I is an interval, and $f = \sum_{i=1}^{m} \lambda_i k(x, x_i)$.

In the case of $I = [\rho, \infty[$ (where $\rho \in \mathbb{R}R$), an approach to compute such an estimator f is the single-class SVM [7]. It approximately computes the smallest set $C \in \mathcal{C}$ containing a specified fraction of all training examples, where smallness is measured in terms of a regularizer corresponding to the norm in the RKHS associated with k, and $\mathcal{C}$ is the family of sets corresponding to half-spaces in the RKHS. When choosing a suitable kernel, this notion of smallness will coincide with the intuitive idea that the quantile estimate should not only contain a specified fraction of the training points, but it should also be sufficiently smooth so that we can be confident that this statement will also be approximately true for previously unseen points sampled from P (for an analysis, see [7]).

Let us briefly describe the main ideas of the approach. The training points are mapped into the RKHS using the feature map Φ associated with k, and then it is attempted to separate them from the origin with a large margin by solving the following quadratic program: for $\nu \in (0, 1]$,[2]

$$\underset{\mathbf{w}\in\mathcal{H}}{\text{minimize}}\,, \boldsymbol{\xi} \in \mathbb{R}^m, \rho \in \mathbb{R} \qquad \frac{1}{2}\|\mathbf{w}\|^2 + \frac{1}{\nu m}\sum_i \xi_i - \rho \tag{9}$$

$$\text{subject to} \qquad \langle \mathbf{w}, \Phi(x_i)\rangle \geq \rho - \xi_i, \quad \xi_i \geq 0. \tag{10}$$

Since nonzero slack variables ξ_i are penalized in the objective function, we can expect that if $\mathbf{w}$ and ρ solve this problem, then the decision function,

$$f(x) = \operatorname{sgn}\left(\langle \mathbf{w}, \Phi(x)\rangle - \rho\right), \tag{11}$$

[2] Here and below we follow the convention that bold face greek character denote vectors, e.g., $\boldsymbol{\xi} = (\xi_1, \ldots, \xi_m)^\top$.

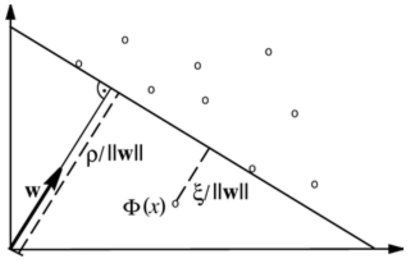

Figure 1: In the 2-D toy example depicted, the hyperplane $\langle \mathbf{w}, \Phi(x) \rangle = \rho$ separates all but one of the points from the origin. The outlier $\Phi(x)$ is associated with a slack variable ξ, which is penalized in the objective function (9). The distance from the outlier to the hyperplane is $\xi / \|\mathbf{w}\|$; the distance between hyperplane and origin is $\rho / \|\mathbf{w}\|$. The latter implies that a small $\|\mathbf{w}\|$ corresponds to a large margin of separation from the origin (from [8]).

will equal 1 for most examples x_i contained in the training set,[3] while the regularization term $\|\mathbf{w}\|$ will still be small. For an illustration, see Figure 1. The trade-off between these two goals is controlled by a parameter ν.

One can show that the solution takes the form

$$f(x) = \operatorname{sgn}\left(\sum_i \alpha_i k(x_i, x) - \rho \right), \tag{12}$$

where the α_i are computed by solving the dual problem,

$$\underset{\boldsymbol{\alpha} \in \mathbb{R}^m}{\text{minimize}} \quad \frac{1}{2} \sum_{ij} \alpha_i \alpha_j k(x_i, x_j) \tag{13}$$

$$\text{subject to} \quad 0 \leq \alpha_i \leq \frac{1}{\nu m} \quad \text{and} \quad \sum_i \alpha_i = 1. \tag{14}$$

Note that due to (14), the training examples contribute with nonnegative weights $\alpha_i \geq 0$ to the solution (12). One can show that asymptotically, a fraction ν of all training examples will have strictly positive weights, and the rest will be zero.

3 Implicit manifold estimation

A richer class of solutions, where some of the weights can be negative, is obtained if we change the geometric setup. In this case, we estimate a region which is a slab in the RKHS, i.e., the area enclosed between two parallel hyperplanes (see Figure 2).

[3] We use the convention that $\operatorname{sgn}(z)$ equals 1 for $z \geq 0$ and -1 otherwise.

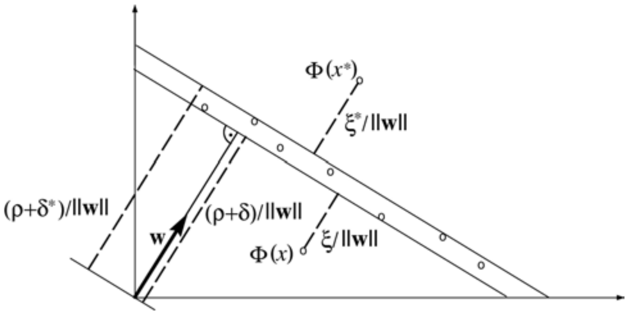

Figure 2: Two parallel hyperplanes $\langle \mathbf{w}, \Phi(x)\rangle = \rho + \delta^{(*)}$ enclosing all but two of the points. The outlier $\Phi(x^{(*)})$ is associated with a slack variable $\xi^{(*)}$, which is penalized in the objective function (15).

To this end, we consider the following modified program:[4]

$$\begin{aligned} \underset{\mathbf{w}\in\mathcal{H}}{\text{minimize}}\,, \boldsymbol{\xi}^{(*)} \in \mathbb{R}^m, \rho\in\mathbb{R} \qquad & \frac{1}{2}\|\mathbf{w}\|^2 + \frac{1}{\nu m}\sum_i (\xi_i + \xi_i^*) - \rho && (15)\\ \text{subject to} \qquad & \delta - \xi_i \le \langle \mathbf{w}, \Phi(x_i)\rangle - \rho \le \delta^* + \xi_i^* && (16)\\ \text{and} \qquad & \xi_i^{(*)} \ge 0. && (17) \end{aligned}$$

Here, $\delta^{(*)}$ are fixed parameters. Note that strictly speaking, one of them is redundant: one can show that if we subtract some offset from both, then we obtain the same overall solution, with ρ offset by the same amount. Hence, we can generally set one of them to zero, say, $\delta = 0$. In the simulations shown below, this is the case; nonetheless, we prefer to keep the δ in the optimization problem.

Before we compute the dual problem, let us discuss the relationship of this convex quadratic optimization problem to other approaches.

- For $\delta = 0$ and $\delta^* = \infty$ (i.e., no upper constraint), we recover the single-class SVM (9)–(10).
- If we drop ρ from the objective function and set $\delta = -\varepsilon$, $\delta^* = \varepsilon$ (for some fixed $\varepsilon \ge 0$), we obtain the ε-insensitive support vector regression algorithm [10], for a data set where all output values $y_1, \dots, y_m$ are zero. Note that in this case, the solution is trivial, $\mathbf{w} = 0$. This shows that the ρ in our objective function cannot be dropped and plays an important role.
- For $\delta = \delta^* = 0$, the term $\sum_i (\xi_i + \xi_i^*)$ measures the distance of the point $\Phi(x_i)$ from the hyperplane $\langle \mathbf{w}, \Phi(x_i)\rangle - \rho = 0$ (up to a scaling

[4] Here and below, the superscript $(*)$ simultaneously denotes the variables with and without asterisk, e.g., $\boldsymbol{\xi}^{(*)}$ is a shorthand for $\boldsymbol{\xi}$ and $\boldsymbol{\xi}^*$.

of $\|\mathbf{w}\|$). As ν tends to zero, this term will dominate the objective function. Hence, in this case, the solution will be a hyperplane that approximates the data well in the sense that the points lie close to it in the RKHS norm.

Let us now compute the dual optimization problem. Here are all constraints, along with the Lagrange multipliers that we will use for them:

$$\xi_i - \delta + \langle \mathbf{w}, \Phi(x_i) \rangle - \rho \geq 0, \qquad \alpha_i \geq 0 \tag{18}$$
$$\xi_i^* + \delta^* + \rho - \langle \mathbf{w}, \Phi(x_i) \rangle \geq 0, \qquad \alpha_i^* \geq 0 \tag{19}$$
$$\xi_i^{(*)} \geq 0, \qquad \beta_i^{(*)} \geq 0 \tag{20}$$

This leads to the Lagrangian

$$\begin{aligned} L(\mathbf{w}, \boldsymbol{\xi}^{(*)}, \rho, \boldsymbol{\alpha}^{(*)}, \boldsymbol{\beta}^{(*)}) &= \frac{1}{2}\|\mathbf{w}\|^2 + \frac{1}{\nu m}\sum_i (\xi_i + \xi_i^*) - \rho \\ &\quad - \sum_i \alpha_i [\xi_i - \delta + \langle \mathbf{w}, \Phi(x_i) \rangle - \rho] \\ &\quad - \sum_i \alpha_i^* [\xi_i^* + \delta^* + \rho - \langle \mathbf{w}, \Phi(x_i) \rangle] \\ &\quad - \sum_i \beta_i \xi_i - \sum_i \beta_i^* \xi_i^* . \end{aligned} \tag{21}$$

The solution of our primal problem (15)–(17) is known to be a saddle point of L. To find it, we need to minimize w.r.t. the primal variables $\mathbf{w}, \boldsymbol{\xi}^{(*)}, \rho$ and maximize w.r.t. the dual variables $\boldsymbol{\alpha}^{(*)}, \boldsymbol{\beta}^{(*)}$. Setting the derivatives w.r.t. the primal variables equal to zero, we obtain

$$\frac{\partial L}{\partial \mathbf{w}} = 0 \iff \mathbf{w} = \sum_i (\alpha_i - \alpha_i^*)\Phi(x_i) \tag{22}$$
$$\frac{\partial L}{\partial \xi_i^{(*)}} = 0 \iff \frac{1}{\nu m} - \alpha_i^{(*)} - \beta_i^{(*)} = 0 \tag{23}$$
$$\frac{\partial L}{\partial \rho} = 0 \iff \sum_i (\alpha_i - \alpha_i^*) = 1. \tag{24}$$

Substituting these conditions into the Lagrangian leads to the dual problem,

$$\underset{\boldsymbol{\alpha} \in \mathbb{R}^m}{\text{minimize}} \quad \frac{1}{2}\sum_{ij} (\alpha_i - \alpha_i^*)(\alpha_j - \alpha_j^*) k(x_i, x_j) - \delta \sum_i \alpha_i + \delta^* \sum_i \alpha_i^* \tag{25}$$
$$\text{subject to} \quad 0 \leq \alpha_i^{(*)} \leq \frac{1}{\nu m} \tag{26}$$
$$\text{and} \quad \sum_i (\alpha_i - \alpha_i^*) = 1, \tag{27}$$

where the box constraints on $\alpha_i^{(*)}$, (26), have been derived from (23) by taking into account that $\alpha_i^{(*)}, \beta_i^{(*)} \geq 0$.[5]

The dual problem can be solved using standard quadratic programming packages. Alternatively, custom methods such as variants of SMO (cf. [7]) can be used. The offset ρ can be computed from the value of the corresponding variable in the double dual, or using the Karush-Kuhn-Tucker (KKT) conditions, just as in other support vector methods [8]. Once this is done, we can evaluate for each test point x whether it satisfies $\delta \leq \langle \mathbf{w}, \Phi(x) \rangle - \rho \leq \delta^*$. In other words, we have an implicit description of the region in $\mathcal{X}$ that corresponds to the region in between the two hyperplanes in the RKHS. For $\delta = \delta^*$, this is a single hyperplane, corresponding to a manifold in $\mathcal{X}$.[6] See Figure 3 for some toy examples of the algorithm in action.

We now analyze how the parameter ν influences the solution. To this end, we introduce the following shorthands for the sets of SV and outlier indices:

$$\begin{aligned} SV &:= \{i \mid \langle \mathbf{w}, \Phi(x_i) \rangle - \rho - \delta \leq 0\} && (28) \\ SV^* &:= \{i \mid \langle \mathbf{w}, \Phi(x_i) \rangle - \rho - \delta^* \geq 0\} && (29) \\ OL^{(*)} &:= \{i \mid \xi_i^{(*)} > 0\} && (30) \end{aligned}$$

It is clear from the primal optimization problem that for all i, $\xi_i > 0$ implies $\langle \mathbf{w}, \Phi(x_i) \rangle - \rho - \delta < 0$ (and likewise, $\xi_i^* > 0$ implies $\langle \mathbf{w}, \Phi(x_i) \rangle - \rho - \delta^* > 0$), hence $OL^{(*)} \subset SV^{(*)}$. The difference of the SV and OL sets are those points that lie precisely on the boundaries of the constraints.[7]

Below, $|A|$ denotes the cardinality of the set A.

Proposition 3.1. *The solution of (15)–(17) satisfies*

$$\begin{aligned} \frac{|SV|}{m} - \frac{|OL^*|}{m} &\geq \nu, && (31) \\ \frac{|OL|}{m} - \frac{|SV^*|}{m} &\leq \nu. && (32) \end{aligned}$$

Two notes before we proceed to the proof:

- The above statements are not symmetric with respect to exchanging the quantities with asterisks and their counterparts without asterisk.

[5] As an aside, note that due to (27), the dual solution is invariant with respect to the transformation $\delta^{(*)} \to \delta^{(*)} + const.$ — such a transformation only adds a constant to the objective function, leaving the solution unaffected.

[6] subject to suitable conditions on k

[7] The present usage differs slightly from the standard definition of SVs (support vectors), which are usually those that satisfy $\alpha_i^{(*)} > 0$. In our definition, SV are those points where the constraints are active. However, the difference is marginal: (i) It follows from the KKT conditions that $\alpha_i^{(*)} > 0$ implies that the corresponding constraint is active. (ii) while it can happen in theory that a constraint is active and nevertheless the corresponding $\alpha_i^{(*)}$ is zero, this almost never occurs in practice.

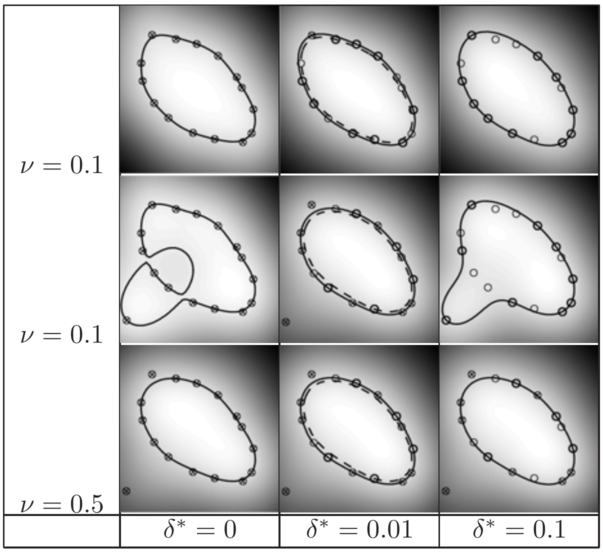

Figure 3: Toy examples of (25)–(27), showing the training points (circles), SVs lying exactly on the hyperplanes (bold circles), and outliers marked by crosses (depicted area $[-1,1]^2$, kernel (4), parameter settings $\sigma = 0.5, \delta = 0$). Lines correspond to hyperplanes constructed in the RKHS (see text); the dashed line is the hyperplane corresponding to the constraint with the $\boldsymbol{\xi}^*$ variables. For $\delta^* = 0$, the two hyperplanes coincide (note that due to finite accuracy, the points do not lie exactly on the hyperplane and are thus marked as outliers); for $\delta^* = 0.1$, the dashed hyperplane is sufficiently far away from the data to reduce the algorithm to the single-class SVM (9)–(10). The *top row* shows a simple toy data set, which in the *middle row* is contaminated with an outlier. The *bottom row* shows how $\nu = 0.5$ handles the outlier.

This is due to the sign of ρ in the primal objective function. If we used $+\rho$ rather than $-\rho$, we would obtain almost the same dual, the only difference being that the constraint (27) would have a "-1" on the right hand side. In this case, the role of the quantities with and without asterisks would be reversed in Proposition 3.1.

- The "ν-property" of single class SVMs is obtained as the special case where $OL^* = SV^* = \{\}$.

Proof. Assume that $(\mathbf{w}, \boldsymbol{\xi}^{(*)}, \rho)$ is a solution of (15)–(17). Thus it is optimal w.r.t. all primal variables, in particular $\boldsymbol{\xi}^{(*)}$ and ρ, i.e., keeping $\mathbf{w}$ fixed. In that case, the problem takes the form

$$\underset{\boldsymbol{\xi}^{(*)} \in \mathbb{R}^m, \rho \in \mathbb{R}}{\text{minimize}} \quad \frac{1}{m} \sum_i (\xi_i + \xi_i^*) - \nu\rho \tag{33}$$

$$\text{subject to} \quad \delta - \xi_i \leq \langle \mathbf{w}, \Phi(x_i) \rangle - \rho \leq \delta^* + \xi_i^* \quad \text{and} \quad \xi_i^{(*)} \geq 0. \tag{34}$$

If we increase ρ by a small $\epsilon > 0$ (cf. Figure 2),[8] (33) decreases proportionally to ν *plus* the fraction of points with $\xi_i^* > 0$ (since these slack variables can be shrunk by the same ϵ without violating the constraints) *minus* the fraction of SVs (remember that all SVs either have $\xi_i > 0$ or lie exactly on the hyperplane $\langle \mathbf{w}, \Phi(x_i)\rangle - \rho - \delta = 0$ — in both cases, an increase of ρ by ϵ will lead to the same increase in the ξ_i variables, in order to satisfy the constraints). If the overall decrease were positive, i.e., if $\nu + \frac{|OL^*|}{m} - \frac{|SV|}{m} > 0$, then we could get a strict decrease in (33) by changing ρ, violating the assumption that we are already at the optimum. Therefore, we have $\frac{|SV|}{m} - \frac{|OL^*|}{m} \geq \nu$.

If, on the other hand, we decrease ρ by an $\epsilon > 0$, the objective function will decrease proportionally to $\frac{|OL|}{m} - \frac{|SV^*|}{m} - \nu$. As above, this quantity cannot by strictly positive, since we are already optimal. Therefore we have $\frac{|OL|}{m} - \frac{|SV^*|}{m} \leq \nu$. □

If in addition we make certain assumptions on the distribution generating the data and on the kernel,[9] then asymptotically, the two inequalities in the proposition become equalities with probability 1. The main idea of the proof can be given in a nutshell: if the capacity of the function class that we are using is well behaved (which it is, since we are regularizing using the RKHS norm $\|\mathbf{w}\|$), then asymptotically, the set of points which lie exactly on the hyperplanes is negligible. Hence, loosely speaking, we have $SV^{(*)} = OL^{(*)}$, and thus $\nu \leq \frac{|SV|}{m} - \frac{|SV^*|}{m} = \frac{|OL|}{m} - \frac{|OL^*|}{m} \leq \nu$. For details, see [8], [9].

To conclude this section, note that an approximate description of the data as the zero set of a function is not only useful as a compact representation of the data. It can also potentially be used in tasks such as denoising and image super-resolution. Given a noisy point x, we can map it into the RKHS and then project it onto the hyperplane(s) that we have learnt. We then compute an approximate pre-image under Φ to get a noise-free version of x. A similar statistical denoising technique has been used in conjunction with kernel PCA (to be described next) with rather encouraging results [8], [4].

4 Other kernel approaches for manifold estimation

There exist several other possibilities to use machine learning methods employing positive definite kernels for estimating manifolds. One of them is known as the RPM algorithm (see [8]); two other ones, to be described below, build on the kernel PCA algorithm.

Kernel PCA The kernel method for computing dot products in an RKHS is not restricted to SV machines. It can be used to develop nonlinear generalizations of any algorithm that can be cast in terms of dot products, such

[8] We choose ϵ small enough so that all constraints that are not active will also not be active after adding the ϵ; it is easy to see that such an ϵ exists.

[9] Essentially, we need to require that the distribution have a density w.r.t. the Lebesgue measure, and that k is analytic and non-constant (cf. [8], [9]).

as principal component analysis. Given data $x_1, \dots, x_m \in \mathcal{X}$, kernel principal component analysis (kPCA) [8] computes the principal components of the points $\Phi(x_1), \dots, \Phi(x_m)$. Since $\mathcal{H}$ may be infinite-dimensional, the PCA problem needs to be transformed into a problem that can be solved in terms of the kernel k. To this end, we consider an estimated covariance matrix in $\mathcal{H}$,

$$\mathbf{C} := \frac{1}{m} \sum_{i=1}^{m} \Phi(x_i)\Phi(x_i)^\top, \tag{35}$$

where $\Phi(x_i)^\top$ denotes the linear form mapping $\mathbf{v} \in \mathcal{H}$ to $\langle \Phi(x_i), \mathbf{v} \rangle$. To diagonalize $\mathbf{C}$, we first observe that all solutions to $\mathbf{Cv} = \lambda \mathbf{v}$ with $\lambda \neq 0$ must lie in the span of Φ-images of the training data (as can be seen by substituting (35) and dividing by λ). Thus, we may expand the solution $\mathbf{v}$ as $\mathbf{v} = \sum_{i=1}^{m} \alpha_i \Phi(x_i)$, thereby reducing the problem to that of finding the α_i. The latter can be shown to take the form $m\lambda\boldsymbol{\alpha} = K\boldsymbol{\alpha}$, where $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_m)^\top$ and $K_{ij} = k(x_i, x_j)$. Absorbing the m factor into the eigenvalue λ, one can moreover show that the p-th feature extractor takes the form

$$\langle \mathbf{v}^p, \Phi(x) \rangle = \frac{1}{\sqrt{\lambda^p}} \sum_{i=1}^{m} \alpha_i^p k(x_i, x). \tag{36}$$

This is derived by computing the dot product between a test point $\Phi(x)$ and the p-th eigenvector in the RKHS; the $\frac{1}{\sqrt{\lambda^p}}$ factor ensures that $\langle \mathbf{v}^p, \mathbf{v}^p \rangle = 1$.

When evaluated on the training example x_n, (36) takes the form

$$\langle \mathbf{v}^p, \Phi(x_n) \rangle = \frac{1}{\sqrt{\lambda^p}} (K\alpha^p)_n = \frac{1}{\sqrt{\lambda^p}} (\lambda^p \alpha^p)_n = \sqrt{\lambda^p} \alpha_n^p. \tag{37}$$

In (35), we have implicitly assumed that the data in the RKHS have zero mean. If this is not the case, we need to subtract the mean $(1/m)\sum_i \Phi(x_i)$ from all points. This leads to a slightly different eigenvalue problem, where we diagonalize

$$K' = (\mathbf{1} - ee^\top) K (\mathbf{1} - ee^\top) \tag{38}$$

(with $e = m^{-1/2}(1, \dots, 1)^\top$) rather than K.

The kPCA algorithm can be used to obtain an implicit description of a manifold containing the data as follows. The principal directions with the smallest eigenvalues (sometimes called "minor components") characterize directions in the RKHS such that when projected onto these directions, the data set has the smallest possible variance which can be obtained in any direction which is in the span of the mapped data.[10] Generally, we are interested in low variance directions which lie in the span of sets of inputs points (e.g., the training set) mapped into the RKHS, as these lead to implicit

[10] Note that for some kernels, the RKHS will be infinite dimensional. In that case, there are infinitely many *zero* variance directions which do not lie in the span of the data.

function expansions in terms of kernel functions. If we consider expansions in terms of the training set, the functions take the form

$$f(x) = \left\langle \mathbf{V}^p, \Phi(x) - \frac{1}{m}\sum_i \Phi(x_i) \right\rangle. \tag{39}$$

A tighter description of the desired manifold may be obtainable by intersecting several such surfaces, e.g., using (39) for values of p corresponding to several small eigenvalues λ_p.

LLE and Laplacian Eigenmaps Kernel PCA can also be used for manifold learning in a rather different way. In this case, the manifold is not learnt as the zero set of a kernel expansion. Rather, we will obtain a low dimensional coordinate embedding of data sampled from the manifold (”dimensionality reduction”).

It turns out that *locally linear embedding (LLE)* [6], currently a rather popular algorithm for nonlinear dimensionality reduction, is a special case of kPCA [3]: The LLE algorithm first constructs W to be the matrix whose row i (summing to 1) contains the coefficients to of the minimal squared error affine reconstruction of x_i from its p nearest neighbors. Denote $M := (\mathbf{1} - W)(\mathbf{1} - W^\top)$, with maximal eigenvalue $\lambda_{\max}$. One can show that M's smallest eigenvalue is 0 and the corresponding uniform eigenvector is e. In LLE, the coordinate values of the m-dimensional eigenvectors $m-d, \ldots, m-1$ give an embedding of the m data points in $\mathbb{R}^d$. If we define $K := (\lambda_{\max}\mathbf{1} - M)$, then by construction, K is a positive definite matrix, its leading eigenvector is e, and the coordinates of the eigenvectors $2, \ldots, d+1$ provide the LLE embedding. Equivalently, we can use the eigenvectors $1, \ldots, d$ of the matrix obtained by projecting out the subspace spanned by e, i.e., $(\mathbf{1} - ee^\top)K(\mathbf{1} - ee^\top)$. Note that this is identical to the centered kernel matrix (38) used in kPCA. We thus know that the coordinates of the leading eigenvectors of kPCA performed on K yield the LLE embedding. This, together with (37), shows that the LLE embedding is identical to the kPCA projections up to a whitening multiplication with $\sqrt{\lambda^p}$.

As shown in [3], several other approaches can be viewed as special cases of kPCA, including certain spectral methods. Many of these methods are based on the computation of a weighted adjacency matrix W on the data, e.g., using the kernel (4) on neighboring points (where several definitions of neighborhood are possible).[11] Define the *graph Laplacian* L by $L_{ii} := d_i$, $L_{ij} = -W_{ij}$ if x_i and x_j are neighbors, and 0 otherwise, where $d_i = \sum_{j\sim i} W_{ij}$ is the degree of the ith vertex. It turns out that similar to LLE, the bottom eigenvectors of the Laplacian can provide a low-dimensional representation of the data [2], and again, a link to KPCA can be established [3].

[11] This local similarity measure can also take into account invariances of the data.

5 Conclusion

Kernel methods have a solid foundation in statistical learning theory and functional analysis. They let us interpret (and design) learning algorithms geometrically in an RKHS, and combine statistics and geometry in an elegant way. The present article has described several methods for using this approach for the estimation of manifolds.

COMPSTAT'2004 Symposium

OUTLIER DETECTION AND CLUSTERING BY PARTIAL MIXTURE MODELING

David W. Scott

Key words: Minimum distance estimation, robust estimation, exploratory data analysis.

COMPSTAT 2004 section: Statistical software.

Abstract: Clustering algorithms based upon nonparametric or semiparametric density estimation are of more theoretical interest than some of the distance-based hierarchical or ad hoc algorithmic procedures. However density estimation is subject to the curse of dimensionality so that care must be exercised. Clustering algorithms are sometimes described as biased since solutions may be highly influenced by initial configurations. Clusters may be associated with modes of a nonparametric density estimator or with components of a (normal) mixture estimator. Mode-finding algorithms are related to but different than gaussian mixture models. In this paper, we describe a hybrid algorithm which finds modes by fitting incomplete mixture models, or partial mixture component models. Problems with bias are reduced since the partial mixture model is fitted many times using carefully chosen random starting guesses. Many of these partial fits offer unique diagnostic information about the structure and features hidden in the data. We describe the algorithms and present some case studies.

1 Introduction

In this paper, we consider the problem of finding outliers and/or clusters through the use of the normal mixture model

$$f(\mathbf{x}) = \sum_{k=1}^{K} w_k \, \phi(\mathbf{x} \,|\, \mu_k, \Sigma_k) \,. \qquad (1)$$

Mixture models afford a very general family of densities. If the number of components, K, is quite large, then almost any density may be well-approximated by this model. Aitkin and Wilson [1] first suggested using the mixture model as a way of handling data with multiple outliers, especially when some of the outliers group into clumps. They used the EM algorithm to fit the mixture model. Assuming that the "good" data are in one cluster and make up at least fifty percent of the total data, then it is easy to see that we have introduced a number of "nuisance parameters" into the problem (to model the outliers).

Implementing this idea in practice is challenging. If there are just a few "clusters" of outliers, then the number of nuisance parameters should not pose too much difficulty. However, as the dimension increases, the total number of parameters grows quite rapidly, especially if a completely general covariance matrix, Σ_k, is used for each component. The most directly challenging problem is finding an appropriate choice of the number of components, K, and initial guesses for the many parameters. An obvious first choice is to use a clustering algorithm such as k-means [15] as an approach to find an initial partition, and then compute the relative size, means, and covariances of each group to use as initial guesses for the EM algorithm.

It is abundantly clear that for many of our fits, we will in fact be using the wrong value of K. Furthermore, even if we happen to be using the appropriate value for K, there may be a number of different solutions, depending upon the specific initialization of the parameters. Starting with a large number of initial configurations is helpful, but as the dimension and sample size increase, the number of possibilities quickly exceeds our capabilities.

However, the least discussed and least understood problem arises because so little is generally known about the statistical distributions of the clusters representing the outliers. It certainly seems more reasonable to know something about the distribution of the "good" data; however, one is on much less firm ground trying to claim the same knowledge about the distributions of the several non-informative clusters. Even in the situation where the "good" data are in more than one cluster, sometimes little is known about the distribution in one or more of those "good" clusters.

In this paper, we discuss how an alternative to the EM algorithm can provide surprisingly useful estimates and diagnostics, even when K is incorrect. Such technology is especially interesting when K is too small, since in this situation the number of parameters to be estimated may be a small fraction of the number in the full, correct model. Furthermore, this technology is of special interest in the situation where little is known about the correct distribution of many of the clusters. This latter capability is of growing importance and interest in the analysis of massive datasets typically encountered in data mining applications.

2 Mixture fits with too few components

We examine some empirical results to reinforce these ideas. One well-known trimodal density in two dimensions is the lagged Old Faithful Geyser duration data, $\{(x_{t-1}, x_t),\ t = 2, \ldots, 298\}$; see [2] and [27]. Successive eruptions were observed and the duration of each eruption, $\{x_t,\ t = 1, \ldots, 299\}$, recorded to the nearest second. A quick count shows that 23, 2, and 53 of the original 299 values occurred exactly at $x_t = 2$, 3, and 4 minutes, respectively. Examining the original time sequence suggests that those measurements are clumped; perhaps accurate measurements were not taken after dark. We modified the data as follows: the 105 values that were only recorded to the nearest minute were blurred by adding uniform noise of 30 seconds in duration. Then all of the data were blurred by adding uniform noise, $U(-.5, .5)$, seconds, and then converted back into minutes.

In Figure 1, maximum likelihood estimates (MLE) of a bivariate normal and three two-component bivariate normal mixture fits are shown. Each bivariate normal density is represented by 3 elliptical contours at the 1, 2, and 3-σ levels. Figure 1 provides some examples of different solutions, depending upon the value of K selected and the starting values for the parameters chosen. In two dimensions, your eye can tell you what is wrong with these fits. In higher dimensions, diagnostics indicating a lack of fit leave unclear if a component should be split into two, or if the assumed shaped of the component is not correct.

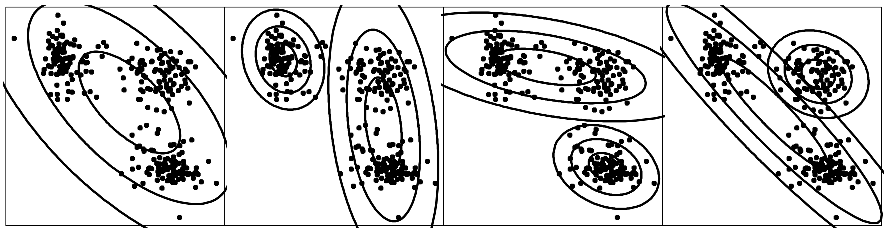

Figure 1: Maximum likelihood bivariate normal mixture fits to the lagged Old Faithful geyser eruption data with $K = 1$ and $K = 2$. The weights in each frame from L to R are (1.0), (.350, .650), (.645, .355), and (.728, .272). Each bivariate normal component is represented by 3 contours at the 1, 2, and 3-σ levels.

3 The L2E criterion

Minimum distance estimation for parametric modeling of $f_\theta(x) = f(x|\theta)$ is a well-known alternative to maximum likelihood; see [7]. In practice, several authors have suggested modeling the data with a nonparametric estimator (such as the histogram or kernel method), and then numerically finding the values of the parameters in the parametric model that minimize the distance between f_θ and the curve; see [6] and [9], who considered Hellinger and L2 distances, respectively. Using a nonparametric curve as a target introduces some choices, such as the smoothing parameter, but also severely limits the dimension of the data and the number of parameters that can be modeled. (Precise numerical integration is quite expensive even in two dimensions. Numerical optimization algorithms require very good accuracy in order to numerically estimate the gradient vectors.)

Several authors have discovered an alternative criterion for parametric estimation in the case of L2 or integrated squared error (ISE); see [25], [13], [5], [20], [21], [22], for example. (This idea follows from the pioneering work of Rudemo [18] and Bowman [8] on cross-validation of smoothing parameters in nonparametric density estimates.) In particular, Scott [20], [21] considered estimation of mixture models by this technique. Given a true density, $g(x)$, and a model, $f_\theta(x)$, the goal is to find a fully data-based estimate of the L2 distance between g and f, which is then minimized with respect to θ. Expanding the L2 criterion

$$d(\hat{f}_\theta, g) = \int \left[\hat{f}_\theta(x) - g(x)\right]^2 dx\,, \tag{2}$$

we obtain the three integrals

$$d(\hat{f}_\theta, g) = \int \hat{f}_\theta(x)^2 dx - 2\int \hat{f}_\theta(x)\, g(x)\, dx + \int g(x)^2 dx\,. \tag{3}$$

The third integral is unknown but is constant with respect to θ and therefore may be ignored. The first integral is often available as a closed form expression that may be evaluated for any posited value of θ. Additionally, we must add an assumption on the model that this integral is always finite, i.e. $f_\theta \in L_2$. The second integral is simply the average height of the density estimate, given by $-2\,\mathrm{E}[\hat{f}_\theta(X)]$, where $X \sim g(x)$, and which may be estimated in an unbiased fashion by $-2n^{-1}\sum_{i=1}^n \hat{f}_\theta(x_i)$. Combining, the L2E criterion for parametric estimation is given by

$$\hat{\theta} = \arg\min_\theta \left[\int \hat{f}_\theta(x)^2 dx - \frac{2}{n}\sum_{i=1}^n \hat{f}_\theta(x_i)\right]. \tag{4}$$

For the multivariate normal mixture model in Equation 1,

$$\int_{\Re^d} \hat{f}_\theta(x)^2 dx = \sum_{k=1}^K \sum_{\ell=1}^K w_k\, w_\ell\, \phi(0\,|\,\mu_k - \mu_\ell, \Sigma_k + \Sigma_\ell). \tag{5}$$

Since this is a computationally feasible closed-form expression, estimation of the normal mixture model by the L2E procedure may be performed by use of any standard nonlinear optimization code; see [20], [21]. In particular, we used the *nlmin* routine in the Splus library for the examples in this paper.

Next, we return to the Old Faithful geyser example. Using the same starting values as in Figure 1, we computed the corresponding L2E estimates, which are displayed in Figure 2. Clearly, both algorithms are attracted to the same (local) estimates, which combine various clusters into one (since $K < 3$). However, there are interesting differences. First we compare the estimated weights: in Figure 1, the MLE weight of the larger component in each frame is 1, 0.65, 0.65, and 0.73, respectively, while in Figure 2 the corresponding L2E weights are 1, 0.74, 0.72, and 0.71. Of more interest, the L2E covariance matrices are either tighter or smaller. Since the (explicit) goal of L2E is to find the most normal fit (locally), observe that a number of points in the smaller clusters fall outside the 3-σ contours in frames 2 and 3 of Figure 2. The MLE covariance estimate is not robust and is inflated by those (slight) outliers. These differences are likely due to the inherent robustness properties of any minimum distance criterion; see [12]. Increasing the covariance matrix to "cover" a few outliers results in a large increase in the integrated squared or L2 error, and hence those points are largely ignored.

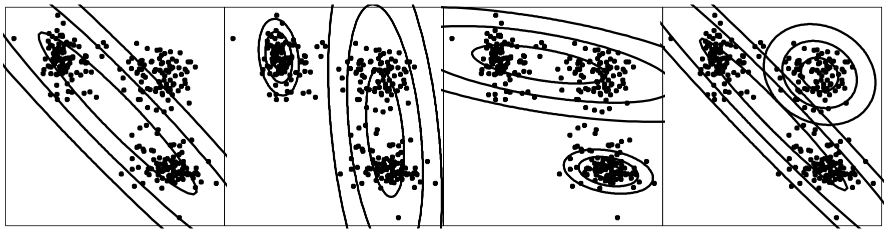

Figure 2: Several L2E mixture fits to the lagged Old Faithful geyser eruption data with $K = 1$ and $K = 2$; see text. The weights in each frame are (1.0), (.258, .742), (.714, .286), and (.711, .289).

4 Partial mixture modeling

The two-component L2E estimates above were computed with the constraint that $w_1+w_2 = 1$. Is this constraint necessary? Can the weights w_1 and w_2 be treated as unconstrained variables? Certainly, when using EM or maximum likelihood, increasing the weights increases the likelihood without bound, so that the constraint is necessary (and active). However, *the L2E criterion does not require that the model $\hat{f}_\theta$ be a density.* The second integral in Equation 3 measures the average height of the density model, but a careful review of the argument leading to Equation 4 confirms the fact that only $g(x)$ is required to be a density, not $\hat{f}_\theta(x)$; see [22].

With this understanding, when we fit a L2E mixture model with $K = 2$, we are only assuming that the true mixture has at least 2 components. That is, we explicitly use our model for the local components of "good" data (local in the sense of our initial parameter guesses), but make no explicit assumption about the (unknown) distribution of the remaining data, no matter how many or few clusters they clump into. Our algorithm is entirely local. Different starting values may lead to quite different estimates.

Thus, we re-coded our L2E algorithm treating all of the weights in Equation 5 as *unconstrained* variables. In Figure 3, we display some of the "unconstrainted" L2E mixture estimates, using the same starting values as in Figure 2. These estimates are qualitatively quite similar to those in Figure 2, with some interesting differences. Comparing the first frames in Figures 2 and 3, the covariance matrix has narrowed as the weight decreased to .783. The sums of the (unconstrained) weights in the final three frames of Figure 3 are 0.947. 0.966, and 1.048. In the first two cases, the total probability modeled is less than unity, suggesting a small fraction of the data are being treated/labeled as outliers with respect to the fitted normal mixture model. The fact that the third total probability exceeds unity is consistent with our previous observation that the best fitting curve in the L2 or ISE sense often integrates to more than 1, when there is a gap in the middle of the data.

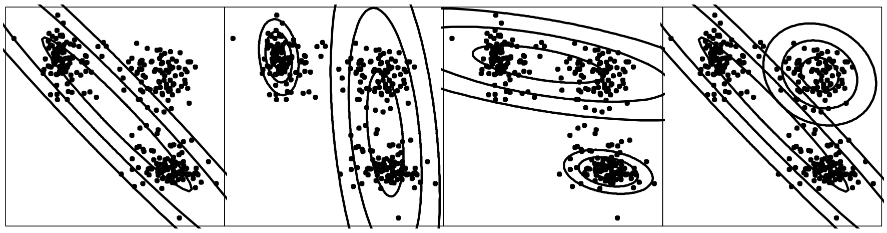

Figure 3: Several L2E partial mixture fits to the lagged Old Faithful geyser eruption data with $K = 1$ and $K = 2$, but without any constraints on the weights; see text. The weights in each frame are $(.783)$, $(.253, .694)$, $(.683, .283)$, and $(.751, .297)$.

Since there are potentially many more local solutions, we display four more L2E solutions in Figure 4. Some of these estimates are quite unexpected and deserve careful examination. The first frame is a variation of a $K = 1$ component which captures 2 clusters. However, the $K = 2$ estimates in the last 3 frames each capture two individual clusters, while completely ignoring the third. Comparing the contours in the last three frames of Figure 4, we see that exactly the same estimates appear in different pairs. Looking at the weights in Figures 3 and 4, we see that the smaller isolated components are almost exactly reproduced while entirely ignoring the third cluster. This feature of L2E is quite novel and we conclude that many of the local L2E results hold valuable diagnostic information as well as quite useful estimates of the local structure of the data.

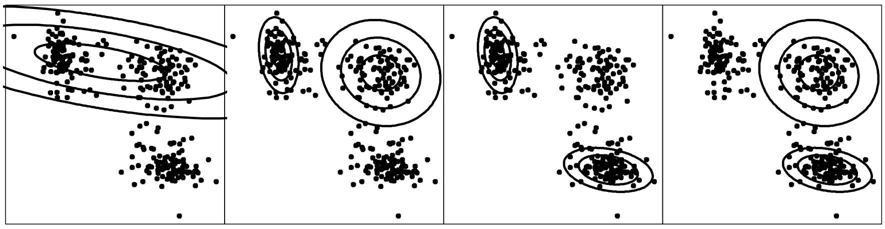

Figure 4: Same as Figure 3 but different starting values; see text. The weights in each frame are $(.683)$, $(.253, .316)$, $(.253, .283)$, and $(.316, .283)$.

Finally, in Figure 5, we conclude this investigation of the geyser data by checking a number of $K = 1$ unconstrained L2E solutions. In this case, the three individual components are found one at a time, depending upon the initial parameter values. Notice that the weights are identical to those in the previous figure. Furthermore, these weights are less than 50%, which is the usual breakdown point of robust algorithms; see [17]. However, the L2E algorithm is local and different ideas of breakdown apply.

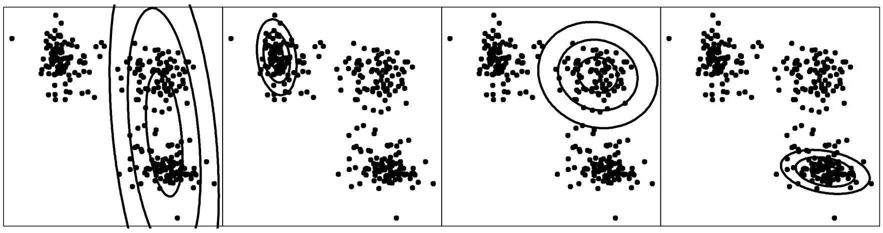

Figure 5: Four more $K = 1$ partial mixture fits to the geyser data; see text. The weights in each frame are (.694), (.253), (.316), and (.283).

5 Other examples

5.1 Star data

Another well-studied bivariate dataset was discussed by Rousseeuw and Leroy [17]. The data are measurements of the temperature and light intensity of 47 stars in the direction of Cygnus. For our analysis, the data were blurred by uniform $U(-.005, .005)$ noise. Four giant stars exert enough influence to distort the correlation of a least-squares or maximum likelihood estimate; see the first frame in Figure 7. In the second frame, a $K = 2$ MLE normal mixture is displayed. Notice the four giant stars are represented by one of the two mixture components and has a nearly singular covariance matrix. The third frame shows a $K = 1$ partial component mixture fit by L2E, with $\hat{w} = 0.937$. The shape of the two covariance matrices of the "good" data is somewhat different in these three frames. In particular, the correlation coefficients are -0.21, 0.61, and 0.73, respectively.

These data were recently re-analyzed by Wang and Raftery [26] with nearest-neighbor variance estimator (NNVE), an extension of the NNBR estimator [10]. They compared their covariance estimates to the minimum volume ellipsoid (MVE) of Rousseeuw and Leroy [17] as well as the (non-robust) MLE. In Figure 7, I have overlaid these 4 covariance matrices (at the 1-σ contour level) with that of the partial density component (PDC) estimate obtained by L2E shown in the third frame of Figure 6. For convenience, I have centered these ellipses on the origin. The NNVE and NNBR ellipses are virtu-

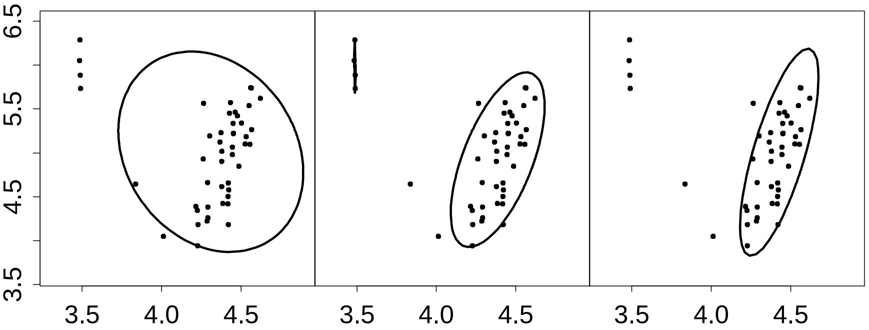

Figure 6: Two-σ contours of MLE ($K = 1$), MLE mixture ($K = 2$), and partial L2E mixture ($K = 1$) fits to the blurred star data.

ally identical, while the MVE ellipse is slightly rotated and narrower. These three are surrounded by the slightly elongated L2E PDC ellipse. Of course, the MLE has the wrong (non-robust) orientation. The correlation coefficients for NNVE and NNBR are 0.65 versus 0.73 for MVE and L2E. Observe that L2E does not explicitly require a search for the good data. The other three algorithms require extensive search and/or calibration of an auxiliary parameter. L2E is driven by the choice of the shape of the mixing distribution. One might choose instead to use t_ν components, as suggested by McLachlan and Peel [16], although the degrees of freedom must be specified. In either case, L2E provides useful diagnostic information as a byproduct of the estimation, rather than as a follow-on step of analysis.

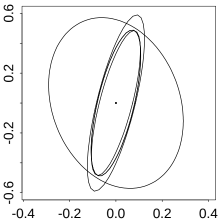

Figure 7: Ellipses representing the 2-σ contours of five estimates of the covariance matrix of the star data; see text.

5.2 Australian athlete data

For our final example, we consider four variables from the AIS data on Australian Athletes [11]. These data are available in the R package with the command `data(ais,package='sn')`. Following Wang and Raftery [26], we selected the variables body fat (BFAT), body mass index (BMI), red cell count (RCC), and lean body mass (LBM). (Wang and Raftery also included ferritin in their analysis.) We blurred the data then standardized each variable.

We fit a $K = 1$ L2E starting with the maximum likelihood estimate. The result was $\hat{w}_1 = 0.98$. A pairwise scatterdiagram of the 202 points is shown in Figure 8, together with contours of the fitted 4-dimensional ellipse. A careful examination of this plots suggests some clusters. In fact, the first 100 measurements are of female athletes and the last 102 measurements are of male athletes.

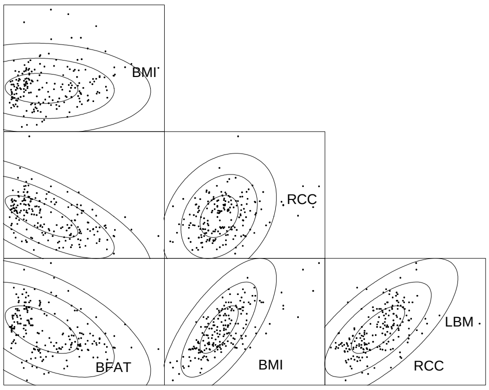

Figure 8: Ellipses representing the (1,2,3)-σ contours of a L2E partial mixture estimate of the Australian athlete data; see text.

Starting with the MLE values for the female athletes, we re-fit a $K = 1$ L2E. Now $\hat{w}_1 = 0.41$ (somewhat less than the 49.5% female population). The contours of the fitted 4-dimensional ellipse are superimposed upon the scatter matrix in Figure 9. The L2E is clearly modeling a large fraction of the female athletes.

Finally, we started the L2E with the male values. However, L2E found a smaller subset of the data lying in a subspace. (L2E is just as susceptible at MLE at being attracted to singular mixture components, depending upon initial guesses. That is why blurring was applied in all our examples to remove trivial singularities due to rounding.) Further experimentation would be interesting.

6 Discussion

We have shown how a minimum distance criterion and a mixture model with only one or two partial components can provide useful estimates and diagnostics. In particular, the value of $\hat{w}_1 + \hat{w}_2$ provides an indication of the

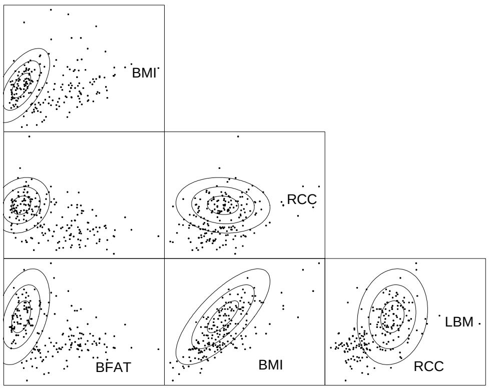

Figure 9: Ellipses representing the (1,2,3)-σ contours of a second L2E partial mixture estimate of the Australian athlete data; see text.

fraction of the data being modeled by a $K = 2$ mixture. In our experience, the proportion of solutions that are interesting when $K = 2$ and the parameters are initialized by some random process is quite small. Further research on this question is open. However, many of the $K = 1$ solutions following random initialization are quite useful. The systematic use of these ideas for clustering is explored further in [23].

Alternatively, Banfield and Raftery [4] allow a number of outliers to be modeled as a spatial Poisson process. It would be interesting to apply that model with $K = 2$ to these data, where the noise is not Poisson, and to compare the parameter estimates.

The identification of outliers without an explicit probability model should always be viewed as preliminary and exploratory. If a probability model is known, then the tasks of parameter estimation and outlier identification can be more rigorously defined. However, even probability models are usually known only approximately at best, and hence outliers so identified are still subject to certain biases.

The general topic of outlier detection is discussed in [3]. Robust estimation is described by Huber [14]. Coupled with a good exploratory such as XGobi [24], the L2E PDC has much potential for helping unlock information in complex data.

INTERDATABASE AND DANDD

Ritei Shibata

Key words: Working with data, environment, database, Internet.

COMPSTAT 2004 section: E-statistics.

Abstract: InterDatabase is a comfortable environment for working simultaneously with different types of data which are scattered over various databases or files on a network or on the Internet. This paper reports an implementation of the InterDatabase based on DandD which is a system for Data and Description. Due to the high level of data abstraction established in a long run DandD project, the implemented InterDatabase is, in fact, a flexible environment which covers almost all fields of science and which can be used for data acquisition, data cleaning, data organisation, data visualisation, data analysis and data modelling.

1 Environmental changes of statistics

Using highly developed computers and networks, it has become faster and easier to get various data from different sources or databases. Some of these are publicly available on the Internet. A major challenge facing statisticians is the creation of powerful environments for working with such a variety of data. InterDatabase is one such environment ([9]). Here, by "Inter" we mean both "Inter-databases" to utilise different databases and "Databases on the Internet" to utilise scattered databases over the Internet. Both are closely related and it does not seem so meaningful to distinguish them once Internet access has been established. Therefore, we can simply say that InterDatabase is an environment for utilising different databases simultaneously. Before describing InterDatabase, we review other related approaches.

2 Approaches

Let us quickly review the following different approaches to the environment for working with various type of data; NetCDF, DDI and MetBroker.

2.1 NetCDF

NetCDF (Network Common Data Form, [4]) is a data abstraction for storing and retrieving multidimensional data and is distributed as a software library which provides a concrete implementation of the abstraction. The software has been developed under the Unidata Program sponsored by the US National Science Foundation to support research and education in the atmospheric sciences. This approach is closely related to our InterDatabase, but not the same. NetCDF is targeted only for multidimensional or array data. However InterDataBase is not restricted to data following such a neat format. Another point is that NetCDF requires reformatting all the data so that it accords with a common rule, called Common Data Language (CDL). This can be a burden unless the data processing procedures have been established from the beginning in each field of application.

2.2 DDI and NESSTAR

DDI (Data Documentation Initiative, [7]) is also close to InterDatabase in concept. It aims to create a universally supported metadata standard for the social science community and is implemented as an XML document. The DDI-tree contains five main branches.

1. Document Description
2. Study Description
3. Data File Description
4. Variable Description
5. Other Study-Related Materials

DDI is mainly concerned with table data such as the results of surveys. The data is therefore assumed to be a simple set of realizations of several variables, so that it would not be an easy job to describe complicated relations among variables, or to include array data in which each axis corresponds to an explanatory variable and the value of the array corresponds to the response variable. Also description procedures are not yet formalised well. For example, description of the sampling design is left free.

NESSTAR is a metadata-driven system which can be used in conjunction with DDI metadata. It searches or navigates data files, based on what is written in the DDImetadata and can display a simple summary. However the system is not aiming at manipulation of several data sets to combine it into one.

2.3 MetBroker

MetBroker([3]) is middleware which provides consistent access to heterogeneous weather databases. It is a mediator that sits between agricultural models and various sources of online data. This approach resolves data heterogeneity problems by writing a suitable program. It is efficient for meeting the needs of specific tasks, but it would be laborious to rewrite the program to meet the needs of users or to accommodate structural changes in databases.

3 Our approach

As was mentioned before, our goal is to provide a good environment to work with different types of data which might be scattered over networks. Our approach is probably closer in concept to DDI or NESSTAR. In InterDatabase, the DandD Client Server System ([8]) is driven by a DandD instance and provides a similar environment. A major difference of InterDatabase from DDI and NESSTAR is the unified general approach to providing such an environment. A high level of data abstraction is necessary to retain such generality and an intimate linkage between the abstraction and development of support softwares is indispensable.

DandD (Data and Description) is a long run project started around 1990. Preliminary works can be found, for example, in [10]. The aim of this project was to establish a formal rule of description of data. A hope was to make it possible to do an automatic analysis of data as well as to make it easier to exchange data with enough description for the aim of analysis. In the first part of the project, data abstraction was a main concern. The basic model had been established to construct necessary number of structures, relational or array, by quoting data vectors which are simple sequences of numbers. All necessary attributes are classified into three levels. The bottom level is for each data vector, the middle level is for each structure constructed, and the top level is for the whole data. The rule had been implemented by a LISP like own language, and some experimental supporting softwares had been developed.

A breakthrough had been occurred by an introduction of XML as a media for implementation of DandD rule in 1997. The project grew to cover various data which are not necessarily included as a body of the XML document. This led to an introduction of the concept of External Data Vector and further led to the idea of InterDatabase. Therefore InterDatabase is a natural extension of our original idea of DandD and it is now a part of DandD together with its support system, DandD server client system ([8]). Let us focus our attention into the closely related features of DandD to InterDatabase.

4 DandD

DandD is a generic name for a system consisting of the following three elements.

1. DandD rule: A syntax and semantics for describing data. The syntax is currently written as a DTD.

2. DandD instance: A document implemented along the DandD rule for the data. Currently it takes the form of XML document.

3. DandD client server system: A software system that provides a suitable environment for handling DandD instances.

As has been mentioned before, the data itself is not necessarily a part of a DandD instance, and it allows us to implement InterDatabase.

4.1 Data vector

In DandD, any data are decomposed into several data vectors. The data vector here is defined as a simple sequence of numbers, which becomes a body of elements denoted by the tag `<DataVector>` in a DandD instance. To keep consistency, only sequences of numbers are allowed as the vector. Therefore, for example, categorical data is always converted to a sequence of numbers and the coding information is attached to the elements as an attribute `Code`. If the body is empty, the three attributes `Access`, `Protocol` and `PostProcessing` tell us all the necessary information to get the body from outside DandD.

The attribute `Access` tells us where to access by its `IPAddress` attribute, and any information needed for the access, for example, user I.D. or password by other attributes. The attribute `Protocol` tells us the physical network protocol for the access and other information such as, for example, a query sentence which is needed to extract the data from a database. The attribute `PostProcessing` is for converting the data obtained from a data server to a simple sequence of numbers. Then the sequence can be regarded as if it were the body of the `DataVector` in the DandD instance. The following is an example of `DataVector`, where the body is empty and should be obtained from a relational database system.

Example 1

```
<DataVector  Id="i1"  LongName="Year" Access="a1"
@Protocol="b1" PostProcessing="c1"/>

     ...

<Access Id="a1" IPAddress="131.113.65.1" UserId="dandd"/>
<Protocol Id="b1" Physical="TCP"/>
<JDBC DatabaseServerType="postgresql" DatabaseName="KobeQuake">
@select year from kobequake
</JDBC>
</Protocol>
<ScanFormat Id="c1">
%s-%*s-%*s
</ScanFormat>
```

The attributes `Access` and `Protocol` of the `DataVector` with I.D. `i1` refer to the elements with I.D.s `a1` and `b1`, respectively. The two attributes `IPAddress` and `UserId` of the Access `a1` tell us the IP address and the user I.D., respectively. The attribute `Physical` of the `Protocol` with I.D. `b1` tells us that the physical access protocol to the data server is `TCP`. Currently the only other available protocol is `UDP`, but more protocols will be introduced according to need. This element has a sub element `JDBC` which further tells us the software protocol to communicate with the data server. The JDBC is an interface to access a database through Java language([5][6]), which absorbs differences of database servers. Other available protocols allowed here are `FTP` and `HTTP`. The attributes `DatabaseServerType` and `DatabaseName` of `JDBC` tell us that the database server is PostgreSQL and that the name of the database to be accessed is KobeQuake, respectively. In fact, the database is a record of the disastrous earthquake that occurred in the Kobe area in Japan on 17 January 1995, and the example above is a part of a DandD example instance `KobeQuake.dad` which is available from the DandD project home page

`http://www.stat.math.keio.ac.jp/DandD`.

The body of `JDBC` is a Structured Query Language (SQL) sentence which gets a column `year` from the table `kobequake` in the relational database `KobeQuake`.

The last element `ScanFormat` is referred to by the I.D. `c1` in the attribute `PostProcessing` of the `DataVector` specifies the processing method after receiving a response from the database server. The response is not necessarily a sequence of numbers and often has to be converted to fit the DandD requirement that the body of `DataVector` is a sequence of numbers. In this example, the response to the query is a sequence of dates of the form of YY-MM-DD and what is needed as the body of this `DataVector` is only the YY part. The body of `ScanFormat` specifies the extraction method by a formula. The syntax is the same as that of the function `scanf` in the language C. Other elements which can be referred to, together with or in place of `ScanFormt`, are `PrintFormat`, `Arithmetic`, `Media` and `Movie`. The `PrintFormat` is used for adding something to each element of the sequence. The syntax is the same as that of the function `printf` in the C language as well. Although this `PrintFormat` element does not appear in this example, it becomes necessary, for example, to add the prefix 20 to all YY to make a four digit representation of the year for consistency with other data vectors obtained from different data sources. The `Arithmetic` is used for a more complicated manipulation, arithmetic operation on each element of the sequence. This is used, for example, when the conversion of the unit from centimetre to metre, or sexagesimal to digit is necessary. The other two functions are experimental and support the case when the response from data server is an image or a movie. In the attribute `PostProcessing` of the `DataVector`, several such manipulations of the element of the response can be referred. Each manipulation is assumed to be applied in order.

Besides the elements mentioned above, the `Code` element can be also referred together in `PostProcessing`. The primary role of the `Code` element was to provide coding information for categorical data. The body is a sequence of quoted strings, which provides codes for natural numbers in the body of `DataVector`, and it is usually referred to in the attribute `Code` of the `DataVector`. If it is referred to in the attribute `PostProcessing`, it means that each element of the current sequence is matched to the body of the `Code` and converted to the matched index. This `Code` is used as a default `Code` attribute of the `DataVector` as well. The conversion of the labels of the levels of categorical data can be described if two different `Code`s are given to the attributes `PostProcessing` and `Code` of a `DataVector`. Then, the code given in `PostProcessing` indicates the code used for the database or for the data file, and the code given in the attribute `Code` indicates the code which should be used in the DandD instance. If both are missing, the obtained sequence is regarded as a sequence of numbers.

The reason why we provided such functionalities at the level of data acquisition from a data server comes from our design principle. The principle of InterDatabase is to provide a good flexible environment for working with various types of data, and so it is better to do any necessary conversions at the stage of data acquisition outside DandD. We are then free from the differences of the data sources. An alternative would be to modify the existing databases or data files according to the needs of the user or to create a new database. However, this is not only laborious but also inefficient for the case of huge data sets which are rarely used as a whole. In InterDatabase, no modification is necessary to the existing data sources. This principle is close to that of DDI or MetBroker, but InterDatabase provides a more general and flexible way of resolving such differences than others since it is free from any particular software. It is sufficient to write explicitly any necessary information in the form of XML, which is needed for processing, analysis, modelling and its utilisation.

4.2 Data

The `DataVector`s defined in the element `DataBody` are organised into several structures within the element `Data`. Two types of structures are available; `Relational` or `Array`. The relational model is general enough to represent any relations among data ([2]). The relational database under the frame work of the relational model is now a standard for database systems because of its generality and ease of system maintenance. A relation is a collection of variables and the realization is a collection of data vectors each of which is a sequence of realized values of each variable. The realization looks like a table and it is usually called a *table* in the Relational Database Management System (RDBMS).

Caution is necessary when using the word *table*. A contingency table or the result of a designed experiment is also called a table in statistics. However such a table is not a table in the sense of RDBMS. In the relation model, each row in the *table* is regarded as a point in the value space of the variables, so that the *table* is nothing more than a set of such points. Therefore, the position of each row in the *table* has no specific meaning. This is in contrast to, for example, a two dimensional contingency table, in which two hidden variables exist, say row index and column index variables, besides the variable for the values in the table. Therefore, it should be reorganised as a *table* in RDBMS, of two index variables and a variable for the values of the table. Each index variable then repeatedly takes the same value as many times as the number of rows or columns. To avoid such a redundancy, we allow an array structure besides the relational structure in DandD, since such a table or multidimensional array frequently appears as a neat data structure and it becomes cumbersome to represent it as a relation. Example 2 gives a practical example of a relational structure in DandD.

Example 2

```
<Data>
 <Relational Id="Futures" LongName="TSLongNameE TSLongNameJ"
      MainKey="dly dlm dld cmdty dvy dvm mkt"
      Control="dly dlm dld"  Nominal="cmdty dvy dvm mkt">
   <Value Id="dly" LongName="Dealing Year"
      RefId="Dealing_Year02 Dealing_Year03" Systems="t1"/>
   <Value Id="dlm"  LongName="Dealing Month"
      RefId="Dealing_Month02 Dealing_Month03" Systems="t1"/>
   <Value Id="dld"  LongName="Dealing Day"
      RefId="Dealing_Day02 Dealing_Day03"  Systems="t1"/>
   <Value Id="cmdty" LongName="Commodity Dealt"
      RefId="Commodity02 Commodity03"/>
   <Value Id="dvy" LongName="Delivery Year"
      RefId="Delivery_Year02 Delivery_Year03" Systems="t2"/>
   <Value Id="dvm" LongName="Delivery Month"
      RefId="Delivery_Month02 Delivery_Month03" Systems="t2"/>
   <Value Id="mkt" LongName="Dealing Market"
      RefId="Market02 Market03"/>
   <Value Id="op" LongName="Opening Price of a Day"
      RefId="S_price02 S_price03" Systems="i1"/>
   <Value Id="hp" LongName="Highest Price in a  Day"
      RefId="H_price02 H_price03" Systems="i1"/>
   <Value Id="lp" LongName=Lowest Price in a Day"
      RefId="L_price02 L_price03" Systems="i1"/>
   <Value Id="cp" LongName="Closing Price of a Day"
       RefId="E_price02 E_price03" Systems=i1"/>
   <Value Id="sp" LongName="Settlement Price of a Day"
       RefId="B_price02 B_price03" Systmes="i1"/>
   <Value Id="amt" LongName="Amount of Dealings in a Day"
       RefId="Amount02 Amount03"/>
   <Value Id="oint"  LongName="Amount of Open Interest"
       RefId="OpenInterest_Amount02 OpenInterest_Amount03"/>
  </Relational>
  <Time Id="t1">
   <Year RefId="dly"/>
   <Month RefId="dlm"/>
   <Day RefId="dld"/>
  </Time>
  <Time Id="t2">
    <Year RefId="dvy"/>
    <Month RefId="dvm"/>
  </Time>
  <Interval Id="i1">
    <Min RefId="lp"/>
    <Max RefId="hp"/>
    <Other RefId="op"/>
    <Other RefId="cp"/>
    <Other RefId="sp"/>
  </Interval>
</Data>
```

This is a part of an example of DandD instance, `Futures2002-2003.dad`, describing the record of daily prices of various commodity futures from December 2002 to January 2003. The record is obtained from the site

`//ftp.tokyoweb.or.jp/tocomftp/pub/`

through FTP as a CSV (comma separated values) file for each month. In the example, relational data is defined by the tag `<Relational>` and the sub elements `<Value>` define the columns of the relational data. The reason why two data vectors are referred in the attribute `RefId` of any `Value` is that the records in the site are separated into two files, `2002-12.csv` for December and `2003-01.csv` for January. Moreover, the site changed the record format after the 1 January 2003 and the records before that day are stored in a directory `past` and newer records are stored in a directory `now`. Therefore, as in Example 1, we need to adjust the old format to the newer one. The following example illustrates a few of the definitions of such data vectors. Here we have omitted some attributes which are not essential for understanding the key points.

Example 3

```
<DataVector Id="Delivery_Year02" Access="acc1" Protocol="prt1"
          PostProcessing="Delivery_Year02scan am1"/>
<DataVector Id="Delivery_Year03" Access="acc1" Protocol="prt2"
          PostProcessing="Delivery_Year03scan"/>

     ...

<Access Id="acc1" IPAddress="ftp.tokyoweb.or.jp"
     UserId="anonymous"/>
<Protocol  Id="prt1" Encoding="Shift_JIS" Physical="TCP">
```

```
     <FTP Id="ftp1" Suffix="/tocomftp/pub/past/2002-12.csv"/>
</Protocol>
<Protocol  Id="prt2" Encoding="Shift_JIS" Physical="TCP">
     <FTP Id="ftp2" Suffix="/tocomftp/pub/now/2003-01.csv"/>
</Protocol>
<Arithmetic Id="am1">
 x+2000
</Arithmetic>
<ScanFormat Id="Dealing_Year02scan">
%4d%*2d%*2d,%*s,%*d,%*d,%*d,%*d,%*d,%*d,%*d,%*d,%*d
</ScanFormat>
<ScanFormat Id="Dealing_Year03scan">
%4d%*2d%*2d,%*s,%*d,%*f,%*f,%*f,%*f,%*f,%*d,%*d,%*d
</ScanFormat>
```

Two data vectors are defined in this example, sharing the same attribute `Access`. The attribute `PostProcessing` of the first vector says that the `ScanFormat` with I.D. `Dealing_Year02scan` and `Arithmetc` with I.D. `am1` should successively be applied to each of the lines returned by an execution of FTP protocol. We need such two step processing because the last two digits of a year are only recorded in the file `2002-12.csv` but the full four digits are recorded in the file `2003-01.csv`. To adjust the format to the newer one, the last two digits are extracted from each line of the CSV file `2002-12.csv` and converted to the four digit year representation. The attribute `Encoding` of the `Protocol` indicates that character code of the lines obtained by FTP is the shift JIS code. The reader may guess other differences of the formats of those two files. Many other different formats for the files are possible.

Consider Example 2 again. The attribute `MainKey` of the `Relational` tells us the main key of the relational data. This is the same idea as in RDBMS. Each record is identified by the combination of the indicated `Values`. This attribute together with the `ForeignKey` attribute enables us to make links between several relational data. Other attributes `Control` and `Nominal` indicate which `Value`s are factors. Possible other factor attributes are `Variable`, `Block`, `Latent` and `Auxiliary`. The concept of factor type is useful not only for applying a model like ANOVA, but also for the visualisation of data. In the example above, the attribute `Control` suggests that the specified variables constitute an x-axis of a plot and the attribute `Nominal` suggests that separate visualisations should be organised according to the values of the variables. This is an example showing how the semantics of variables can be described in a formal way. Such a formal description plays an important role in an automatic visualisation or a semi automatic data analysis.

It is crucial to describe several relations among *variables* by the `Systems` attribute of `Value`. Note that the *relation* here is not the same as that in the relational model, which is a relation of the given records as a set of points in a value space. In Example 2, two `Time` relations and an `Interval` relation are defined. The Time indicates that the specified Values constitute a calendar system. The Interval indicates that the four Values are closely related, constituting an interval given by Min and Max with several aggregated values, the opening price, the closing price and the settlement price given by Other. Note that futures price moves time by time in a day.

5 InterDatabase implemented by DandD

We have briefly explained some important aspects of a DandD instance, in conjunction with InterDatabase. One of the advantages of our implementation is that any number of DandD instances can be created for the same set of data. The data view is not unique and changes from stage to stage and from person to person. For example, it would be natural to organise data reflecting the way it has been collected, describing the attributes and background information as precisely as possible for possible future needs. However, we may find a better data organisation and a necessary and sufficient description after browsing the data or even after modelling. Also, the data view heavily depends on the aims of data utilisation. For example, the choice of response variable depends on the aim. It would not be realistic to fix such a view, and rather natural to allow different views for a set of data. In DandD, different views can be easily created. It is usually enough to modify an existing DandD instance. No modification of data sources is necessary. As a consequence, many DandD instances will be produced in the course of data acquisition and modelling. Thus a mechanism is necessary to organise different data views or DandD instances.

5.1 Network of DandD instances

A mechanism Relatives is available in DandD instance. This make it possible to construct a network of DandD instances, to trace changing data views. The element Relatives has sub elements Parent, Child and Sibling. Each element indicates which DandD instances are the parents, children or siblings through its URL. Then, other related views can be easily searched on the Internet and accumulated as experiences, without maintaining any library. We hope that such an accumulation leads to more productive work with data. Also, other mechanisms Model or Summary should help the user obtain a better understanding of the data.

5.2 Data updates

Data is updated day by day or time by time. As a consequence it is important to have a mechanism to pursue the changes in a database. Further work is necessary to implement such a mechanism, although our InterDatabase is robust enough to accommodate such changes.

EXPLORATORY VISUAL ANALYSIS OF GRAPHS IN GGOBI

Deborah F. Swayne and Andreas Buja

Key words: GGobi, graphical software, system R, covariate displays.

COMPSTAT 2004 section: Data visualisation.

Abstract: Graphs have long been of interest in telecommunications and social network analysis, and they are now receiving increasing attention from statisticians working in other areas, particularly in biostatistics. Most of the visualization software available for working with graphs has come from outside statistics and has not included the kind of interaction that statisticians have come to expect. At the same time, most of the exploratory visualization software available to statisticians has made no provision for the special structure of graphs.

Graphics software for the exploratory visual analysis of graph data should include the following: graph layout methods; a variety of displays and methods for exploring variables on both nodes and edges, including methods that allow these covariate displays to be linked to the network view; methods for thinning or otherwise trimming a large graph. In addition, the power of the visualization software is greater if it can be smoothly linked to an extensible and interactive statistics environment.

In this paper, we will describe how these goals have been addressed in GGobi through its data format, architecture, graphical user interface design, and its relationship to the R software [7].

1 Introduction

A graph consists of nodes and edges; the edges connect pairs of nodes. In social network analysis, the nodes frequently represent people or institutions; the edges represent interactions such as conversations or trading relationships. The graphs encountered in telecommunications are similar: the nodes typically represent telephone numbers or IP (Internet Protocol) addresses; the edges capture telephone calls or exchanges of packets.

For a data analyst studying graph data, the description of the graph is often only part of the story, because the nodes and the edges may each correspond to multivariate data. For example, if the graph captures a set of telephone numbers and telephone calls, we may have demographic data or usage data about the bill-payer for each telephone number, and we may also know the time and duration of phone calls. We therefore observe variables on nodes and on edges.

How do exploratory data analysts approach such data? First, we need to visualize the graph, that is, to lay it out by using node positions that have been calculated to help us interpret the graph structure. This is not a well-defined objective, but often the distance between nodes in the layout should reflect their distance from one another according to some distance metric on the graph. Another guideline is that minimizing edge crossings usually makes a graph more readable by cutting down on clutter. Still, there is no "best" layout method, or even a best layout for a particular graph: for example, one layout may clarify a graph's overall structure while deemphasizing local structure, while in another layout, a local region of interest may be clearly drawn but the overall structure looks like spaghetti. Graph layout in an interactive context, then, should offer several layout algorithms and a lot of interaction methods for tuning and exploration.

The layout algorithms should be fast enough to be used in real time. For example, we might draw only straight-line edges, and we might not sacrifice any time to choose the perfect position for node labels. The suite of layout algorithms should include methods for laying out graphs in 3D (or higher-D), which we can rotate to shift our viewpoint and focus on local structure.

Other important interaction methods include the following:

- We should be able to tune the layout by moving nodes interactively.
- We should be able to pan and zoom the display of the graph.
- We should have a variety of ways to thin or subset the graph by eliminating or collapsing nodes and edges. At times, we may not want to eliminate nodes, but to find ways to highlight nodes and edges of interest while "downlighting" the rest. In that way, we retain context as we focus on a subset of interest.

So far, we have considered only the structure of the graph, ignoring the multivariate data associated with the nodes and edges. Once the layout is displayed, one wants to explore the data together with the graph, to investigate the relationships between the variables and the shape of the graph. The use of linked views, by now a standard feature of interactive data visualization software, is well suited to this goal. The graph view can be linked to displays of multivariate data on both nodes and edges.

These additional views can be used to highlight, label or paint nodes and edges in the graph view according to variable values, so that we can explore the distribution of data values in the graph (see Fig. 2). Equally, we can highlight data in the covariate views. For example, we might want to thin the graph according to covariate values. In the case of telephone calls, we could erase the edges corresponding to the shortest calls, and then erase all the nodes that no longer have edges.

Finally, this software will be more powerful and more extensible if it can be programmed using some scripting language, and if it is connected to a software system for data analysis that includes a library of standard graph algorithms.

Graph drawing is an active research area in computer science with a long history [2]. The layouts produced are highly tuned and often beautiful. Since they are not produced within the context of data analysis, the graphics are typically not interactive, and the programmers have not adopted the linked views approach. Some tools (e.g. Pajek [1]) offer a library of graph algorithms in addition to layout, and some can even be extended with plugins (e.g. Tulip, `www.tulip-software.org`). Still, the designers clearly do not have exploratory data analysis (EDA) in mind.

Within the field of statistics, graph visualization has not gotten very much attention. A notable exception is the work of [12], which has never been released to the public. Even the social network analysis community, which combines an interest in graph drawing with an interest in multivariate data analysis, has not to our knowledge produced tools which combine both sets of visualization capabilities. We therefore feel that there exists a gap in current software offerings for the exploration of graph data. GGobi [10] is our attempt to fill this gap.

This paper is structured as follows. Section 2 introduces GGobi, the software which will be discussed in the rest of the paper. Section 3 describes GGobi's methods for graph layout. Section 4 describes some of GGobi's methods for manipulating displays, especially graph views. Section 5 explains how GGobi can be embedded in other software, and what this design offers for graph data analysis. Section 6 describes the data format that is used to specify relationships between nodes and edges, graph elements and variables. We use a real telecommunications dataset for illustration throughout the paper. The meaning of its variables has been masked to protect the privacy of the customers.

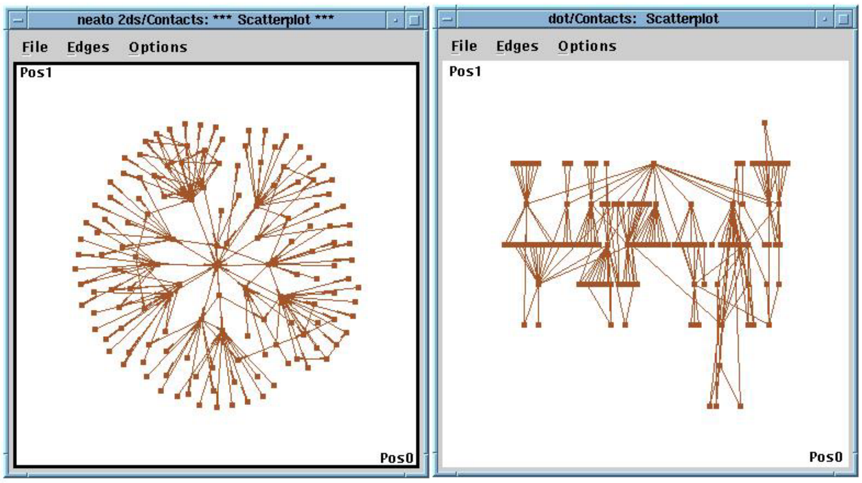
2 GGobi

GGobi is general-purpose multivariate data visualization software, designed to support EDA. GGobi displays include scatterplots, scatterplot matrices, barcharts, time series plots, and parallel coordinate plots. All displays can be linked for color and glyph brushing as well as for point and edge labeling. GGobi is known for its powerful projection facilities for high-dimensional rotations. Among GGobi's many other manipulations are panning and zooming, subsampling, and interactive moving of points and groups of points in data space.

GGobi can be easily extended, either by being embedded in other software or by the addition of plugins; either way, it can be controlled using an Application Programming Interface (API). An illustration of its extensibility is that it can be embedded in R.

GGobi is a direct descendent of a data visualization system called XGobi [9] that has been in use since the early 1990's. XGobi supported the specification and display of graphs, but it did not include any graph layout methods. Graph data was an afterthought with XGobi, while it was a consideration in the GGobi design process from the beginning.

GGobi supports a plain ASCII format involving multiple input files (as in



neato 2ds/Contacts: *** Scatterplot ***
File

Figure 1: These two displays show layouts of the *snetwork.xml* data generated by the GraphViz layout methods. On the left is a 2-D “neato” layout; on the right a “dot” layout.

XGobi) for the simplest data specifications, but an XML (Extensible Markup Language) file format has to be used for anything richer, and graphs are an example. The format is briefly described in Section 6.

3 Graph layout

We have used GGobi’s plugin mechanism to add graph layout. Because this is specialized software, it is convenient that this functionality can be optional. There are two plugins available for GGobi that can be used for laying out graphs.

3.1 The graph layout plugin

The simplest plugin is called GraphLayout. It includes three layout methods, two of which rely on the library included with GraphViz [6], a freely available collection of tools for manipulating graph structures and generating graph layouts. All three methods work by generating a new dataset on the fly and making it available through the GGobi interface, so scatterplots of the new position variables can be displayed, and edges added to them.

The three layout methods are:

Radial: The radial layout [12] places a designated node at the center, and arranges the rest of the nodes in concentric circles around it. The resulting layout is a tree arranged radially, with any extra edges added. If the underlying graph is not very tree-like, the layout can result in a great many edge crossings, and the layout doesn't do anything to minimize these crossings. In addition to the two position variables, the method generates a few other variables, such as the number of steps between node j and the center.

Dot: "Dot" produces hierarchical layouts of directed graphs in 2D; the other layout methods ignore edge direction. It first finds an optimal rank assignment for each node, then sets the vertex order within ranks, and finally finds optimal coordinates for the nodes.

Neato: The "neato" layout algorithm produces "spring" model layouts of undirected graphs. In spring models, the graph is modelled as a set of objects connected by springs, assuming both attractive and repulsive forces, and an iterative solver is used to find a low-energy configuration. Only the positions at the final configuration are returned by the algorithm. Neato is the most general-purpose method of the three. Further, neato can generate layouts in spaces from 2D to 10D, and edge weights can be used to further tune the layout.

The first layout method is illustrated in Fig. 2; the latter two are illustrated in Fig. 1.

There is a manual for the plugin which describes its use in more detail. The dot and neato layout methods are described in the GraphViz documentation, which can be found on
`www.research.att.com/sw/tools/graphviz/refs.html`.
The GraphViz software can be obtained from `www.graphviz.org`.

3.2 The ggvis plugin: multidimensional scaling

The "ggvis" plugin is a reimplementation of XGVis [4] a multidimensional scaling (MDS) tool which is part of the XGobi software. MDS is a method for visualizing data where objects are characterized by dissimilarity values for all pairs of objects. It interprets these dissimilarities as distances and constructs maps in R^k. It was originally developed as a data analysis method in the social sciences, but it is also used to lay out graphs.

Like neato, ggvis computes layouts through iterative optimization, but unlike neato, the display is redrawn at each iteration, so we can watch the layout take shape. We can also intervene during the optimization process, by moving points interactively when they are trapped in local minima, or by adjusting parameters of the MDS objective function.

GGVis puts a large number of parameters under interactive user control. As a consequence, ggvis layouts are highly tunable. One of the most useful ggvis parameters is the exponent of a power transformation of the target distances; lowering it below one lets the short distances dominate, while exponents greater than one expose the long distances. This lets us decide whether we want to spread the leaves out, highlighting the structure in the leaves, or to collapse them, revealing the connectivity in the interior of the graph.

In addition to parameters, we can make use of color and glyph groupings of the nodes. We may subselect one group at a time for layout, or we may lay out the groups simultaneously but as unconnected graphs. Or we may lay out a subgroup and use it as an anchor set for laying out the remaining nodes.

There is also a diagnostic plot that permits us to judge how closely the pairwise distances in the layout match the target distances.

3.3 Multiple edge sets

Sometimes one wants to compare different edge sets for the same set of nodes. In the case of telephone calls, for instance, the extended community associated with a phone number changes from week to week, with changes both in the set of phone numbers in the community, and in the total length of the conversations between any pair of nodes.

One strategy to compare these different edge sets is to start by determining a layout based on the union of all nodes and the union of all edges. Since any of the edge sets can be associated with the set of nodes used to determine the layout, it's easy to compare them: Open multiple scatterplots of the nodes in the graph view, and assign a different edge set to each one. That technique could even be the basis for an animation of edges and edge variables over time.

4 Graph exploration

Once the layout has been produced and the graph is displayed, a great deal of exploration is possible without using any further plugins. Most of this functionality depends on using linked views. As one would expect, nodes in the graph view are linked to points in scatterplots of node variables, or to bars in a barchart; this is a familiar style of linking. It is perhaps less obvious that an edge in the graph view and a point in a scatterplot of edge variables are also linked: these are just different ways of rendering the same record. Here are some of the manipulations available in GGobi:

Move Points: In this mode, any point can be moved to manually tune the layout. To move a group of points, one brushes them with a common glyph and color; by moving any member of the group, one moves the whole group. Under certain circumstances, point motion can be linked across plots of layouts, namely, when the nodes are shared across graphs that differ only in edge sets and share a single layout in separate windows.

Edit Edges: To edit the graph interactively, add nodes (by clicking the mouse where you want the new node to appear) and edges (by pressing down the mouse button at the source node and dragging the edge to the destination). To view or modify the default properties (such as record label or variable values), use the left button; to simply have the new record added quickly, use the right or middle button. To delete nodes or edges, use "shadow" brushing as described below.

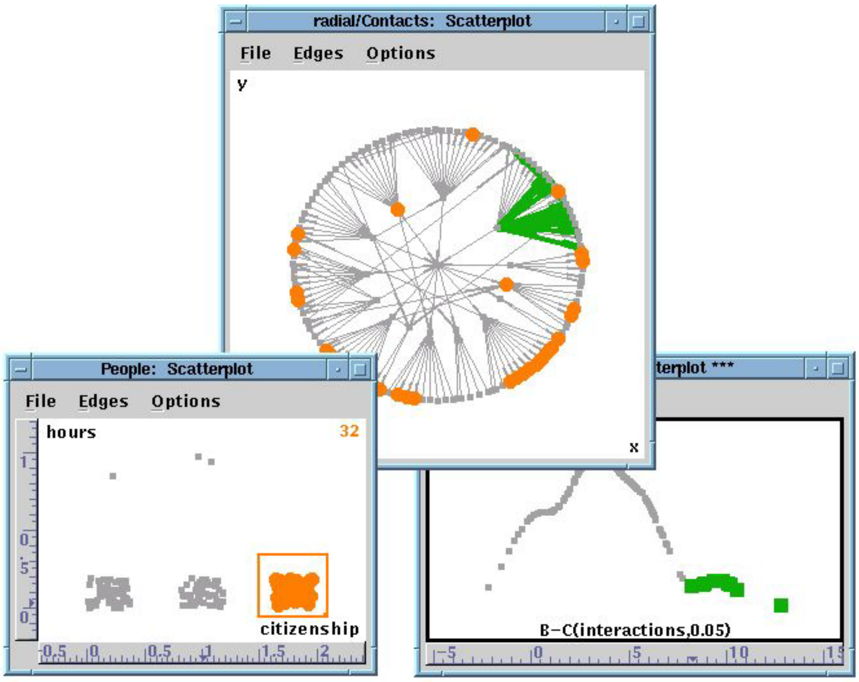

Figure 2: An illustration of linked brushing with graphs. The nodes in the graph are linked to the data in the scatterplot at the lower left; the edges to the data in the scatterplot at the lower right.

Identify: When the identification mode is active, bringing the cursor near a point causes a label to be displayed, both in the current display and in other displays. By default, this is the case label supplied in the data file (or the row number), but it can also be a list of variable name - value pairs or an id. If edge identification is selected, the nearest edge will be labelled instead of the nearest point.

Brushing (interactively): Linked brushing is probably the most familiar use of linked views. In the case of graphs, it is probably clear by now that it can be used in at least two ways. First, a plot of node data is linked to a graph view such that brushing points in one plot causes the same points to change color or glyph in the other. Second, a plot of edge data is linked to the graph view such that brushing points in the edge data plot affects the edges in the graph view, and vice versa. This latter functionality is an innovative feature of ggobi.

One brushing style allows a point or an edge to be “shadow” brushed, so that it’s drawn in a faint color and can later be removed from the displays altogether.

Fig. 2 shows linking between a radial layout of the *snetwork.xml* data and two scatterplots. Two rectangular arrays of data are involved, one for the nodes and the other for the edges. The window at the lower right contains a 1-D plot (an ASH, or Average Shifted Histogram ([8]) of a transformation of one of the edge variables, *interactions*. The highest values have been brushed with large green rectangles (rendered in dark gray in the gray-scale printed version of this paper), and the corresponding edges in the radial layout view are wide and green. All the green edges are connected to a single node, which tells us that a single individual participates in all of the longest interactions in the data. The window at the lower left contains a jittered scatterplot of *hours vs citizenship*, the two variables recorded for each person. The points representing the people with the highest values of the citizenship variable (visa holders) have been brushed with large orange circles (rendered as large medium-gray circles in gray scale), and the corresponding points are brushed in the graph view. A couple of subgraphs contain no visa holders at all, and a couple of other subgraphs are dominated by visa holders, but we also see a great deal of interaction between visa holders and other people in the data. (Recall that the data is actually about telephone calls, but that its meaning has been thoroughly obscured to protect customer privacy.)

The line characteristics (color, type and thickness) are implied when the point characteristics (color, type and size) are specified in the *Choose color & glyph* panel.

One of the options available in the brushing mode is shadow brushing [3]; that is, to select points or edges to be drawn in a “shadow” color, close to the color of the background. This is especially appealing for graph visualization because clutter is often severe, yet we often don’t want to lose sight of the graph structure when viewing a subset of the data. (Sometimes, of course, we don’t want to draw those points at all, even as shadows, and then we exclude them using the *Color & glyph groups* tool.)

Coloring by variables: Since interactive brushing of continuous variables can be tedious, an automatic scheme is available as part of the *Color schemes* tool. In the *snetwork.xml* data, one of the edge variables (*interactions*) is continuous, so we can choose a sequential color scale and apply it to the “Contacts” edge set using the *interactions*. (Since the distribution of that variable is highly skewed, we might also apply a transformation first.)

Panning and Zooming: It is essential to be able to zoom in on interesting regions of the graph view, and that functionality is available in GGobi’s scale mode. (GGobi displays are not linked for scaling.)

All these methods are described in more detail in the GGobi manual, available on `www.ggobi.org`.

4.1 The graph manipulation plugin

All of the interactive methods just listed are useful for multivariate data, not just for graphs. In addition to those methods, we have added a plugin for methods of exploration that are peculiar to graphs. It has two functions as of this writing, both of them designed for focussing on contiguous subsets of the graph.

The first function responds to a button click by shadow-brushing leaf nodes and the edges connected to them recursively until no leaf nodes are highlighted. It can be a useful way to quickly hide a lot of clutter in a a messy graph, and get a look at the center.

The second is a method for focussing on a node and its nearest neighbors. It is used in conjunction with the *Identification* mode in GGobi. Move the cursor near a point of interest, and then click a mouse button. All points will be shadow brushed with the exception of the nearest point and its neighbors within one or two steps. In this way, one can walk around the graph, focussing on one small neighborhood at a time.

5 Graphs in GGobi's API

While GGobi is a stand–alone application, it has been designed and constructed as a programming library and can be embedded within other applications. It has a large, and still evolving, Application Programming Interface (API) which developers can use to integrate the GGobi functionality with other code. For data analysts, GGobi becomes much more powerful once it is embedded in a statistics environment with an extension language.

Our most developed example is the Rggobi package, which allows GGobi to be embedded in the R process. Users can then launch GGobi (using R data frames or data files outside R), and then read and set data values and case attributes (such as color and glyph), and even add event handlers which cause R to respond to GGobi events. Edge sets can also be added, and the attributes of edges (color, line type and line thickness) are handled exactly like point attributes.

In this first simple example, we create a matrix to represent the nodes, and open it in ggobi. We next create an empty data set, dimensioned to hold six records. Finally we create a 6 by 2 array to define the edges as 6 rows of source - destination pairs, named in terms of the node labels, and add the edge set to the running ggobi.

```
x <- matrix(c(0,0,2,1, 0,2,0,1, 0,0,0,1), 4, 3,
     dimnames = list(c("a", "b", "c", "d"), c("X", "Y", "Z")))
gg <- ggobi(x)

d2 <- gg$createEdgeData(6, name="edges")
e2 <- rbind(c("a","b"), c("b","c"), c("a","c"),
            c("a","d"), c("b","d"), c("c","d"))
gg$setEdges(e2, edgeset = d2)
```

In the second example, we deal with a more complex case, in which there are variables corresponding to the edges as well as to the nodes. We start again, using the matrix x just described. Next we add a second dataset, 3 by 2, composed of the data corresponding to the edges. Finally we add three edges to the second dataset.

```
gg <- ggobi(x)

z <- matrix(c(1,2,1, 1,2,2), 3, 2,
     dimnames = list(letters[10:12], c("X", "Y")))
d2 <- gg$setData(z, name="z")

e1 <- rbind(c("a", "b"), c("b", "c"), c("a", "d"))
gg$setEdges(e1, edgeset=gg[["z"]])
```

We plan to extend the API and the Rggobi package so that they can work with other graph packages currently under development as part of the Bioconductor project (www.bioconductor.org).

6 Data format: Specifying graphs in XML

GGobi relies on XML (the Extensible Markup Language) for everything beyond the simplest of input data. The use of XML has allowed us to design a system of mark-ups or tags that describe one or more datasets in great detail within a single file, even specifying the relationships between records in different datasets.

We based GGobi's XML format on a pre-existing XML format designed for the Omegahat project (www.omegahat.org) and the S language (R and S-Plus). Some of the information that can be specified in the GGobi XML file includes variable types and axis ranges, the symbol and color corresponding to a record, and multiple data sets and the rules for linking them.

GGobi's XML format is described elsewhere [11], so we will only explain here how the specification of data records is used to describe graphs. A data record specification may be as simple as this:

```
<record> 1.0 2.5 </record>
<record> 1.7 2.2 </record>
```

This is a pair of records for a dataset with two variables. If we want to identify these records as nodes, we must also give them unique ids. (Ids can also be used for linking and identification, but that usage is described elsewhere.)

```
<record id="Macbeth"> 1.0 2.5 </record>
<record id="Banquo">  1.7 2.2 </record>
```

If we want a set of edges to be drawn on a scatterplot or a graph view of these nodes, we need a second dataset. If there is to be an edge from "Macbeth" to "Banquo," the second dataset must contain a record like this:

```
<record source="Macbeth" destination="Banquo"> </record>
```

If there are variables corresponding to that edge, they are specified within the record, just as they are for nodes.

```
<record source="Macbeth" destination="Banquo">
   27 42 4.6
</record>
```

As we implied in Section 3.3, it's possible to specify more than one edge set corresponding to the same node set within the same XML file, and that offers a way to compare related edge sets.

There are graph specification languages in XML under development, and we expect it will be easy to translate between those formats and GGobi's, though those other languages probably won't fully support multivariate data.

For the interested reader, the GGobi distribution includes several graph datasets in XML. Some include position variables so that additional layout isn't required: *buckyball.xml* and *cube6.xml* describe geometric objects, with no additional variables. Another, *snetwork.xml,* is fully multivariate and does not include variables that can be used for displaying the graph; that is the dataset that served as an example throughout this paper.

7 Conclusions

As more statisticians become interested in graph data analysis, they approach this area with the expectations and expertise acquired in working with general multivariate data. They expect first of all to be able to work in environments like R, with a set of algorithms, a variety of static display methods, and a scripting language. This set of goals is being pursued in the Bioconductor project and elsewhere.

Second, statisticians and other data analysts who have come to rely on direct manipulation graphical methods will want to use them with this form of data as well: to quickly update plots, changing variables and projection, to pan and zoom displays, and to use linked views to explore the graph and the distribution of multivariate data in the graph. GGobi's data format supports describing the graph and the data together, and its architecture allows the addition of plugins, so it's natural to extend GGobi, applying all its functionality to graph data.

Finally, we want to integrate the direct manipulation graphics, algorithms and scripting language so that we can use them all together. This expectation is not yet as automatic as the first two: People often still imagine building a single monolithic application that can do everything. As the example of graph data shows, however, there are many specialized problems that are often overlooked, so no monolithic piece of software can satisfy the needs of all users. If instead it's possible to integrate complementary software tools, and to extend them with plugins and packages, then even the most unusual cases can be handled without too much trouble.

The GGobi software and documentation, including several plugins and the Rggobi package, are available on the web site www.ggobi.org.

PLS REGRESSION AND PLS PATH MODELING FOR MULTIPLE TABLE ANALYSIS

Michel Tenenhaus

Key words: Multiple factor analysis, PLS regression , PLS path modeling, generalized canonical correlation analysis.

COMPSTAT 2004 section: Partial least squares.

Abstract: A situation where J blocks of variables are observed on the same set of individuals is considered in this paper. A factor analysis logic is applied to tables instead of individuals. The latent variables of each block should well explain their own block and in the same time the latent variables of same rank should be as positively correlated as possible. In the first part of the paper we describe the hierarchical PLS path model and remind that it allows to recover the usual multiple table analysis methods. In the second part we suppose that the number of latent variables can be different from one block to another and that these latent variables are orthogonal. PLS regression and PLS path modeling are used for this situation. This approach is illustrated by an example from sensory analysis.

1 Introduction

We consider in this paper a situation where J blocks of variables $X_1, \ldots, X_J$ are observed on the same set of individuals. The problem under study is completely symmetrical as all blocks of variables play the same role. All the variables are supposed to be standardized. We can follow a factor analysis logic on tables instead of variables. In the first section of this presentation we suppose that each block X_j is multidimensional and is summarized by m latent variables plus a residual E_j. Each data table is decomposed into two parts: $X_j = t_{j1}p_{j1}^{'} + \cdots + t_{jm}p_{jm}^{'} + E_j$. The first part of the decomposition is $t_{j1}p_{j1}^{'} + \cdots + t_{jm}p_{jm}^{'}$. The latent variables ($t_{j1}, \ldots, t_{jm}$) should well explain the data table X_j and in the same time the latent variables of same rank $h(t_{1h}, \ldots, t_{Jh})$ should be as *positively* correlated as possible. The second part of the decomposition is the residual E_j which represents the part of X_j not related to the other block, i.e. the specific part of X_j.

We show that the PLS approach allows to recover the usual methods for multiple table analysis. In section two we suppose that the number of latent variables can be different from one block to another and that these latent variables are orthogonal. PLS regression and PLS path modeling are used for this situation. This approach is illustrated by an example from sensory analysis in the last section.

2 Multiple Table Analysis: a classical approach

In Multiple Table Analysis it is usual to introduce a super-block X_{J+1} merging all the blocks X_j. This super-block is summarized by m latent variables $t_{J+1,1}, \ldots, t_{J+1,m}$ also called auxiliary variables. The causal model describing this situation is given in Figure 1. This model corresponds to the hierarchical model proposed by Wold [16].

The latent variables $t_{j1}, \ldots, t_{jm}$ should well explain their own block X_j. In the same time the latent variables of same rank $(t_{1h}, \ldots, t_{Jh})$ and the auxiliary variable $t_{J+1,h}$ should be as *positively* correlated as possible. In the usual Multiple Table Analysis (= MTA) methods, as Horst's [6] and Carroll's [1] Generalized Canonical Correlation Analysis, orthogonality constraints are imposed on the auxiliary variables $t_{J+1,h}$ and the latent variables t_{jh} related to block j have no orthogonality constraints. We define for the super-block X_{J+1} the sequence of blocks $E_{J+1,h}$ obtained by deflation: each block $E_{J+1,h}$is defined as the residual of the regression of X_{J+1} on the latent variables $t_{J+1,1}, \ldots, t_{J+1,h}$. Figure 2 corresponds to step h. For computing the latent variables t_{jh} and the auxiliary variables $t_{J+1,h}$ we use the general PLS algorithm [16] defined as follows for step h of this specific application:

External estimation:

- Each block X_j is summarized by the latent variable $t_{jh} = X_j w_{jh}$
- The super-block $X_{J+1,h}$ is summarized by the latent variable $t_{J+1,h} = E_{J+1,h-1} w_{J+1,h}$

Internal estimation:

- Each block X_j is also summarized by the latent variable $z_{jh} = e_{jh} t_{J+1,h}$, where e_{jh} is the sign of the correlation between t_{jh} and $t_{J+1,h}$. We will however choose $e_{jh} = +1$ and show that the correlation is then positive.
- The super-block $E_{J+1,h-1}$ is summarized by the latent variable $z_{J+1,h} = \sum_{j=1}^{J} e_{J+1,j,h} t_{jh}$, where $e_{J+1,j,h} = +1$ when the centroid scheme is used, or the correlation between t_{jh} and $t_{J+1,h}$ for the factorial scheme, or furthermore the regression coefficient of t_{jh} in the regression of $t_{J+1,h}$ on $t_{1h}, \ldots, t_{Jh}$ for the path weighting scheme.

We can now describe the PLS algorithm for the J-block case. The weights w_{jh} can be computed according to two modes: Mode A or B.

In Mode A simple regression is used:

$$w_{jh} \propto X_j^{'} t_{J+1,h}, j = 1 \text{ to } J, \text{ and } w_{J+1,h} \propto E_{J+1,h-1}^{'} z_{J+1,h} \qquad (1)$$

where $\propto$ means that the left term is equal to the right term up to a normalization.

For Mode B multiple regression is used:

$$w_{jh} \quad \propto \quad (X_j^{'}X_j)^{-1}X_j^{'}t_{J+1,h}, j = 1 \text{ to } J,$$

$$\text{and } \; w_{J+1,h} \propto (E_{J+1,h-1}^{'}E_{J+1,h-1})^{-1}E_{J+1,h-1}^{'}z_{J+1,h} \qquad (2)$$

The normalization depends upon the method used. For some method w_{jh} is of norm 1. For other methods the variance of t_{jh} is equal to 1.

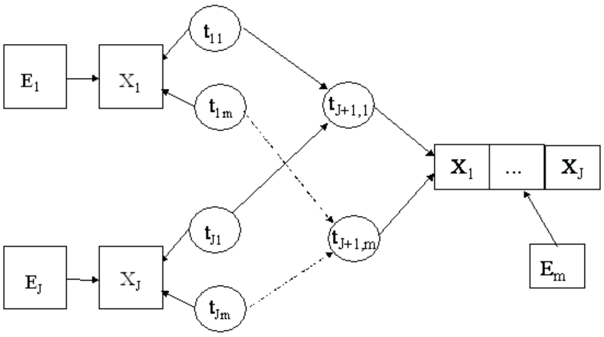

Figure 1: Path model for the J-block case.

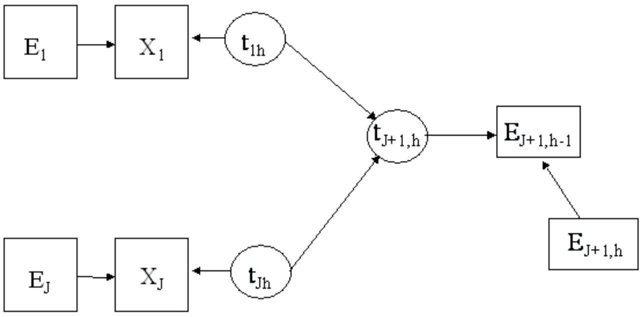

Figure 2: Path model for the J-block case : Step h.

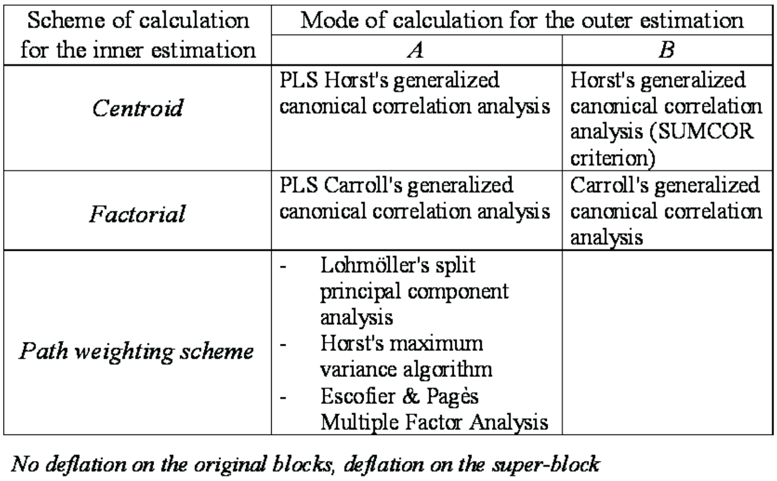
It is now easy to check that the correlation between t_{jh} and $t_{J+1,h}$ is always positive: $t_{J+1,h}^{'}t_{jh} = t_{J+1,h}^{'}X_jw_{jh} \propto t_{J+1,h}^{'}X_jX_j^{'}t_{J+1,h} > 0$ when Mode A is used. The same result is obtained when Mode B is used. This justifies the replacement in both (1) and (2) of the internal estimation $z_{j,h}$ by the external estimation $t_{J+1,h}$.

The PLS algorithm can now be described. We begin by an arbitrary choice of the weights w_{jh}. We get the external estimations of the latent variables, then the internal ones. Using the equations (1) or (2) we get new weights. This procedure is iterated until convergence always verified in practice, but only mathematically proven for the two-block case.

The various options of PLS Path Modeling (Mode A or B for external estimation; centroid, factorial or path weighting schemes for internal estimation) allow to find again many methods for Multiple Table Analysis: Generalized Canonical Analysis (the Horst's one [6] and the Carroll's one [1], Multiple Factor Analysis [4], Lohmöller's split principal component analysis [9], Horst's maximum variance algorithm [7]. The links between PLS and these methods have been demonstrated in [9] or [11] and studied on practical examples in [5] and [10]. These various methods are obtained by using the PLS algorithm according to the options described in Table 1. The super-block only is deflated; the original blocks are not deflated.



Scheme of calculation for the inner estimation	Mode of calculation for the outer estimation	
	A	*B*
Centroid	PLS Horst's generalized canonical correlation analysis	Horst's generalized canonical correlation analysis (SUMCOR criterion)
Factorial	PLS Carroll's generalized canonical correlation analysis	Carroll's generalized canonical correlation analysis
Path weighting scheme	- Lohmöller's split principal component analysis - Horst's maximum variance algorithm - Escofier & Pagès Multiple Factor Analysis	

No deflation on the original blocks, deflation on the super-block

Table 1: Multiple Table Analysis and PLS algorithm.

Discussion on the orthogonality constraints

There is some advantage on imposing orthogonality constraints only on the latent variables related to the super-block: no dimension limitation due to block sizes. If orthogonality constraints were imposed on the block latent variables, then the maximum m of latent variables would be the size of the smallest block. The super-block X_{J+1} is summarized by m orthogonal latent variables $t_{J+1,1}, \ldots, t_{J+1,m}$. Each block X_j is summarized by m latent variables $t_{j1}, \ldots, t_{jm}$. But these latent variables can be highly correlated and consequently do not reflect the real dimension of the block. In each block X_j the latent variables $t_{j1}, \ldots, t_{jm}$ represent the part of the block correlated with the other blocks. A principal component analysis of these latent variables will give the actual dimension of this part of X_j.

It can be preferred to impose orthogonality on the latent variables of each block. But we have to remove the dimension limitation due to the smallest block. This situation is going to be discussed in the next section.

3 Multiple Table Analysis: new perspectives

We will describe in this section a new approach more focused on the blocks than on the super-block. This approach is called PLS-MTA : a PLS approach to Multiple Table Analysis.

We now suppose a variable number of common components in each block:

$$X_j = t_{j1}p_{j1}^{'} + \cdots + t_{jm_j}p_{jm_j}^{'} + E_j \tag{3}$$

A two steps procedure is proposed to find these components.

Step 1

For each block X_j we define the super-block $X_{J+1,-j}$ obtained by merging all the other blocks X_i for $i \neq j$. For each j we carry out a PLS regression of $X_{J+1,-j}$ on X_j. So we obtain m_j orthogonal and standardized PLS components $\tilde{t}_{j1}, \ldots, \tilde{t}_{jm_j}$which represent the part of X_j related with the other blocks. The choice of the number m_j of components is determined by cross-validation.

Step 2

One of the procedures described in Table 1 is used on the blocks $\tilde{T}_j = \left\{\tilde{t}_{j1}, \ldots, \tilde{t}_{jm_j}\right\}$ for h = 1. We obtain the rank one components $t_{11}, \ldots, t_{J1}$ and $t_{J+1,1}$. Then, to obtain the next components we only consider the blocks with $m_j > 1$. For these blocks we construct the residual $\tilde{T}_{j1}$ of the regression of $\tilde{T}_j$ on t_{j1}. A MTA is then applied on these blocks and we obtain the rank two components $t_{12}, \ldots, t_{J2}$ (for j with m_j *> 1*) and $t_{J+1,2}$. The components t_{j1} and t_{j2} are uncorrelated by construction, but the auxiliary variables $t_{J+1,1}$ and $t_{J+1,2}$ can be slightly correlated as we did not impose orthogonality constraint on these components. This research of components is iterated until the various m_j common components are found. These components can finally be expressed in term of the original variables.

There is a great advantage on imposing orthogonality constraints on each block components: the new m_j orthogonal and standardized components $t_{j1}, \ldots, t_{jm_j}$ are deduced from the m_j orthogonal and standardized PLS components $\tilde{t}_{j1}, \ldots, \tilde{t}_{jm_j}$ by a rotation. That means that

$$[t_{j1}, \ldots, t_{jm_j}] = [\tilde{t}_{j1}, \ldots, \tilde{t}_{jm_j}]A_j \tag{4}$$

where A_j is an orthogonal (rotation) matrix.

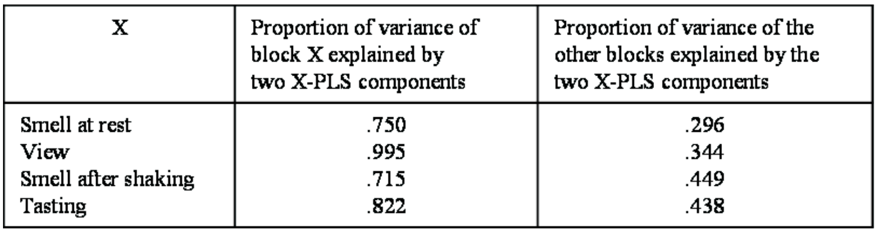
4 Application

We are going to use PLS-MTA on wine data which has been collected by C. Asselin and R. Morlat and are fully described in [3]. A set of 21 red wines with Bourgueil, Chinon and Saumur origins are described by 27 variables distributed in four blocks: X_1 = Smell at rest = [smell intensity at rest, aromatic quality at rest, fruity note at rest, floral note at rest, spicy note at rest], X_2 = View = [visual intensity, shading (from orange to purple), impression of surface], X_3 = Smell after shaking = [smell intensity, smell quality, fruity note, floral note, spicy note, vegetable note, phelonic note, aromatic intensity in mouth, aromatic persistence in mouth, aromatic quality in mouth], X_4 = Tasting = [intensity of attack, acidity, astringency, alcohol, balance (acidity, astringency, alcohol), mellowness, bitterness, ending intensity in mouth, harmony]. Another variable describing the global quality of the wine will be used as an illustrative variable.

We now describe the application of PLS-MTA methodology on these data.

Step 1

PLS regressions of $[X_2, X_3, X_4]$ on X_1, $[X_1, X_3, X_4]$ on X_2, $[X_1, X_2, X_4]$ on X_3, and $[X_1, X_2, X_3]$ on X_4 all lead to two PLS components when we decide to keep a component if it is significant (Q^2 is larger than 0.05). The X- and Y- explanatory powers of these components are given in table 2.



X	Proportion of variance of block X explained by two X-PLS components	Proportion of variance of the other blocks explained by the two X-PLS components
Smell at rest	.750	.296
View	.995	.344
Smell after shaking	.715	.449
Tasting	.822	.438

Table 2: Proportion of X and Y variances explained by the first two X-PLS components.

Then the "smell at rest" block $\widetilde{T_1} = \{\widetilde{t}_{11}, \widetilde{t}_{12}\}$, the "view" block $\widetilde{T}_2 = \left\{\widetilde{t}_{21}, \widetilde{t}_{22}\right\}$, the "smell after shaking" block $\widetilde{T}_3 = \{\widetilde{t}_{31}, \widetilde{t}_{32}\}$, and the "tasting" block $\widetilde{T_4} = \{\widetilde{t}_{41}, \widetilde{t}_{42}\}$ are defined with the standardized PLS X-components.

Step 2

The PLS components being orthogonal, it is equivalent to use Mode A or B for the left part of the causal model given in Figure 3 (PLS-Graph output [2]. Due to the small number of observations Mode A has to be used for the right part of the causal model of Figure 3. We use the centroid scheme for the internal estimation. We give in Figure 3 the MTA model for the first rank components and in Table 3 the correlations between the latent variables.

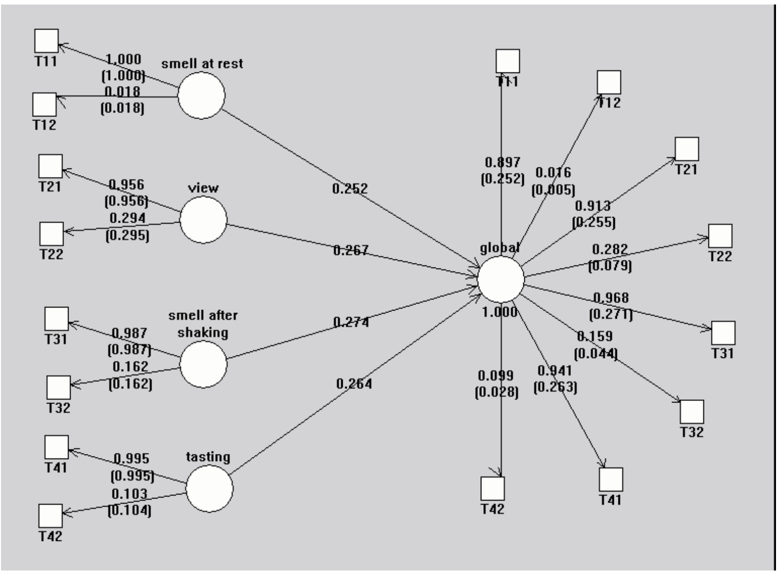


Figure 3: Path model for the first rank components (PLS-Graph output).

	Smell at rest	View	Smell after shaking	Tasting	Global
Smell at rest	1.00				
View	.78	1.00			
Smell after shaking	.88	.91	1.00		
Tasting	.74	.92	.92	1.00	
Global	.90	.96	.98	.95	1.00

Table 3: Correlations between the rank 1 latent variables.

In Figure 3 the figures above the arrows are the correlation loadings and the figures in brackets below the arrows are the weights applied to the standardized variables. Correlations and weights are equal on the left side of the path model because the PLS components are uncorrelated.

Rank one components are written as:

$$\begin{aligned}
t_{11} &= .9998 \times \widetilde{t}_{11} + .0176 \times \widetilde{t}_{12} \\
t_{21} &= .9558 \times \widetilde{t}_{21} + .2950 \times \widetilde{t}_{22} \\
t_{31} &= .9869 \times \widetilde{t}_{31} + .1619 \times \widetilde{t}_{32} \\
t_{41} &= .9947 \times \widetilde{t}_{41} + .1042 \times \widetilde{t}_{42} \\
t_{51} &= .2516 \times \widetilde{t}_{11} + .0045 \times \widetilde{t}_{12} + .2552 \times \widetilde{t}_{21} + .0788 \times \widetilde{t}_{22} + .2707 \times \widetilde{t}_{31} \\
&\quad + .0445 \times \widetilde{t}_{32} + .2628 \times \widetilde{t}_{41} + .0276 \times \widetilde{t}_{42}
\end{aligned}$$

We may note that the rank one components are highly correlated to the first PLS components $\widetilde{t}_{11}, \widetilde{t}_{21}, \widetilde{t}_{31}$ and $\widetilde{t}_{41}$.

To obtain the rank two components it is now useful to use equation (4) which here becomes:

$$[t_{j1}, t_{j2}] = [\tilde{t}_{j1}, \tilde{t}_{j2}] \begin{bmatrix} \cos\theta_j & \sin\theta_j \\ -\sin\theta_j & \cos\theta j \end{bmatrix} \tag{5}$$

as

$$A_j = \begin{bmatrix} \cos\theta_j & \sin\theta_j \\ -\sin\theta_j & \cos\theta j \end{bmatrix} \tag{6}$$

is the orthogonal rotation matrix in the plan with an angle θ_j. For each of the new components $t_{11}, \ldots, t_{41}$ it can be checked that the squares of the coefficients of the PLS components $\tilde{t}_{j1}, \tilde{t}_{j2}$ sum up to one. It is then easy to get the rank two components:

$$\begin{aligned} t_{12} &= -.0176 \times \widetilde{t}_{11} + .9998 \times \widetilde{t}_{12} \\ t_{22} &= -.2950 \times \widetilde{t}_{21} + .9558 \times \widetilde{t}_{22} \\ t_{32} &= -.1619 \times \widetilde{t}_{31} + .9869 \times \widetilde{t}_{32} \\ t_{42} &= -.1042 \times \widetilde{t}_{41} + .9747 \times \widetilde{t}_{42} \end{aligned}$$

However, to get the external latent variable t_{52} for the super-block we need to apply the complete algorithm. We first regress each block $\tilde{T}_j = \left\{\tilde{t}_{j1},\ \tilde{t}_{j2}\right\}$ on t_{j1}. Then the path model used for rank one components is used on the standardized residual tables $\tilde{T}_{j1} = \{\tilde{t}_{j11},\ \tilde{t}_{j21}\}$. The results are given in Figure 4.

	Smell at rest	View	Smell after shaking	Tasting	Global
Smell at rest	1				
View	.407	1			
Smell after shaking	.803	.398	1		
Tasting	.822	.145	.780	1	
Global	.928	.394	.950	.906	1

Table 4: Correlations between the rank two latent variables.

It is more clear to express the rank two component in term of the original standardized variables. We then get the previous expressions for $t_{12}, \ldots, t_{42}$ and the following one for t_{52}:

$$\begin{aligned} t_{52} \quad = \quad & -.005 \times \widetilde{t}_{11} + .288 \times \widetilde{t}_{12} + .014 \times \widetilde{t}_{21} - .045 \times \widetilde{t}_{22} - .078 \times \widetilde{t}_{31} \\ & +.463 \times \widetilde{t}_{32} - .029 \times \widetilde{t}_{41} + .295 \times \widetilde{t}_{42} \end{aligned}$$

In Table 4 we give the correlations between the rank two components. The sensory components of rank one and two are uncorrelated by construction. The global components are also practically uncorrelated (r = -.000008).

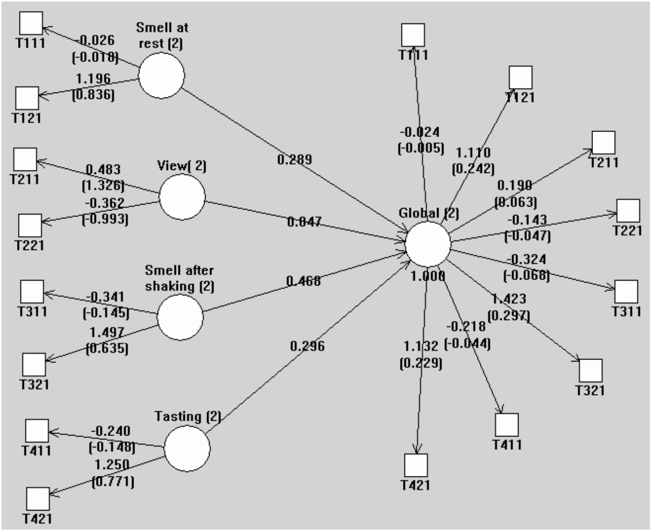

Figure 4: Path model for the second rank components in term of residuals.

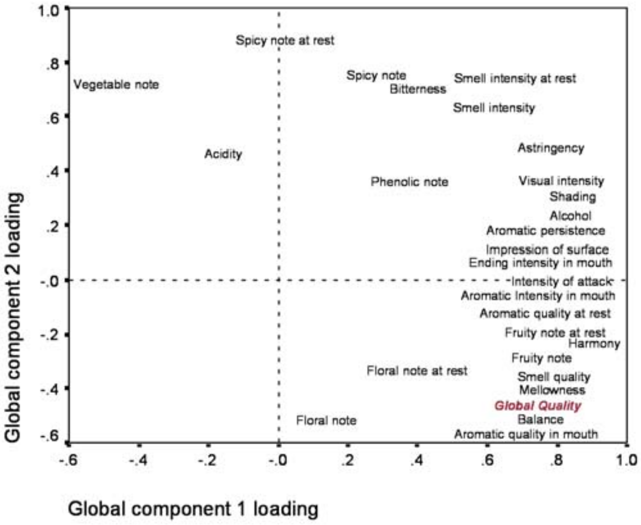

Figure 5: Variable loadings with the global components.

5 Discussion

PLS-MTA comes to carry out a kind of principal component analysis on each block and on the super-block such that the components of same rank are as positively correlated as possible. So, for each dimension h, the interpretations

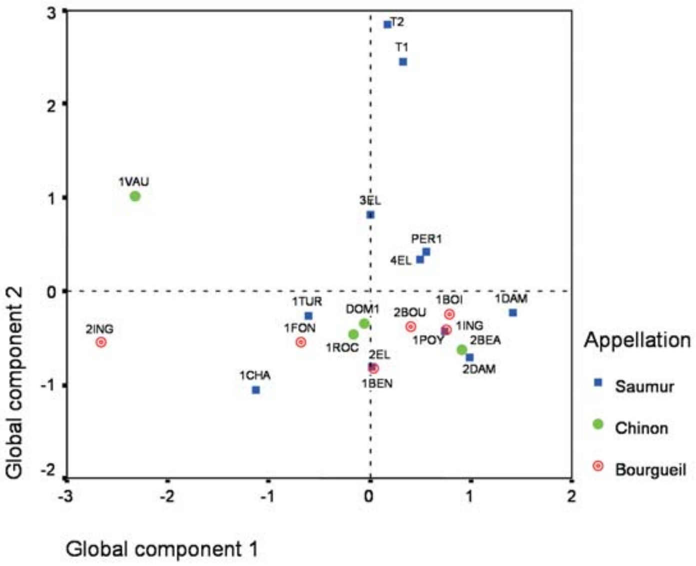

Figure 6: Wine visualization in the global component space.

of various block components t_{hj}, $j = 1, \ldots, J+1$ can be related. In Figure 5 the "Smell at rest", "View", "Smell after shaking" and "Tasting" loadings with the global components are displayed. It makes sense as the correlations of the variables with the block components and the global components are rather close. The global quality judgement on the wines has also been displayed as an illustrative variable. In Figure 6 the wines are also displayed using the global components. The best wines are located in the south-eastern quadrant.

1001 GRAPHICS

Martin Theus

Key words: Statistical graphics, defaults, rendering, interaction.

COMPSTAT 2004 section: Data visualisation.

Abstract: Statistical graphics, or in more modern terms, data visualization, is not a new discipline. Whereas in the early days the construction of a graph was technically not easy and usually even required some artistic capabilities, generating statistical graphs is very easy in today's statistical software packages. This obviously leads to a less careful construction of these plots. In an object oriented software package like R we can call the generic function `plot` with almost any arbitrary object as argument, and some plot method will render this object, whether it makes sense or not.

This paper investigates how well chosen plot defaults and rendering techniques can guarantee much better results in a graphical data analysis. Furthermore, standard plots and examples of plot ensembles are presented which are suitable for analyzing variables of a specific structure.

1 Introduction

Everybody knows the phrase "A picture can be worth a 1000 words". Advocates of statistical graphical methods and data visualization sometimes use this phrase to support their position. Whereas everyone knows that there are many examples which prove that they are right, there is a far greater number of examples (although less quoted) which prove the opposite. All positive examples are usually very well thought out. E.g. Minard's visualization of Napoleon's march on Moscow is a very popular example for the power of a good visualization. The power of Minard's graph lies in the well chosen combination of spatial plotting of time series information, not to mention several artistic and aesthetic considerations, which are not that obvious at a first glance. This brings us back to the phrase "A picture is worth a 1000 words", which only holds true if the picture is really well chosen. Today, where the next statistical graphics is only one keystroke or mouse-click away, we tend to produce many graphs which would probably need more than a 1000 words to be interpreted.

In the next Section of this paper we will investigate the influence of the right choice of plot defaults on the quality, i.e. the interpretability and usability, of a graph. This should make us more alert to default plot settings, which are often inappropriate for the solution sought initially. The final section of the paper goes beyond single graphs, and shows strategies for analyzing multivariate data with ensembles of standard statistical graphs.

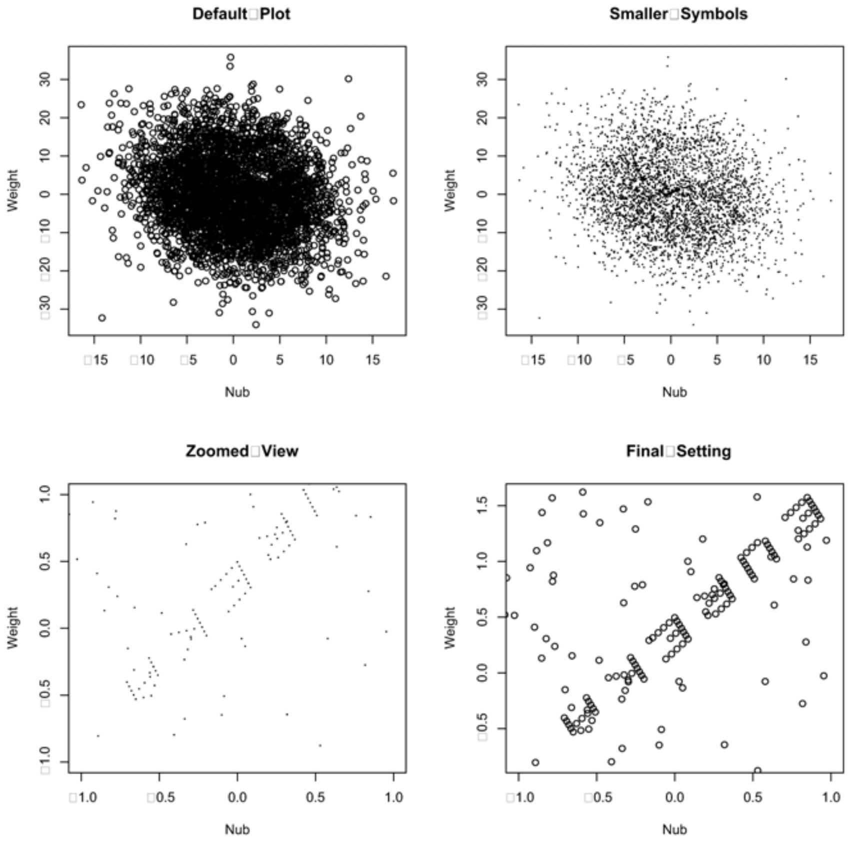

Figure 1: The pollen data plotted in R.

2 On plot defaults

2.1 The scatterplot — less can be more

A scatterplot of two quantitative variables is probably the most elementary and fundamental plot in statistics. At a first glance there do not seem to be many degrees of freedom to choose parameters to improve a scatterplot. Reviewing Cleveland [1] and [2] the only thing we can do with scatterplots is to change scales and plot symbols. Obviously Cleveland's work was written at times where pen plotter and amber CRTs were the latest technology. Furthermore, datasets with more than just a few hundred observations were very uncommon. Today's problems often look much different. A couple of thousand points are often regarded as rather small, but would have used up a whole ink cartridge of a pen plotter 25 years ago. This calls for new, advanced rendering strategies.

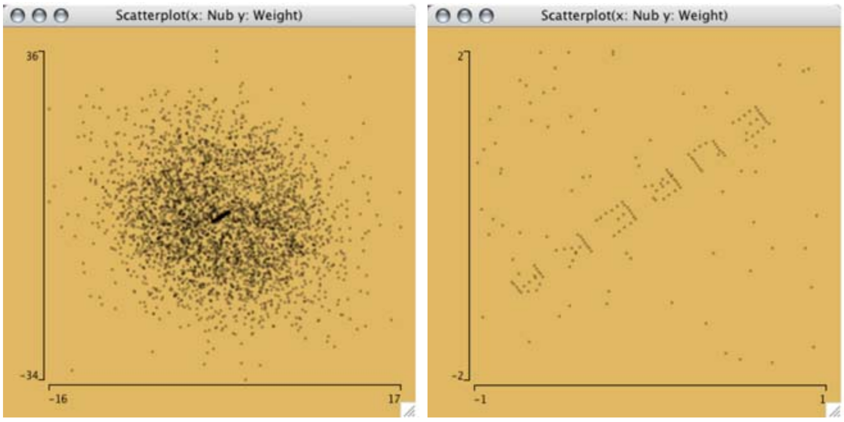

Figure 2: The pollen data plotted in Mondrian.

Figure 1 shows an example where the default plot symbol is unsuitable to find the interestring structure in a dataset. The dataset is the so called "pollen" data from the 1985 ASA data competition, and consists of a 5-dim. normal distribution with the word "EUREKA" added to the center of the data. The upper left plot shows the data plotted with the default setting of the R `plot` function. The '`o`' which is used as the default plot symbol is only suitable for small datasets with less than 100 points. The upper right plot shows the same data now plotted with '`.`' as plot symbol and reveals — by squeezing your eyes — the unusually high density in the center of the plot. The plots in the lower row show how we isolate the feature by zooming in. The corresponding R-code is:

```
> names(pollen)
[1] "Ridge"   "Nub"     "Crack"   "Weight"  "Density" "Number"
> attach(pollen)
> par(mfrow=c(2,2))
> plot(Nub, Weight, main="Default Plot")
> plot(Nub, Weight, pch=".", main="Smaller Symbols")
> plot(Nub, Weight, pch=".", xlim=c(-1,1), ylim=c(-1,1),  ...
> plot(Nub, Weight, xlim=c(-1,1), ylim=c(-0.8,1.6), ...
```

Figure 2 shows the same data plotted in Mondrian [6]. The default scatterplot in Mondrian uses $\alpha-$transparency to cope with overplotting. $\alpha-$transparency allows us to use suitably sized points in a scatterplot, without losing the information about density in the scatterplot. The amount of transparency gets bigger with the number of points to plot. In Figure 2 the unusual feature is immediately visible without the need to optimize plot parameters. More information on how to plot scatterplots can be found in Cook et al. [3].

2.2 The histogram — yet another optimal representation?

The histogram is probably number two in the list of most often used statistical graphs. There exist dozens of rules (cf. D. Scott [5]), which number of bins is the "best" under which circumstances. "Best" usually means, that the sum of the squared differenceS between the true density and the estimation via the histogram is minimized with some variance constraint.

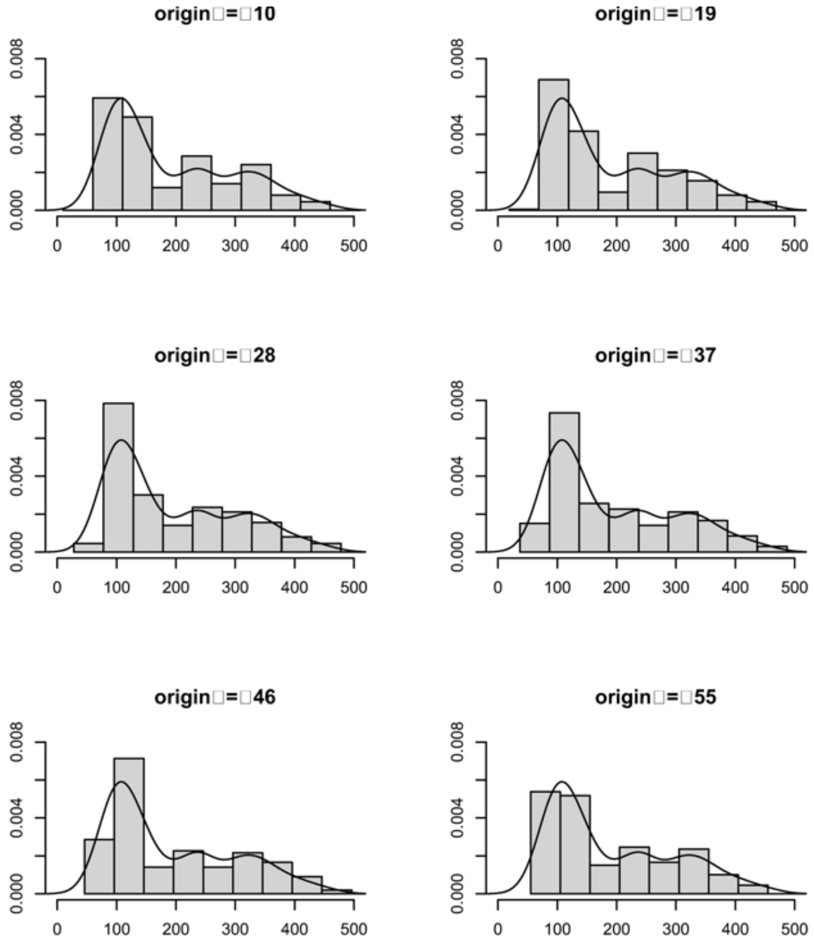

Figure 3: 6 histograms with superposed density estimatorS for the variable "displacement" of the "mpg-auto" dataset from the UCI ML repository. The number of bins has been determined according to "Sturges Rule".

In cases where the data comes from a single generating process following a continuous, only mildly skewed random variable, these rules will deliver sufficiently nice results[1]. The more critical situation arises, when the data is a mixture of several generating processes from both continuous and discrete random variables. In these situations, we have to cope with gaps, discrete patterns and accumulation points. Unfortunately real data usually comes from the latter kind of process.

Figure 3 shows an example of six histograms for the variable "displacement" of the "mpg-auto" dataset from the UCI Machine Learning Repository with origins at 10, 19, 28, 37, 46 and 55. The number of bins has been determined according to "Sturges Rule". The bin width has been "beautified" to 50 within the R `hist` function. Obviously non of the six origins gives us a satisfying estimation of the underlying density, nor does the kernel density estimator. The explanation is not too hard to find. Most cars in the dataset have only a very small displacement of 80 to 160. Bigger cars — all 6 cylinder engines in the dataset — form another mode at 220 to 260. Two discrete spikes can be found at 300 and 340, with some larger outliers, all corresponding to 8 cylinder engines.

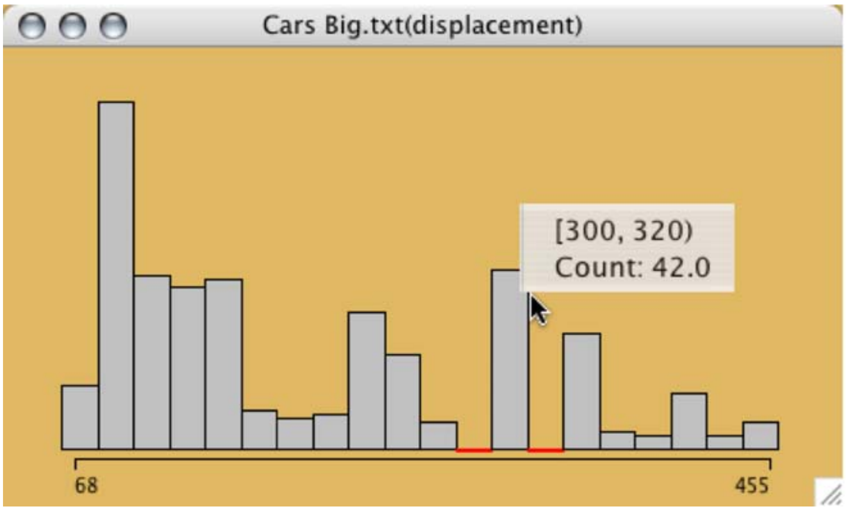

Figure 4: A histogram starting at 60 with bin wiDth 20, yielding 20 binS for the variable "displacement".

Figure 4 shows a histogram starting at 60 with bin width 20, yielding 20 bins for the variable "displacement", showing all of the above features. Finding a parameter setting revealing these features is easy in an interactive environment, but harder in a command line interface, where each new setting

[1] Although in these cases almost any origin and bin width will lead to almost optimal results.

must be retyped, until a satisfying setting is found. Finding explanations for the above described structural features can be done most conveniently within an interactive environment, which allows linked highlighting. This leads to the next section.

Plotting subgroups in histograms

It is common practice to color a subgroup in a histogram. Usually this should answer the question, whether this subgroup is any different from the whole population or not.

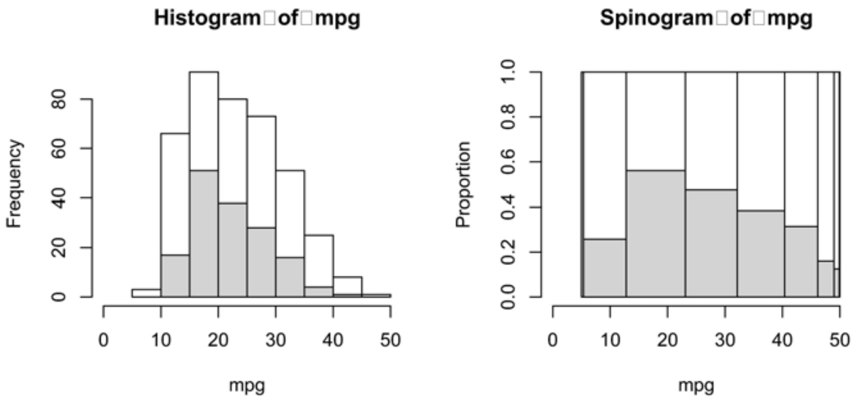

Figure 5: Left: A histogram for the variable “mpg” with model years 74–78 highlighted. Right: A Spinogram, showing the same data.

Figure 5 shows an example of this situation. The left histogram has all model years from 74 to 78 highlighted. At first glance we would expect that the selected subgroup has approximately the same distribution as the whole population. To verify this, we use a spinogram.

A spinogram is a histogram, where all bars have the same height. In order to keep the proportionality of the area of a bar and the number of cases in the bar, the width is adjusted, i.e. whereas in a histogram with equally spaced bins the height of a bar is proportional to the number of cases in this group, in a spinogram the width is proportional. Obviously the x-axis of a spinogram then is transformed to a no longer linear but still continuous scale. This puts more visual weight on areas with high density and less weight on areas with low density. The highlighting in a spinogram is still done from bottom to top. This allows the comparison of proportions of the highlighted cases across the whole range of the underlying variable. Whereas this comparison is easily possible, the comparison of proportions in highlighted histograms is almost impossible. This is due to the fact that our visual system is well able to compare positions along a common scale, but almost incapable of judging length or position in different scales (cf. Cleveland [1] 262pp). Coming back to the example in Figure 5 the spinogram reveals that the cars in the years 74 – 78 mostly have mpg-values close to the overall mean, i.e. the tails of the distribution of this group are less populated than in the rest of the sample.

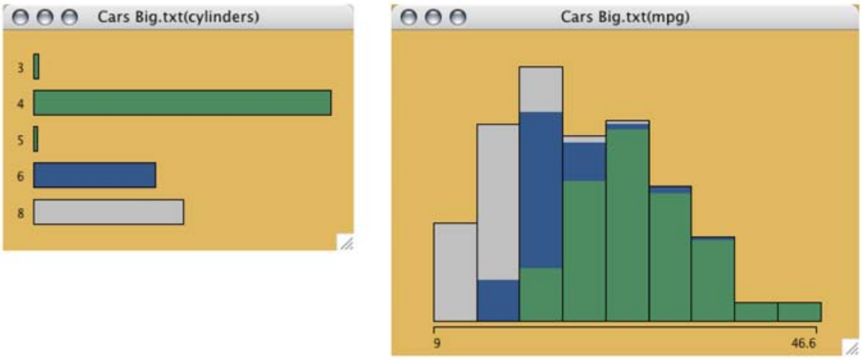

Figure 6: A histogram of the variable “mpg” colored according to the number of cylinders.

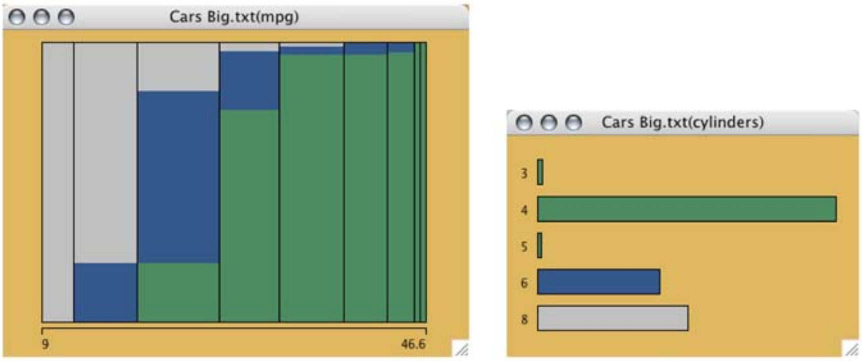

Figure 7: The same data as in Figure 6, now plotted as a spinogram.

Spinograms also allow you to look at the conditional distribution of more than one highlighted group. Figure 6 shows a histogram of “mpg” color brushed according to the number of cylinders of the engine (cars with 3-5 cylinders are joined in one group). Again, the histogram suffers from the differently scaled proportions and is hard to read. Figure 7 shows the corresponding spinogram, which makes the comparison across bars much easier. This kind of display is especially useful in classification problems, which need to assign more than two groups. With multiple groups, the stacking order of the groups in the spinogram becomes an important issue. A more comprehensive illustration of how to visualize conditional distributions can be found in Hofmann and Theus [4].

2.3 Mosaic plots — but which one?

Mosaic plots have been adopted more and more in the statistics community over the last 10 years. They form a very powerful framework to visualize multidimensional categorical data. Mosaic plots are especially good at visualizing associations between 2, 3, 4 or even 5 variables at a time. They are weaker for looking at only few variables, each having many categories.
Figure 8 shows a mosaic plot for the "mpg-auto" data for "Model year" and "Cylinder". Due to the strong variation in the variable "cylinders" over the different years, it is quite hard to read across the years while following a particular number of cylinders. The same problem arises when labeling the categories of the conditioned variable, i.e. "Cylinders". In Figure 8 an equidistant labelling was chosen, which does not fit any particular year, but should be a good estimate for all years. In this situation a fluctuation diagram, as shown in Figure 9, is much more appropriate to display the data. In a fluctuation diagram all cells get the same space assigned in a grid like layout.
The area which is filled by a tile within a cell is still proportional to the number of observations in this cell. Thus the only cell which is completely filled with a tile is the cell with the maximum cell count. The advantage of this kind of display is obvious. Using the grid like layout it it now easy to follow a particular category of a variable throughout the whole plot. Comparing Figures 8 and 9 we can see the structure in the data more clearly in the fluctuation diagram. The number of 4 cylinder cars is steadily growing over the 13 years, whereas the 8 cylinder cars seem to disappear in the early 80s. The number of 6 Cylinder cars is relatively stable over the years, whereas 3 and 5 cylinder cars are only found rarely.

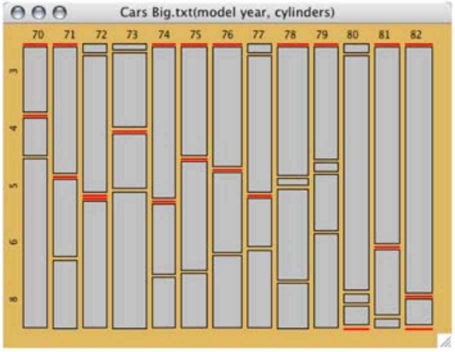

Figure 8: A mosaic plot for "Model year" and "Cylinder".

Besides fluctuation diagrams two other variations of the standard mosaic

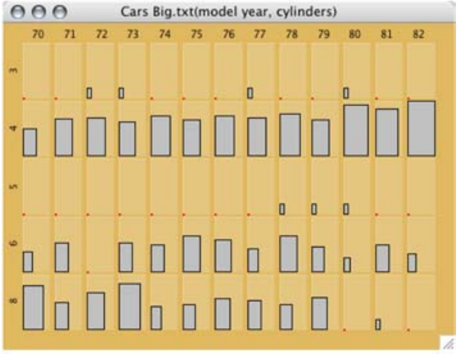

Figure 9: A fluctuation diagram for “Model year” and “Cylinder”.

plot have proven to be useful. In the *same bin size* display all tiles are of equal size, which is useful to detect empty cells in high dimensional datasets and the *multiple barchart* view which scales the size of the tiles along only one axis.

3 Plot ensembles

The last section gave some hints on how to choose the right plot parameters and/or plot types, in order to get meaningful plots. This helps to optimize a single plot or view.

In an exploratory data analysis process we often try to answer statistical questions with graphics. E.g. looking at the “mpg-auto” data we might be interested in the influence of the originating country or continent and the number of cylinders on the gas consumption of a car. This relationship between two categorical and one continuous variable can be investigated by using an ensemble of 4 linked plots.

The plot ensemble in Figure 10 features a barchart for cylinders and origin, a mosaic plot of the two variables and a boxplot of “mpg” conditioned on number of cylinders (alternatively we also could use a boxplot of “mpg” conditioned on the originating country). In this ensemble we see the interaction structure of the two influencing variables in the mosaic plot, as well as their marginal distribution in the two barcharts. The boxplot shows the distribution of “mpg” for each cylinder group and via highlighting we can investigate the interaction structure of the “origin” and “cylinders” on “mpg”. In Figure 10 the group of all Japanese cars has been highlighted.

The next example in Figure 11 shows how we can look at the temporal distribution of spam e-mails. In the barchart of the classification variable “spam” all spam e-mails have been selected. In the barchart for “Day of Week”, as well as the corresponding spineplot, we see the absolute and relative distribution of spam e-mails over the course of a week. Whereas the

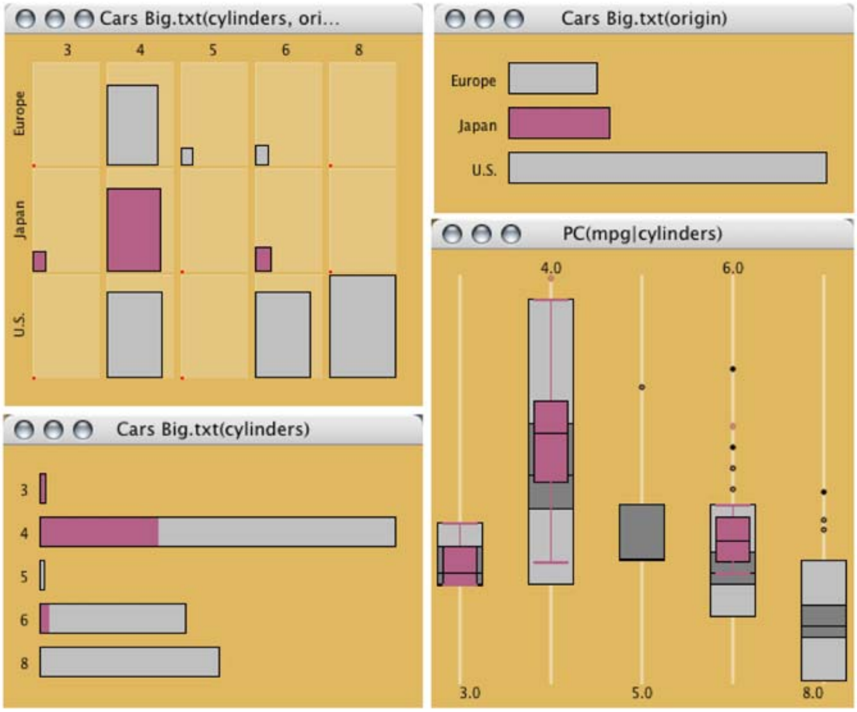

Figure 10: An ensemble of four plots to investigate the influence of country and cylinder on "mpg".

absolute amount of spam e-mails grows towards the middle of the week, the relative amount is highest at the weekends. In the histogram of "Time of Day" we see an almost constant amount of spam mails over the 24 hours of a day, whereas due to the small number of ordinary e-mails outside business hours, the proportion of spam is very high during the night.

The ensembles in Figure 10 and 11 are only two examples which show that a specific question in an exploratory data analysis can be answered with ensembles of (linked) plots. If statistical packages do not offer the whole suite of basic plots users can not plot data in the most suitable way. If for instance a package only offers point plots for quantitative data, these plots are used to try to visualize discrete data.

4 Conclusion

The rise of computers with graphical capabilities has lead to new graphical data analysis possibilities, but also caused an inflation in the use of statistical graphics. Only well designed graphics can be "worth a 1000 words".

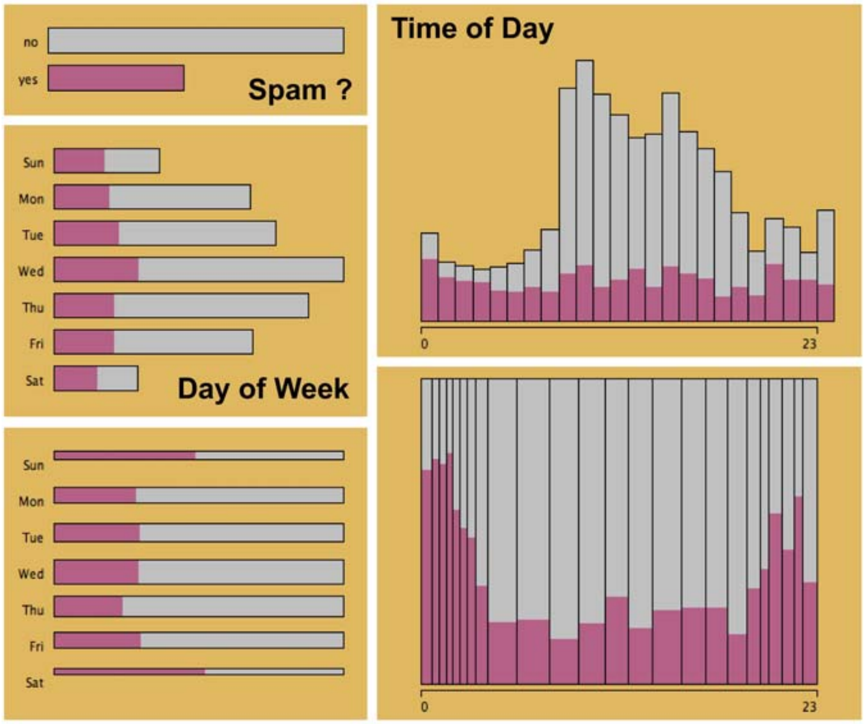

Figure 11: An ensemble of plots to investigate the temporal distribution of spam e-mails.

Many statistical software packages do not take care over default settings. This deficit can often be explained by the fact that the underlying code and graphical model is quite old, and was not adapted to modern data problems and rendering methods yet.

Using $\alpha-$channel transparency can help a lot when trying to avoid overplotting problems in scatterplots and parallel coordinate plots. The histogram as a means of density estimation is an example of a plot where “no default” is the only good default[2]. Spinograms are a good choice when trying to visualize a sub-population of a continuous variable. A histogram, which is often used instead, is not useful for this task. Mosaic plots are complemented by three variations to build a suite of plots, which can visualize multivariate discrete data. Where the one plot is good, the other one fails.

Generally, for a comprehensive graphical data exploration, we need a wide range of plots, which can be applied exactly for the purpose they serve best. No craftsman would enter a construction site with a toolbox consisting of just a single type of tool.

[2] In a recent talk an expert an Support Vector Machines (SVM) noted that he would suggest that all implementations of SVMs should always force the user to explicitly specify parameters, since there is nothing such as a default parameter setting which would generally yield acceptable results

Figure 12: Statistical graphics code information on data in an abstract form. A successful decoding by a human is only possible, if the abstraction is suitable for the kind of data coded.

Figure 12 illustrates the process of coding information in a statistical graph. Given some data we code — and often condense — the information about this data via a computer based procedure into an abstract representation. The crucial part is the decoding process by the human observer. A successful decoding by a human is only possible, if the abstraction is suitable for the kind of data coded.

Additionally we must keep in mind that the human visual system has many limitations as basically described in Cleveland's [1] overview in the context of graph reading. His investigations have been limited to the state of statistical graphics in the early 80s. Today's rendering techniques offer new possibilities and challenges.

COMPSTAT'2004 Symposium

FITTING BRADLEY TERRY MODELS USING A MULTIPLICATIVE ALGORITHM

Ben Torsney

Key words: Bradley Terry model, discrete data, factorial structure, general equivalence theorem, maximum likelihood estimation, multiplicative algorithm, optimal design theory, paired comparisons.

COMPSTAT 2004 section: Design of experiments.

Abstract: We consider the problem of estimating the parameters of a Bradley Terry Model by the method of maximum likelihood, given data from a paired comparisons experiment. The parameters of a basic model can be taken to be weights which are positive and sum to one. Hence they correspond to design weights and optimality theorems and numerical techniques developed in the optimal design arena can be transported to this estimation problem. Furthermore extensions of the basic model to allow for a factorial structure in the treatments leads to an optimisation problem with respect to several sets of weights or distributions. We can extend techniques to this case. In section 1 we introduce the notion of paired comparisons experiments and the Bradley Terry Model. In section 2 the parameter estimation problem is outlined with optimality results and a general class of multiplicative algorithms outlined in sections 3 and 4 respectively. A specific algorithm is applied to the Bradley Terry log-likelihood in section 5 and treatments with a factorial structure are considered in section 6. Finally in section 7 extensions to triple comparisons and to extended rankings are briefly outlined.

1 Paired comparisions

1.1 Introduction

We consider paired comparison experiments in which J treatments or products are compared in pairs. In a simple form a subject is presented with two treatments and asked to indicate which he/she prefers or considers better. In reality the subject will be an expert tester; for example, a food taster in examples arising in food technology. The link with optimal design theory (apart from the fact that a specialised design, paired comparisons, is under consideration) is that, the parameters of one model, Bradley Terry model, for the resultant data are like weights. Hence the theory characterising and the methods developed for finding optimal design weights can be applied to characterising and finding the maximum likelihood estimators of these Bradley Terry weights.

1.2 The data

In a simple experiment a set of such testers is available and each is presented with one pair from a set of J treatments, say $T_1, T_2, \ldots, T_J$. The number of comparisons, n_{ij} of T_i to T_j, we assume has been predetermined. Sufficient summary data comprises the set $\{O_{ij} : i = 1, 2, \ldots, J;\ i = 1, 2, \ldots, J;\ i < j$ or $i > j\}$, where O_{ij} is the observed frequency with which T_i is preferred to T_j. Of course $O_{ij} + O_{ji} = n_{ij}$.

1.3 Models

1.3.1 A general model In the absence of other information the most general model here is to propose:

$$O_{ij} \sim B_i(n_{ij}, \theta_{ij}) \tag{1}$$

where

$$\theta_{ij} = P(T_i \texttt{ is prefered to } T_j)$$

Apart from the constraint $O_{ij} + O_{ji} = n_{ij}$, independence between frequencies is to be recommended. So apart from the constraint $\theta_{ij} + \theta ji = 1$, these define unrelated binomial parameters. The maximum likelihood estimator of θ_{ij} is O_{ij}/n_{ij} (the proportion of times T_i is preferred to T_j in these n_{ij} comparisons), and formal inferences can be based on the asymptotic properties of these.

1.3.2 Bradley Terry Model This is a more restricted model in that it imposes interrelations between the θ_{ij}. It proposes that:

$$\theta_{ij} = \frac{p_i}{p_i + p_j} \tag{2}$$

where $p_1, p_2, \ldots, p_J$ are positive parameters. See [1].
These can be viewed as indices or quality characteristics, one for each treatment. These are only unique up to a constant multiple, since θ_{ij} is invariant to proportional changes in p_i and p_j. A constraint needs to be imposed for uniqueness. One possibility is:

$$\sum p_i = 1$$

This implies $0 < p_i < 1$. We return to this later.

1.3.3 Motivation for Bradley Terry Model However we can show that θ_{ij} is uniquely determined by a latent difference. Let $p_i = \exp(\lambda_i)$. Then:

$$\theta_{ij} = \frac{\exp(\delta_{ij})}{1 + \exp(\delta_{ij})} \tag{3}$$

where $\delta_{ij} = \lambda_i - \lambda_j$.

Thus θ_{ij} is uniquely determined by the difference in the transformed quality characteristics λ_i, λ_j, while it is invariant to shifts in their values.
Further $\theta_{ij} = F(\delta_{ij})$, where $F(\delta)$ is the logistic distribution function. If we assume that the difference in quality, between the two treatments, has a logistic distribution, then θ_{ij} is the probability of a difference of at most δ_{ij}; or the difference in quality is given by:

$$\delta_{ij} = F^{-1}(\theta_{ij}) = F^{-1}\{p_i/(p_i + p_j)\}$$

See [6]. Other choices of $F(.)$ can lead to alternative models with parameters similar to $p_1, p_2, \ldots, p_J$.

2 Parameter estimation

In terms of the original parameters the likelihood of the data is a product of binomial likelihoods, namely:

$$L = \prod\prod_{r<s} (\theta_{rs})^{O_{rs}} (\theta_{sr})^{O_{sr}} \tag{4}$$

Let $p = (p_1, p_2, \ldots, p_J)$ and , for convenience, let $O_{ii} = 0$, $i = 1, 2, \ldots, J$, and $O_{i.} = \sum_j O_{ij}$.
Then the likelihood of the data under the Bradley Terry model is given by making the substitutions $\theta_{rs} = p_r/(p_r+p_s)$, $\theta_{sr} = p_s/(p_r+p_s)$, $,O_{rs}+O_{sr} = n_{rs}$, to yield:

$$L(p) = \left\{\prod_i (p_i)^{O_{i.}}\right\} \left\{\prod\prod_{r<s} (p_r + p_s)^{(-n_{rs})}\right\} \tag{5}$$

We wish to choose p $(p > 0)$ to maximise $L(p)$. Since θ_{ij} is invariant to proportional changes in the p_i's, so is $L(p)$. In fact $L(p)$ is a homogeneous function of degree zero in p; i.e. $L(cp) = L(p)$, where c is a scalar constant. It is constant on rays running out from the origin. It will therefore be maximised all along one specific ray. We can identify this ray by finding a particular optimising p^*. This we can do by imposing a constraint on p. Possible constraints are $\sum p_i = 1$ or $\prod p_i = 1$, or $g(p) = 1$ where $g(p)$ is a surface which cuts each ray exactly once. In the case $J = 2$ a suitable $g(p)$ is defined by $p_2 = h(p_1)$, where $h(.)$ is a decreasing function which cuts the two main axes, as in the case of $h(p_1) = 1 - p_1$, or has these as asymptotes, as in the case of $h(p_1) = 1/p_1$. In general a suitable choice of $g(p)$ is one which is positive and homogeneous of some degree h. Note that other alternatives are $\sum p_i = C$ or $\prod p_i = C$, where C is any positive constant; e.g. $C = J$.

The choice of $\prod p_i = 1$, being equivalent to $\sum \ln(p_i) = 0$, confers on $\alpha_i = \ln(p_i)$ the notion of a main effect. We will opt for the choice of $\sum p_i = 1$, which conveys the notion of p_i as a weight. We wish to maximise the likelihood or log-likelihood subject to this constraint and to non-negativity too. This is an example of the following general problem:

Problem (P):
Maximise $\phi(p)$ subject to $p_i \geq 0$, $\sum p_i = 1$.

We wish to maximise $\phi(p)$ with respect to a probability distribution.
Here we will take $\phi(p) = \ln\{L(p)\}$.

There are many examples of this problem arising in various areas of statistics, especially in the area of optimal regression design. We can exploit optimality results and algorithms developed in this area. The feasible region is an open but bounded set. Thus there should always be a solution to this problem allowing for the possibility of an unbounded maximum, multiple solutions and solutions at vertices (*i.e.* $p_t = 1$, $p_i = 0$, $i \neq t$).

3 Optimality conditions

We can define optimality conditions in terms of the point to point directional derivative defined by Whittle [19]. The directional derivative of $F_\phi(p,q)$ of a criterion $\phi(.)$ at p in the direction of q is the limit as $\epsilon \downarrow 0$ of:

$$[\phi\{(1-\epsilon)p + \epsilon q\} - \phi(p)]/\epsilon$$

i.e.

$$F_\phi(p,q) = dg/d\epsilon \mid \epsilon = 0^+$$

where $g(\epsilon) = \phi\{(1-\epsilon)p + \epsilon q\}$.

This derivative exists even if $\phi(.)$ is not differentiable; but if $\phi(.)$ is differentiable then:

$$F_\phi(p,q) = (q-p)^T d$$

where $d = \partial\phi/\partial p$.

Let $F_i = F_\phi(p, e_j)$, where e_j is the j^{th} unit vector in $\Re^J$. Then:

$$F_j = d_j - p^T d = d_j - \sum p_i d_i, \text{ where } d_j = \partial\phi/\partial p_j.$$

We call F_j the j^{th} vertex directional derivative of $\phi(.)$ at p. Note that $\sum p_j F_j = 0$, so that, in general some F_j are negative and some are positive.

If $\phi(.)$ is differentiable at p^*, then a necessary condition for $\phi(p^*)$ to be a local maximum of $\phi(.)$ in the feasible region of Problem (P) is:

$$F_j^* = F_\phi\{p^*, e_j\} = 0 \texttt{ for } p_j^* > 0,$$

$$F_j^* = F_\phi\{p^*, e_j\} \leq 0 \texttt{ for } p_j^* = 0,$$

If $\phi(.)$ is concave on its feasible region, then these first order stationarity conditions are both necessary and sufficient. This is the general equivalence theorem in optimal design. See [19], [5].

It is clear that all p_j^* must be positive in the case of the Bradley Terry likelihood, so that the second condition is redundant.

4 Algorithms

4.1 A multiplicative algorithm

Problem (P) has a distinct set of constraints, namely the variables $p_1, p_2, \ldots,$ p_J must be nonnegative and sum to 1. An iteration which neatly submits to these and has some suitable properties is the multiplicative algorithm:

$$p_j^{(r+1)} = \frac{p_j^{(r)} f(d_j^{r)})}{\sum p_i^{(r)} f(d_i^{(r)})} \tag{6}$$

where $d_j^{(r)} = \partial\phi/\partial p_j \mid p = p^{(r)}$ while $f(d)$ is positive and strictly increasing in d and may depend on one or more free parameters.

This type of iteration was first proposed by [13], taking $f(d) = d^\delta$, with $\delta > 0$. This, of course, requires positive derivatives. Subsequent empirical studies include Silvey et al [11], which is a study of the choice of δ when $f(d) = d^\delta$, $\delta > 0$; Torsney [15], which mainly considers $f(d) = e^{\delta d}$ in a variety of applications, for which one criterion $\phi(.)$ could have negative derivatives; Torsney and Alahmadi [16] who consider other choices of $f(.)$; Torsney and Mandal [18] who consider objective choices of $f(.)$; and [8] who explore developments of the algorithm based on a clustering approach in the context of a continuous design space. Torsney and Mandal [17] and Mandal et al [9] also apply these algorithms to the construction of constrained optimal designs.

Titterington [12] describes a proof of monotonicity of $f(d) = d^\delta$ in the case of D-optimality. Torsney [14] explores monotonicity of particular values for δ for particular $\phi(p)$. Torsney [14] also establishes a sufficient condition for monotonicity of $f(d) = d^\delta$, $\delta = 1/(t+1)$, when the criterion $\phi(p)$ is homogenous of degree $-t, t > 0$ with positive derivatives and proves this condition to be true in the case of linear design criteria such as the c-optimal and the A-optimal criteria, for which $t = 1$, so that $\delta = 1/2$. In other cases the value $\delta = 1$ can be shown to yield an EM algorithm, which is known to be monotonic and convergent; see [13]. Beyond this there are minimal results on convergence, although this will depend on the choice of $f(.)$ and of parameters like δ. See [11] for some empirical results. In principal the choice of $f(.)$ is arbitrary but objective bases for choices are addressed in the formal properties now listed.

4.2 Properties of the algorithm

Under the conditions imposed on $f(.)$, the above iterations possess the following properties which are considered in more detail in [15], [16] and [7]:

1. $p^{(r)}$ is always feasible.
2. $F_\phi\{p^{(r)}, p^{(r+1)}\} \geq 0$, with equality when the d_j's corresponding to nonzero p_j's have a common value d $(= \sum p_i d_i)$, in which case $p^{(r)} = p^{(r+1)}$.

3. An iterate $p^{(r)}$ is a fixed point of the iteration if the derivatives $d_j^{(r)}$ corresponding to nonzero $p_j^{(r)}$ are all equal; equivalently if the corresponding vertex directional derivatives $F_j^{(r)}$ are zero. Thus a solution to Problem (P) is a fixed point of the iteration. So also are solutions subject to setting a given subset of weights to zero; see [15].
4. We mentioned that $f(.)$ may depend on one or more free parameters. Torsney and Alahmadi [16] explore methods for choosing a single positive parameter δ for various given choices of $f(.)$. Torsney and Mandal [18] explore methods for choosing $f(.)$, which can accommodate negative partial derivatives or for which (positive) partial derivatives can be replaced by vertex directional derivatives. A further paper is in preparation on choosing $f(.)$ when the criteria has positive derivatives.

5 Fitting Bradley Terry Models

Our criteria is:

$$\phi(p) = \ln\{L(p)\} = \sum_i O_{i.} \ln(p_i) - \sum\sum_{r<s} n_{rs} \ln(p_r + p_s) \tag{7}$$

Since $L(p)$ is a homogeneous function of degree zero $\sum p_i d_i = 0$. In fact $d_j = F_j$. So there are always positive and negative d_j unless all are zero. We require a function $f(d)$ which is defined for positive and negative d, where we take d to represent a partial derivative. Noting that all p_j^* must be positive a suitable choice of $f(.)$ should be governed by the fact that at the optimum $d_j^* = 0,\ j = 1, 2, \ldots, J$.

This suggests that suitable function is one that is 'centred' on zero and changes reasonably quickly about $d = 0$. It should also be desirable to treat positive and negative derivatives symmetrically. Torsney and Mandal [18] start from a function $h(x)$ defined on $\Re$, such that $h(x) > 0,\ h'(x) > 0,\ h(0) = 1$. They propose:

$$f(x) = \begin{cases} h(x) & : \ x < 0 \\ 2 - h(-x) & : \ x > 0 \end{cases}$$

i.e.

$$f(x) = (1 + s) - sh(-sx), \quad s = sign(x)$$

Clearly $f(x)$ is increasing, while for $y > 0$, $(y,\ f(y))$ and $(-y,\ f(-y))$ are reflections of each other in the point $(0, 1) = (0, f(0))$; i.e. $f(-y) = [2-f(y)]$. Equivalently $f'(y)$ is symmetric about zero. Note that $0 < f(x) < 2$, so that $f(x)$ is bounded; also $f(0) = 1$.

Torsney and Mandal [18] consider various choices of $h(x)$, including $h(x) = 2H(\delta x)$, where δ is a positive parameter and $H(.)$ is a cumulative distribution function such that $H(0) = 1/2$. Here we opt for $H(.) = \Phi(.)$, so that iterations prove to be:

$$p_j^{(r+1)} = \frac{p_j^{(r)}\Phi(\delta d_j^{r)})}{\sum p_i^{(r)}\Phi(\delta d_i^{(r)})}$$

Example: We use this algorithm in two examples.

Example 1:
In this case $J = 8$ coffee types were compared through 26 pairwise comparisons on each pair, yielding a total of N = 728 observations; i.e. $\sum\sum O_{ij} = 728$. A suitable δ is $\delta = 1/N$. In effect we are standardising through replacing observed by relative frequencies in the log-likelihood, and then taking $\delta = 1$. Starting from $p_j^{(0)} = 1/J$, the numbers of iterations needed to achieve $\max|d_j| = \max|F_j| \leq 10^{-n}$, $n = 0, 1, \ldots, 7$ respectively are 17, 21, 25, 32, 38, 45, 51, 59. The optimal p^* is: (0.190257, 0.122731, 0.155456, 0.106993, 0.091339, 0.149406, 0.080953, 0.102865). Iterations were monotonic.

Example 2:
In this example $J = 9$ quality of life dimensions were compared in pairs by each of 50 patients with early signs of rheumatoid arthritis (RA). The 9 dimensions were: ability to physically function, pain, stiffness, ability to work, fatigue, depression, interference with social activities, side effects, and financial burden. This data arose from the Consortium of Practicing Rheumatologists long-term observational multi-center study of early severe RA. Patients entered in this additive cohort had less than 1 year of symptom onset. The responses were obtained at their first telephone interview. Formed in 1992, the Consortium prospectively followed them to delineate early outcome and factors, such as treatment, functional, radiographic, psychosocial, and economic outcomes. Data on disease severity, functional status, psychosocial health, cost, radiographic damage, laboratory serologies and acute phase reactants were recorded at Baseline and at 6 months, 1 year, and annually thereafter. As a chronic illness, RA impacts every dimension of quality of life. Even among RA patients, however, differences in life situations, clinical presentation, and disease course can be striking, leading to varying patient rankings of the importance of difference disease and life factors. The 9 factors were selected to represent aspects of RA that patients could easily identify and compare.

There were a total of $N = 1800$ comparisons; i.e. $\sum\sum O_{ij} = 1800$. In 8 cases there were ties. These were split 50:50 between the relevant treatments. Again a suitable δ is $\delta = 1/N$. Starting from $p_j^{(0)} = 1/J$, the numbers of iterations needed to achieve $\max|d_j| = \max|F_j| \leq 10^{-n}$, $n = 0, 1, \ldots, 6$ respectively are 28, 42, 56, 69, 84, 96, 110. The optimal p^* is: (0.265361, 0.172154, 0.151644, 0.059151, 0.123506, 0.030753, 0.037740, 0.055038, 0.104653), the order of the components corresponding to the order of the dimensions as listed above. Iterations were monotonic.

There is a further issue here. These 1800 responses have been obtained from only 50 patients. Each patient has responded on each pairwise comparison. We have assumed independence between the resulting 36 observations. Dittrich et al [3] also contemplate this 'independent decisions' model, an independence which allows for inconsistent responses by a patient. However they extend it to a 'dependent decisions' model. For an individual patient's comparison of T_i and T_j let $Y_{ij} = 1$ if he/she records that T_i is preferred to T_j and $Y_{ij} = 0$ otherwise. In the case of three dimensions their model is:

$$P(y_{12}, y_{13}, y_{23}) =$$

$$C\{[(\sqrt{(p_1/p_2)})^{y_{12}}(\sqrt{(p_1/p_3)})^{y_{13}}(\sqrt{(p_2/p_3)})^{y_{23}}][(\omega_1^{y_{12}y_{13}})(\omega_2^{y_{12}y_{23}})(\omega_3^{y_{13}y_{23}})]\}$$

where C is a normalising constant.

All parameters must be positive. A constraint is still needed on the p_j as above, but none are needed on the ω_j. However we could transform to $q_j = \omega_j/(\omega_1 + \omega_2 + \omega_3)$, so that $(q1 + q2 + q3) = 1$, while $\alpha = (\omega_1 + \omega_2 + \omega_3)$ is a free positive parameter, which could be treated like the variable q arising in models allowing for ties discussed in section 7 below. The above class of algorithm could then be used to find the optimal values of both the p_i's and q_j's. This would need the individual responses on each pair of dimensions from each respondent.

If $\omega_1 = \omega_2 = \omega_3 = 1$, we recover the independence model.

Furthermore extensions of Bradley Terry models are available when respondents record consistent rankings; see below. However there is scope for extending this work.

6 Treatments with a factorial structure

In Example 1 the 8 coffees comprised the 8 combinations arising from 2 brew strengths, 2 roast colours, and 2 brands. Simpler versions of the Bradley Terry Model have been proposed in terms of definitions of main effects and possibly low order interactions. We consider main effects only for the moment in the case of 3 factors.

Suppose that we have $J = KLM$ treatments arising from the KLM factor level combinations of 3 factors, denoted by α, β, γ with K, L and M levels respectively. We have treatments T_{klm}, $k = 1, \ldots, K$; $l = 1, \ldots, L$; $m = 1, \ldots, M$, with associated Bradley Terry parameters p_{klm} , such that T_{klm} is preferred to T_{qrs} with probability $\{p_{klm}/(p_{klm} + p_{qrs})\}$. This is allowing for main effects and interactions of all orders.

A main effects or additive model corresponds to:

$$p_{klm} = \alpha_k \beta_l \gamma_m$$

i.e.

$$\ln(p_{klm}) = \ln(\alpha_k) + \ln(\beta_l) + \ln(\gamma_m)$$

where $\alpha_k,\ \beta_l,\ \gamma_m\ >\ 0$.

The likelihood is again a homogeneous function of degree zero in each of the three sets of main effect parameters. Constraints need to be imposed on each of them. Various choices can be considered as above with appropriate extensions of the above algorithm. If we opt for the constraints

$$\sum \alpha_k = \sum \beta_l = \sum \gamma_m = 1$$

we wish to maximise the log-likelihood with respect to several distributions. At the optimum all partial derivative should be zero. (Note that alternatives could be $\sum \alpha_k = K,\ \sum \beta_l = L,\ \sum \gamma_m = M$).

A suitable set of iterations are:

$$\alpha_k^{(r+1)} = \frac{\alpha_k^{(r)} f_\alpha(d_k^\alpha)}{\sum \alpha_t^{(r)} f_\alpha(d_t^{(\alpha)})}$$

$$\beta_l^{(r+1)} = \frac{\beta_l^{(r)} f_\beta(d_l^\beta)}{\sum \beta_t^{(r)} f_\beta(d_t^{(\beta)})}$$

$$\gamma_m^{(r+1)} = \frac{\gamma_m^{(r)} f_\gamma(d_m^\gamma)}{\sum \gamma_t^{(r)} f_\gamma(d_t^{(\gamma)})}$$

where $f_\alpha(.),\ f_\beta(.),\ f_\gamma(.)$ are positive increasing functions and $d_k^{(\alpha)} = \partial\phi/\partial\alpha_k$ at $\alpha = \alpha^{(r)}$ etc.

This set of iterations enjoys the same properties as those for a single distribution, including $F_\phi(\lambda^{(r)}\ \lambda^{(r+1)}) \geq 0$, where $\lambda = (\alpha^T, \beta^T, \gamma^T)^T$. See [18]. In our example $K = L = M = 2$. Taking $\delta = 1/N, f_\theta(d^{(\theta)}) = \Phi(\delta d^{(\theta)})$ and $\theta_j^{(0)} = 1/2, j = 1, 2,$ for $\theta = \alpha, \beta, \gamma,$ representing brew strength, roast colour and coffee brand respectively, the numbers of iterations needed to achieve $\max|d_j^{(\theta)}| = \max|F_j^{(\theta)}| \leq 10^{-n}$, for $n = 0, 1, \ldots, 7$ respectively are 7, 12,15,19, 23,27, 31, 36. Optimal values are: $\alpha^* = (0.574904, 0.425096)$, $\beta^* = (0.551050, 0.448950)$, $\gamma^* = (0.504887, 0.495113)$;
and the optimal p^*: is (0.159949, 0.156852, 0.130313, 0.127790, 0.118269, 0.115980, 0.096356, 0.094491).
Iterations were monotonic.

Notes:

1. Other variations of the above iterations are possible. One is to cycle through the three sets of main effect parameters running the iterations for each one in turn, while keeping the others fixed.
2. Obviously the approach is extendable to any number of factors.

3. There are extensions of the Bradley Terry model which allow for interactions and the above iterations can be extended to these too. For example a model including an interaction between brew strength and roast colour corresponds to:

   $$p_{klm} = \alpha_k \beta_l \gamma_m (\alpha\beta)_{kl}$$

   i.e.

   $$\ln(p_{klm}) = \ln(\alpha_k) + \ln(\beta_l) + \ln(\gamma_m) + \ln((\alpha\beta)_{kl})$$

   where $(\alpha\beta)_{kl} > 0$.
   The likelihood is now additionally homogenous in two sets of respects; namely, it is invariant to proportional changes in the terms $(\alpha\beta)_{kl}$ when the constant of proportionality either varies with α or with β. Several sets of consistent constraints are needed. One possibility is the set

   $$\sum(\alpha\beta)_{kl} = K,\ l = 1, 2, \ldots, L;\ \sum(\alpha\beta)_{kl} = L,\ k = 1, 2, \ldots, K$$

   or sums could be replaced by products.

   Further development of our class of iterations is needed. For each α and each β the $(\alpha\beta)_{kl}$ in effect define a set of probability distributions except that the probabilities are scaled to add to a constant differing from 1. One option would be to alternate between iterations (appropriately modified to satisfy these re-scaling constraints) for each set. An alternative derives from Linear Programming Theory. The non-negativity and equality constraints imply that the set $\{(\alpha\beta)_{kl} : k = 1, 2, \ldots, K;\ l = 1, 2, \ldots, L\}$ belongs to a bounded convex polyhedron whose vertices are Basic Feasible Solutions. The convex weights defining the $(\alpha\beta)_{kl}$ defines one distribution. An extra set of equations for updating these can be added to the sets for main effects.

7 Extensions of the Bradley Terry Model

There are extensions of the basic Bradley Terry Model which can be fitted using the above methods. These include:
(a) Models allowing a 'no-preference' option. Two possibilities are:
(i)

$P(T_i \texttt{ is preferred to } T_j) = p_i/(p_i + p_j + p_0)$

$P(T_j \texttt{ is preferred to } T_i) = p_j/(p_i + p_j + p_0)$

$P(\texttt{No preference}) = p_0/(p_i + p_j + p_0)$

One extra parameter has been introduced p_0 which must be positive and these probabilities and hence the likelihood are homogenous of degree zero in $p_0, p_1, \ldots, p_J$. Finding maximum likelihood estimates of these defines another example of Problem (P).

(ii) Rao and Kupper [10] proposed :

$P(T_i$ `is preferred to` $T_j) = p_i/(p_i + qp_j)$

$P(T_j$ `is preferred to` $T_i) = p_j/(p_j + qp_i)$

where $q > 1$.
This model has a latent logistic distribution motivation since $P(T_i$ `is preferred to` $T_j) = F(\lambda_i - \lambda_j - \tau),\ \tau \geq 0$, where $F(.)$ is the logistic distribution function and $p_i = \exp(\lambda_i),\ q = \exp(\tau)$.

(iii) Davidson [2] proposed:

$P(T_i$ `is preferred to` $T_j) = p_i/(p_i + p_j + q(p_i p_j)^{1/2})$

$P(T_j$ `is preferred to` $T_i) = p_j/(p_i + p_j + q(p_i p_j)^{1/2})$

$P($`No preference`$) = q(p_i p_j)^{1/2}/(p_i + p_j + q(p_i p_j)^{1/2})$.

where $q > 1$.

Each of (ii) and (iii) lead to likelihoods which are homogenous of degree zero in the p_i's. Also note that $\{A/(A + qB)\} = \{r_1 A/(r_1 A + r_2 B)\}$, where $r_1 = q^{-1/2}$ and $r_2 = 1/r_1$. This is homogenous of degree zero in r_1 and r_2. Hence we could impose the constraint $r_1 + r_2 = 1$. However $r_1 \geq r_2$. A further transformation is $s_1 = r_1 - r_2,\ s_2 = 2r_2$. Now constraints are $s_1, s_2 > 0,\ s_1 + s_2 = 1$. We can now maximise the likelihood with respect to two distributions using our family of algorithms. To determine q we need to re-scale to $r_1 r_2 = 1$.

Henery [4] replaces q in (ii) by $q_{ij} = q_i * q_j$ with $q_i * q_j \geq 1$. The latter condition implies that at most one q_i can be less than 1, (the minimum in fact). If none satisfy this condition then the above transformation could be applied to each q_i, leading to an optimisation of the likelihood with respect to $(J+1)$ distributions. If the minimum was known to be less than 1, and it's subscript i were known too, then an appropriate variation of the approach takes $r_{1i} = (1/q_i)^{1/2}$, where r_{1i} is the value of r_1 for this particular q_i.

Kuk [6] considers applications to the outcome of football matches and extends the model to include two sets of the parameters $\{p_i\}$ and two sets of the parameters $\{q_j\}$, one each for 'home' and 'away' games. The likelihood is homogenous of degree zero in the two sets of p_i's as a whole and in three sets of variables which are based on transformations of the q_j's similar to that defining r_1 and r_2 above. Thus we wish to maximise the likelihood with respect to four distributions.

(b) Triple Comparisons.
An extension of pairwise comparisons is to invite subjects to place three treatments in order of preference . Let:

$$\theta_{ijk} = P(T_i \texttt{ is preferred to } T_j \texttt{ and } T_j \texttt{ is preferred to } T_k)$$

Various possible extensions of the Bradley Terry Model include:

$\theta ijk = p_i p_j / \{(p_i + p_j + p_k)(p_j + p_k)\}$;

$\theta_{ijk} = (p_i)^2 p_j / D,$

where $D = (p_i)^2 p_j + (p_j)^2 p_i + (p_i)^2 p_k + (p_k)^2 p_i + (p_j)^2 p_k + (p_k)^2 p_j$

(c) Extended Rankings.
The latter model extends to rankings of more than three treatments, while both models define likelihoods which are homogenous of degree zero in $p_1, p_2, \ldots, p_J$, each of which must be positive. Maximum likelihood estimation of these is equivalent to another example of Problem (P). Equally if the treatments have a factorial structure, the likelihood can be expressed as a function of several distributions and optimised with respect to these using the algorithms described.

8 Discussion

The primary focus of this paper is one of cross fertilisation, an arguably somewhat limited even simple minded one. It is to point out that a class of maximum likelihood estimation problems could be attacked using tools for solving optimal design problems because in each case one or several sets of optimising weights or distributions are sought. Hence the equivalence theorems characterising optimality in the optimal design arena and related algorithms can be transported over to the parameter estimation arena. This is one new contribution of this work. One other is using a new version of the above mentioned algorithms, one which can accomodate negative derivatives.

COMPSTAT'2004 Symposium

MODELLING MULTIPLE TIME SERIES: ACHIEVING THE AIMS

Granville Tunnicliffe-Wilson and Alex Morton

Key words: Cross-spectral analysis, extended autoregression, prediction, transfer functions.

COMPSTAT 2004 section: Time series analysis.

Abstract: We review the traditional aims and methodology of multiple time series modelling, and present some recent developments in the models available to achieve these aims, in the context of both regularly and irregularly sampled data. These models are analogues of the vector autoregressive process, based on the generalised shift, or Laguerre, operator. They form a subclass of vector autoregressive moving-average processes; they retain many of the attractive features of the standard vector AR model, but have an added dimension of flexibility, that leads to improvements in predictive ability.

1 Reviewing the objectives and methodology

The aims of time series analysis are revealed in the titles of some of the early books on the subject. *The Extrapolation, Interpolation and Smoothing of Stationary Time Series with Engineering Applications*, by Wiener [19], has a comprehensive title, but *Prediction and Regulation* by Whittle [18], and *Time Series analysis, Forecasting and Control* by Box and Jenkins [5] make more explicit the application to control, which was undoubtedly one of Wiener's objectives. The objectives are also clearly stated in the title of *Statistical analysis and Control of Dynamic Systems* by Akaike and Nakagawa [2], the original publication of which, in Japanese, took place in 1972.

The time series model may itself be the immediate objective of the modelling, as in predator-prey systems and a host of other scientific applications, where an understanding of the mechanisms of interaction between time series variables is required. However, prediction is an encompassing objective. The model is generally identified by its predictive capacity, whatever the aim of the application. Smoothing, or more generally signal extraction, depends on the structure identified by the predictive model. Control applications rely on the ability to predict an output series from an input series.

Methodology developed in the early years is still widely used. Spectral analysis has tended to give way to time domain methods, particularly in econometric forecasting. There is, however, one context, that of modelling causal (or one-sided) dependency, in which cross-spectral analysis, is currently an under-used tool. It is generally very efficient, both statistically and in terms of the time and effort required to obtain useful results. Early books which presented this methodology, such as Jenkins and Watts [10], are now, fortunately, supplemented by some recent, well received texts. These cover the use of spectral analysis for identifying the transfer function coefficients ν_k, by which a dependent series y_t is related to lagged values of the explanatory series x_t:

$$y_t = \nu_0 x_t + \nu_1 x_{t-1} + \nu_2 x_{t-2} + \cdots + n_t. \tag{1}$$

Although cross-spectral analysis is based on frequency domain regression, its results can be expressed as estimates, over an appropriate lag window, of the transfer function coefficients. We illustrate this with a simple example, partly to encourage the re-introduction of such methods, but also to demonstrate, in part, why the subject moved away from them.

Figure 1(a) shows temperatures measured every minute by sensors in the cab and trailer of a transport vehicle. It is clear that the cab temperature lags the trailer temperature. Figure 1(b) shows the transfer function coefficients in this relationship, as estimated by cross spectral analysis. The estimates were produced almost automatically, with little user intervention. Limits on the plot show that significant values are spread over lags 0 to 4, with a peak at lag 2. This represents a one-sided, or causal, relationship, that may be used to predict the cab temperature from the trailer temperature as shown in Figure 2(a).

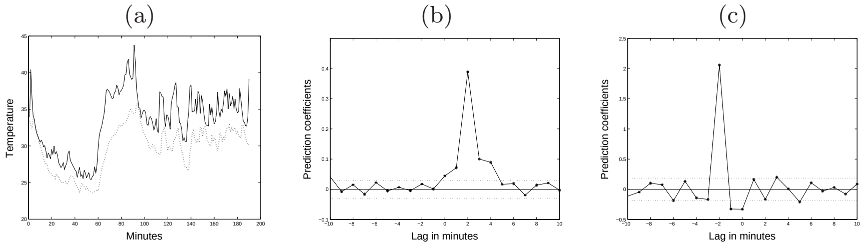

Figure 1: (a) Graphs of temperatures inside a transport vehicle trailer (solid line) and in the cab (dotted line), (b) lagged prediction coefficients obtained by cross-spectral analysis, for predicting cab temperature from trailer temperature, and (c) for predicting trailer temperature from cab temperature.

However, the desired aim was to predict trailer temperatures from the sensor in the cab. Figure 1(c) shows the estimated transfer function coefficients when the roles of the series are reversed. The significant values are spread over lags 0 to -2. The relationship is no longer causal and these coefficients cannot be used for prediction. But reasonable linear predictions of the trailer temperature from the cab temperature can still be constructed, as shown in Figure 2(b).

In general, cross-spectral estimation of prediction coefficients is limited to one-sided or causal relationships. It can, therefore, be used successfully to estimate input-output relationships in open loop systems, but the estimates are distorted when applied to input-output data gathered under closed loop, feedback control, conditions. A solution to this problem was presented by

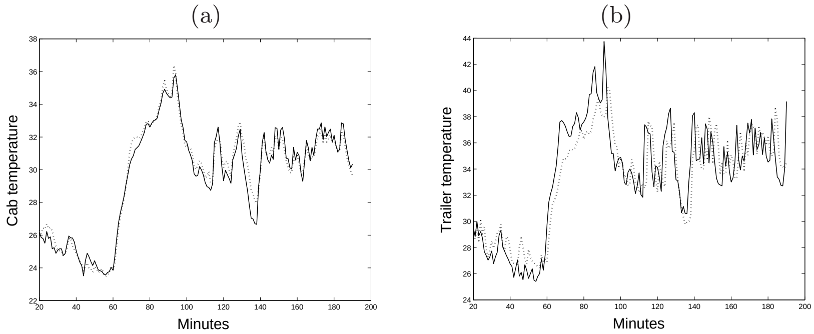

Figure 2: Predictions of transport vehicle temperatures: (a) The cab temperatures (solid line) with values predicted (dotted line) from the trailer temperatures, (b) the trailer temperatures (solid line) with values predicted (dotted line) from the cab temperatures.

Akaike and Nakagawa in the industrial context of designing a cement kiln controller. It was based on multivariate autoregressive modelling of the records of plant variables. The identified model could also be used directly in plant control by expressing it in state space form. The predictions in Figure 2(b) were obtained in this way.

From that point on, time domain methods, and, particularly in the multivariate context, empirical autoregressive modelling, have dominated the methodology for time series analysis. However, the spectacular success in the univariate context, of autoregressive moving-average (ARMA) models and their extensions to integrated and seasonal processes, has not carried over to the multivariate context. Despite the fact that multivariate ARMA models were formulated many years ago [15], and much effort has been been put into procedures for their identification, see for example Tiao and Tsay [16], there are very few examples of real applications compared with those of the multivariate (pure) autoregressive model. More successful has been the state space identification of multivariate time series models, see for example Aoki [3], in which the states are selected to form a basis of the multivariate time series prediction space. Although these state models have a multivariate ARMA representation, this is not required for their application to prediction and control.

In the econometric literature, the multivariate (or vector) autoregressive model is still dominant. Structural forms have been used to incorporate economic constraints, and Bayesian formulations to incorporate prior beliefs, as in Doan, Litterman and Sims [7]. The use of the concept of co-integration to characterise and test for persistence in the relationships between multivariate series, has depended very much on vector autoregressions to account for any residual autocorrelation in the error correction model. The reason for this dominance must be, in large part, the simplicity of the multivariate autoregressive model, and its convenience for order selection, estimation and theoretical analysis. It also has the potential, by choice of a sufficiently high order, to approximate closely any linear process.

The question is therefore, whether the multivariate autoregressive model does provide, essentially, for all our requirements in the world of linear multiple time series modelling. In asking this we will leave aside the problem of seasonality, and restrict the question to non-seasonal series, because seasonality can often be removed or modelled separately. The answer, we believe, is yes in many cases. But there are important reasons why, in practice, the multivariate autoregressive model is *not* fully adequate. The fact that ARMA models are used for univariate series suggests that pure autoregressive models may be less than adequate. The reason may simply be parsimony. The autoregressive approximation may require rather more coefficients than an ARMA model, to achieve the same predictive accuracy. If a criterion such as AIC [1] is used to select the order automatically, then the penalty on the number of parameters may compromise this predictive accuracy, particularly at high lead times, when the series length is small.

The number of coefficients in a multivariate autoregressive model will generally be much greater, for a given order (maximum lag) of model, than for a univariate model. The loss of predictive ability that results from the requirement to choose a relatively low order model may therefore be much more important. The class of models we describe in the next two sections provides one possible, and simple, way to mitigate this loss of predictive ability, without foregoing most of the attractive features of the standard multivariate autoregression.

2 A basis for prediction

In both the discrete and the continuous case, the same idea underlies the models that we formulate in the next section. A chosen, finite, number p of weighted functions of the present and past values of the process will be used as linear predictors of future values. We will call these the *ZAR states* in the discrete case, and *CZAR states* in the discrete case. For continuous time series the models are expressed in terms of a continuous record of the process, but they are also very useful in applications to irregularly sampled data, or, in the case of multiple time series, when different series are recorded regularly but at different sampling rates. In these contexts, the state space form of the model is integrated to determine the state transition from the time of each observation to the next.

A discrete model, very closely related to the univariate form of the discrete model which we describe, was presented by Wahlberg and Hannan [17]. A continuous model, exactly equivalent to the univariate form of the continuous model which we describe, was presented by Belcher, Hampton and Tunnicliffe Wilson [4].

In the case of a discrete process x_t, $t = \ldots, 1, 2, 3, \ldots$, the ZAR states

$x_{t,k}$, at time t, are defined for orders $k = 0, 1, \ldots, p-1$, by

$$x_{t,k} = W^k x_t \tag{2}$$

where the operator W is known as the generalised shift operator, and is defined in terms of the backward shift operator B and a specified smoothing coefficient, or discount factor, θ, by

$$W = \frac{B-\theta}{1-\theta B} = -\theta + (1-\theta^2)(B + \theta B^2 + \theta^2 B^3 + \ldots). \tag{3}$$

In practice W is applied by the recursive calculations,

$$x_{t,k+1} = x_{t-1,k} - \theta x_{t,k} + \theta x_{t-1,k+1}, \tag{4}$$

taking $x_{t,0} = x_t$. The choice of θ is in the range $0 \leq \theta < 1$, and in the case $\theta = 0$, the state $x_{t,k}$ reduces to the lagged value x_{t-k}.

For the continuous time process $x(t)$, the CZAR states $x_k(t)$, at time t, are defined, for order $k = 0, 1, \ldots p-1$, by

$$x_k(t) = Z^k x(t) \tag{5}$$

where the operator Z is defined formally in terms of the Laplace (or differential) operator s, and a decay rate constant κ in the range $\kappa > 0$, by

$$Z = \frac{1 - s/\kappa}{1 + s/\kappa} = \frac{\kappa - s}{\kappa + s}. \tag{6}$$

There is, however, no requirement of differentiability placed upon a series to which this operator is applied, because it is well defined as

$$Zx(t) = -x(t) + 2\kappa \int_{\tau=0}^{\infty} \exp(-\kappa\tau) x(t-\tau) d\tau, \tag{7}$$

for any second order stationary process $x(t)$.

The operators are equally well defined when x_t or $x(t)$ is a vector process of dimension m, though we note that a set of mp scalar functions of the present and past is then defined.

Figure 3 shows the weight functions applied to present and past values for the orders $k = 1, \ldots, 5$ for the discrete operator, taking $\theta = 0.5$, and orders $k = 1$, 3 and 5 for the continuous case, taking, without loss of generality, $\kappa = 1$.

In each case, if we were to let $p \to \infty$, we would obtain a basis for the present and past values of the series (taking time t as the present). The idea is that if we are to limit the number p, of linear functions of the present and past, that we use for predicting the future, then the states defined above give us greater flexibility in the discrete case, than the simple choice of lagged values x_t, x_{t-1}, $\ldots x_{t-p+1}$. The effective range of past values that are weighted

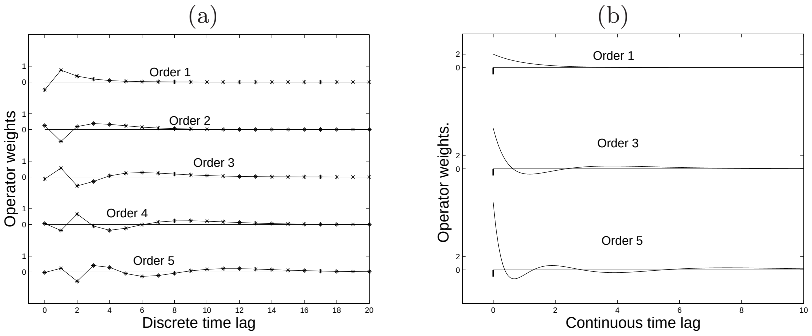

Figure 3: (a) Discrete weights for the first 5 orders of the ZAR operator, (b) continuous weights for orders 1, 3 and 5 of the CZAR operator.

into the predictors is approximately $p(1+\theta)/(1-\theta)$, rather than p. In the continuous case the effective range is approximately $2p/\kappa$.

There is no guarantee that, for a given discrete process, the choice of $\theta > 0$ will define better predictors. However, consider a continuous process $x(\tau)$, that is sampled at times $\tau = \delta t$, to give the discrete process x_t. Defining the ZAR states of x_t by setting $\theta = 1 - \kappa\delta$, these will converge, appropriately, to the CZAR states of $x(\tau)$, as $\delta \to 0$. The consequence of using the simple lagged states x_{t-k}, regardless of how small δ might become, would lead in the limit to states that were equivalent to $x(\tau)$ *and its derivatives to order* $p-1$. There is in general no guarantee that these would exist. That is why the pure autoregressive model in continuous time, that uses these derivatives as its states, *is unable to approximate* an arbitrary continuous time stationary process, though the order is increased indefinitely.

For this reason, the advantage of the CZAR model, proposed in the next section, over the standard continuous time autoregressive (CAR) model is undeniable, in terms of empirical approximation. The success of the univariate application of the CZAR model lead us to consider the discrete ZAR form. The foregoing argument suggests that whenever a discrete process might be considered to be a sampled continuous process, the discrete ZAR model should be preferred to the standard AR model, for its approximation.

The weight functions that we use to define the ZAR and CZAR states are closely related to the respective discrete and continuous Laguerre functions, which have the possible advantage of providing orthogonal bases of the past and present. Partington [14] describes a variety of similar weight functions that could be used to define a basis of the past observations of a discrete process. Bray [6] uses a basis that differs from the Laguerre functions, but may be orthogonalised to provide a similar basis.

Our use of the operator Z was developed from the application of the Cayley-Hamilton transformation to reparameterisation of continuous time models by Belcher et al. [4]. This transformation has been widely used to map from continuous time to discrete time systems. Most famously, Wiener [19] solved the prediction problem for continuous time series by transforming it to that of prediction for a discrete parameter process. The exposition by Doob [8, p. 582] sets this out clearly. The operator W may be motivated as the discrete analogue of Z, in which the Möebius transformation of the unit disk to itself replaces the Cayley-Hamilton transformation.

3 Extended autoregressive models

We propose models for zero mean stationary processes based on the previously introduced concepts. These are readily extended by the addition of a constant term or other fixed regressors, to processes with non-zero mean. In the following, θ and κ are taken to be pre-specified coefficients, with α_i and φ_i model parameters. The ZAR(p, θ) model for a discrete vector process x_t, that is implied by the use at time $t-1$ of the linear predictors defined by (2), is

$$x_t = \alpha_1 x_{t-1} + \alpha_2 x_{t-1,1} + \cdots + \alpha_p x_{t-1,p-1} + e_t, \tag{8}$$

where e_t is white noise with variance σ_e^2. When this model is true, e_t is the linear innovation in x_t. This is the most convenient form for many purposes, such as model estimation and prediction, and we call it the *predictive form*, but we also present an algebraically equivalent form of this model, which we term the *natural form*, as follows:

$$x_t = \varphi_1 x_{t,1} + \varphi_2 x_{t,2} + \cdots + \varphi_p x_{t,p} + n_t, \tag{9}$$

where n_t follow the AR(1) model:

$$n_t = \theta n_{t-1} + \varepsilon(t), \tag{10}$$

$\varepsilon(t)$ being white noise with variance σ_ε^2. We also write (9) as

$$\varphi(W) x_t = \left(1 - \varphi_1 W - \varphi_2 W^2 - \cdots - \varphi_p W^p\right) x_t = n_t. \tag{11}$$

We describe (9) as the natural form of the model because the process defined, for any fixed t, by

$$y_k = W^{-k} x_t, \tag{12}$$

is also a stationary process, and 9) is just a *standard* autoregressive approximation of y_k.

We also note that (9) is equivalent to an ARMA$(p, p-1)$ model with a pre-specified moving average operator $(1 - \theta B)^{p-1}$. The model presented by Wahlberg and Hannan [17], and the model of Morton and Tunnicliffe Wilson [12], are very similar, except that they have ARMA(p, p) representations.

The CZAR(p, κ) model for a continuous vector process $x(t)$ is analogous. The predictive form of model is

$$dx(t) = [\alpha_1 x(t) + \alpha_2 x_1(t) + \cdots + \alpha_p x_{p-1}(t)]\, dt + dB(t), \tag{13}$$

when $B(t)$ is Brownian motion with diffusion variance σ_b^2. The natural, algebraically equivalent, form of this model is

$$x(t) = \varphi_1 x_1(t) + \varphi_2 x_2(t) + \cdots + \varphi_p x_p(t) + n(t), \tag{14}$$

where $n(t)$ now follows the continuous time AR(1) model, or CAR(1) model:

$$dn(t) = -\kappa n(t)dt + dH(t), \tag{15}$$

where $H(t)$ is Brownian motion with variance σ_h^2. We also write (14) as

$$\varphi(Z)x(t) = \left(1 - \varphi_1 Z - \varphi_2 Z^2 - \cdots - \varphi_p Z^p\right) x(t) = n(t). \tag{16}$$

We describe (14) as the natural form of the model because the process defined, for any fixed t, by

$$y_k = Z^{-k} x(t), \tag{17}$$

is also a stationary process, and (14) is just a *standard* autoregressive approximation of y_k. We note that (14) is equivalent to a CARMA$(p, p-1)$ model with moving average operator $(\kappa + s)^{p-1}$.

4 Examples

Our first example illustrates the effect on predictions of using a discrete trivariate ZAR model for the three series of monthly flour prices that were modelled by Tiao and Tsay [16].

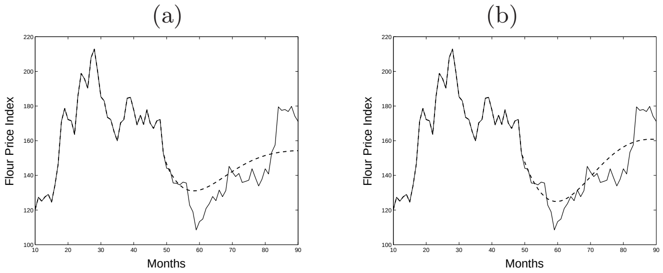

Figure 4: Predictions of monthly flour prices at Buffalo, using past values of three series of flour prices, at Buffalo, Minneapolis and Kansas City: (a) predictions (dotted line) from a standard AR(2) model, (b) predictions from a ZAR(2, 0.5) model.

In Figure 4 we see forecasts of just one of the three series, but made using two trivariate models. Using the AIC [1], a standard AR(2) model and a ZAR(2,0.5) model were selected. This example illustrates the fact that forecasts made using the ZAR model tend to show less damped behaviour. Although these are in-sample forecasts, and too much must not be read into one such example, the ZAR model forecasts tend to predict better the turning points of the irregular cyclical behaviour of the series.

The three flour price series were very similar in nature, and it is natural to represent them by a symmetric vector autoregression. Our second example is very different; the data arise from what is clearly an input-output system. The rainfall is measured at two locations in a river catchment, and the river-flow from the catchment is also measured. Figure 5 shows the hourly measurements over a period slightly in excess of four days. The river-flow record is much more slowly changing than the rainfall record and visual inspection shows that the response from input to output is spread over a period of several hours, possibly with a range of time constants reflecting some relatively rapid, and some relatively slow runoff. The objective is to use the rainfall record to predict the river flow. The transfer function of this response is difficult to estimate using spectral analysis because it is so dispersed over many lags. The use of the ZAR model is appropriate here because of this dispersed response. Using the AIC a standard AR(2) model was selected for the three series, whereas a ZAR(6, 0.75) was selected. The choice of 0.75 for the smoothing parameter is not critical, but was chosen because the low frequency delay in the W operator is about $1.75/0.25 = 7$ hours.

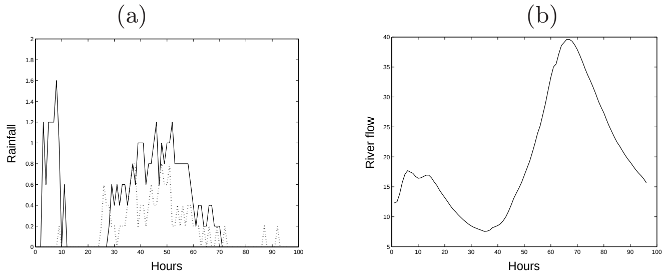

Figure 5: Hourly records of rainfall and river-flow in a single catchment: (a) the solid and broken lines show the rainfall at two gauges in the catchment, (b) the river flow .

A model of relatively low order can then capture a response covering a period of more than one day. In fact the AR(2) model gave very poor in-sample predictions, whereas the ZAR(6, 0.75) produced extremely good in-sample predictions. A fair comparison is illustrated using models of the same order, an AR(3) and a ZAR(3,0.75) model.

Figure 6(a) shows 'predictions' of the river flow from hour 20 using the fitted AR(3) model. The model parameters are estimated using the first 80 values of all three series. Given these parameters, the predictions of river-flow shown from hour 20 are constructed using the rain-fall series alone over that period. A state space representation is used with the Kalman filter to compute this. The peak river-flow is substantially under-predicted. Figure 6(b) shows the corresponding predictions using the ZAR(3,0.75) model.

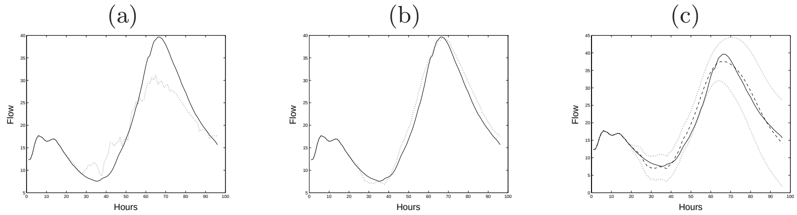

Figure 6: Predictions of the river flow (solid line) using different models and information: (a) the dotted line shows predictions using a trivariate AR(3) model, based on river flow information up to hour 20, and full knowledge of the rainfall throughout the record, (b) similar predictions using a trivariate ZAR(3,0.75) model, (c) predictions (broken line) are obtained as in (b), except that the known rainflow is used only up to hour 50, and thereafter all the series are predicted: the dotted lines show 90% probability limits for the forecasts.

These are very close to the actuality. Figure 6(c) is constructed using the same ZAR(3,0.75) model, but no observations of rainfall or river-flow are used beyond hour 50. The prediction limits are shown on this figure and rapidly widen beyond that hour, but they provide a realistic and useful bound on the peak river flow many hours later. The last 20 observations were not used in model estimation, so their predictions are genuinely out-of sample. In this example the ZAR model reveals its potential.

Our first example of the CZAR model relates to discrete time series with different, and varying, sampling intervals. Figure 7(a) shows monthly Claimant Count (CC) figures that have been long used as a measure of unemployment. A more recent measure of unemployment has been the Labour Force Survey (LFS) estimate, which is shown in the same figure. The LFS estimate was recorded annually, then quarterly. In the figure, the quarterly measurements have been interpolated monthly. These series were analysed by Harvey and Chung [9], in which one of the aims was to estimate the slope of the LFS series by using a bivariate model to 'borrow' information from the more frequently observed CC series. A continuous time model is natural for such series, and we estimated the bivariate CZAR(2,0.5) model. We report the use of this model for slope estimation, in Morton and Tunnicliffe Wilson [12]. Here, we illustrate its application to prediction. Figure 7(b) shows forecasts of the LFS unemployment and their error limits obtained from this model. The bivariate model enables good monthly forecasts to be produced, from a point where only 8 annual values have been recorded.

Our final example is a bivariate model of data which is truly sampled irregularly. Kirchner and Weil [11] present a compendium of marine fossil records which indicate the pattern of extinctions and originations of marine animals over the past 545 million years (Myrs). The records are arranged into 108 stratigraphic intervals which vary in length from 2.5 to 12.5 Myrs,

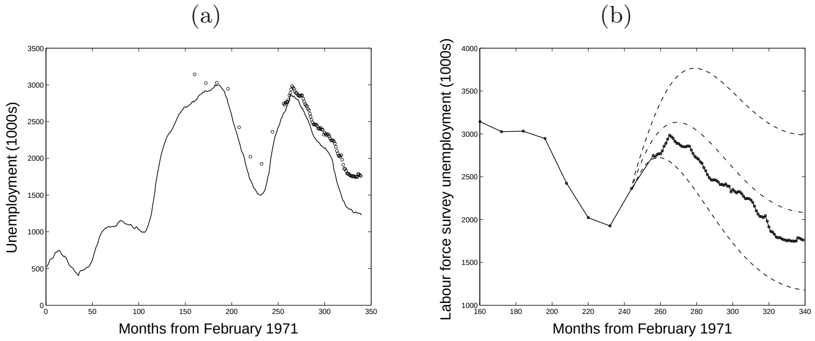

Figure 7: (a) The Claimant Count (solid line) unemployment series, and the Labour Force Survey (small circles) unemployment series, (b) the Labour Force Survey series (solid line) with forecasts and forecast error limits (broken lines) .

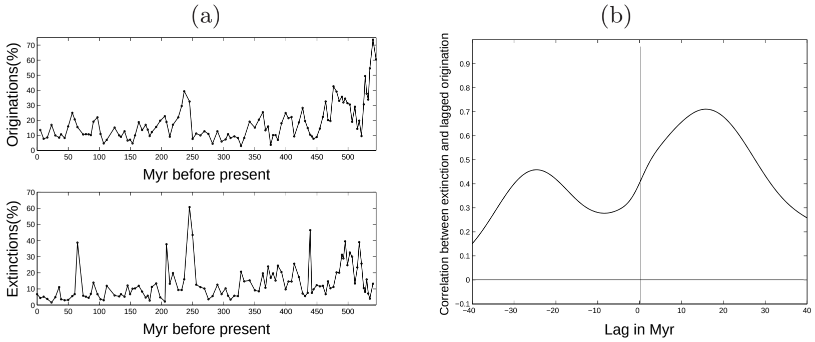

Figure 8: (a) The series of originations and extinctions of genera, (b) the estimated lagged cross-correlation function between these series .

and for each of these the number of families and genera of marine animals to appear and disappear is documented.

The objective is to investigate the relationship between the series, and in particular, the recovery of species following mass extinctions. Figure 8(a) shows the series of genera. We fitted a bivariate CZAR(5,0.5) model to the logarithms of these series. Figure 8(b) shows the cross-correlation function derived from this model. The peak is at the lag of 16 Myr, which is similar to that obtained by Kirchner and Weil using other methods.

TOTAL LEAST SQUARES AND ERRORS-IN-VARIABLES MODELING: BRIDGING THE GAP BETWEEN STATISTICS, COMPUTATIONAL MATHEMATICS AND ENGINEERING

Sabine Van Huffel

Key words: Total least squares, errors-in-variables, orthogonal regression, singular value decomposition, numerical algorithms.

COMPSTAT 2004 section: Numerical methods for statistics.

Abstract: The main purpose of this paper is to present an overview of the progress of a modeling technique which is known as Total Least Squares (TLS) in computational mathematics and engineering, and as Errors-In-Variables (EIV) modeling or orthogonal regression in the statistical community. The basic concepts of TLS and EIV modeling are presented. In particular, it is shown how the seemingly different linear algebraic approach of TLS, as studied in computational mathematics and applied in diverse engineering fields, is related to EIV regression, as studied in the field of statistics. Computational methods, as well as the main algebraic, sensitivity and statistical properties of the estimators, are discussed. Furthermore, generalizations of the basic concept of TLS and EIV modeling, such as structured TLS, Lp approximations, nonlinear and polynomial EIV, are introduced and applications of the technique in engineering are overviewed.

1 Introduction and problem formulation

The Total Least Squares (TLS) method is one of several linear parameter estimation techniques that has been devised to compensate for data errors. The basic motivation for TLS is the following: Let a set of multidimensional data points (vectors) be given. How can one obtain a linear model that explains these data? The idea is to modify all data points in such a way that some norm of the modification is minimized subject to the constraint that the modified vectors satisfy a linear relation. Although the name "total least squares" appeared in the literature only 25 years [15] ago, this method of fitting is certainly not new and has a long history in the statistical literature, where the method is known as "orthogonal regression", "errors-in-variables regression" or "measurement error modeling". The univariate line fitting problem was already discussed since 1877 [2]. More recently, the TLS approach to fitting has also stimulated interests outside statistics. One of the main reasons for its popularity is the availability of efficient and numerically robust algorithms in which the Singular Value Decomposition (SVD) plays a prominent role [15].

Another reason is the fact that TLS is an application oriented procedure. It is suited for situations in which all data are corrupted by noise, which is almost always the case in engineering applications. In this sense, TLS and EIV modeling are a powerful extension of classical least squares and ordinary regression, which corresponds only to a partial modification of the data.

A comprehensive description of the state of the art on TLS from its conception up to the summer of 1990 and its use in parameter estimation has been presented in [33]. While the latter book is entirely devoted to TLS, a second [34] and third book [35] present the progress in TLS and in the broader field of errors-in-variables modeling respectively from 1990 till 1996 and from 1996 till 2001.

The problem of *linear parameter estimation* arises in a broad class of scientific disciplines such as signal processing, automatic control, system theory and in general engineering, statistics, physics, economics, biology, medicine, etc. It starts from a model described by a linear equation:

$$\xi_1\beta_1 + \ldots + \xi_p\beta_p = \eta \tag{1}$$

where $\xi_1, \ldots, \xi_p$ and η denote the variables and $\beta = [\beta_1, \ldots, \beta_p]^T \in \mathbb{R}^p$ plays the role of a parameter vector that characterizes the specific system. A basic problem of applied mathematics is to determine an estimate of the *true* but *unknown* parameters from certain measurements of the variables. This gives rise to an *overdetermined* set of n linear equations $(n > p)$:

$$X\beta \approx y \tag{2}$$

where the ith row of data matrix $X \in \mathbb{R}^{n\times p}$ and vector $y \in \mathbb{R}^n$ contain respectively the measurements of the variables $\xi_1, \ldots, \xi_p$ and η.

In the classical least squares approach, as commonly used in ordinary regression, the measurements X of the variables ξ_i are assumed to be free of error and hence, all errors are confined to the observation vector y. However, this assumption is frequently unrealistic: sampling errors, human errors, modeling errors and instrument errors may imply inaccuracies of the data matrix X as well. One way to take errors in X into account is to introduce *perturbations also in* X. Therefore, the following TLS problem was introduced in the field of computational mathematics [14], [15] ($R(X)$ denotes the range of X and $\|X\|_F$ its Frobenius norm [16]):

Definition 1.1 (Total Least Squares problem). *Given an overdetermined set of n linear equations $X\beta \approx y$ in p unknowns β. The total least squares problem seeks to*

$$\min_{\widehat{\Delta},\widehat{\epsilon},\widehat{\beta}} \| \, [\widehat{\Delta} \; \widehat{\epsilon}] \, \|_F \quad \textit{subject to} \;\; (X - \widehat{\Delta})\widehat{\beta} = y - \widehat{\epsilon} \tag{3}$$

$\widehat{\beta}$ is called a TLS solution and $[\widehat{\Delta} \; \widehat{\epsilon}]$ the corresponding TLS correction.

This paper is organized as follows. Section 2 describes the univariate EIV regression problem from a statistical point of view. Section 3 then formulates the TLS problem from a computational point of view and shows the relationship with univariate EIV regression. Next, Section 4 presents the SVD based basic TLS algorithm, while Section 5 describes major properties of the TLS approach. Furthermore, extensions of the technique are discussed in Section 6 while Section 7 overviews the many applications of TLS in engineering fields. Finally, Section 8 gives the conclusions.

2 Univariate EIV regression: a statistical approach

2.1 Model formulation

For the simplest EIV model, the goal is to estimate from bivariate data a straight line fit between 2 variables, both of which are measured with error.

Definition 2.1 (Univariate Ordinary Regression). *For a sample size of n, $(\xi_i, y_i), i = 1, \ldots, n$, the standard regression model with one explanatory variable is given by*

$$\beta_0 + \xi_i\beta_1 + \epsilon_i = y_i, \quad i = 1, \ldots, n \tag{4}$$

where the independent variable ξ_i is either fixed or random and the error ϵ_i has zero mean and is uncorrelated with ξ_i.

The unknown intercept β_0 and slope β_1 are usually estimated using a Least-Squares (LS) approach for reasons of computational efficiency.

Definition 2.2 (Univariate EIV Regression). *For a sample size of n, (x_i, y_i), $i = 1, \ldots, n$, the univariate EIV regression model is defined as follows. The unobservable true variables (ξ_i, η_i) satisfy*

$$\beta_0 + \xi_i\beta_1 = \eta_i, \quad i = 1, \ldots, n \tag{5}$$

however, one observes $(x_i, y_i), i = 1, \ldots, n$, which are the true variables plus additive errors (δ_i, ϵ_i):

$$\xi_i = \xi_i + \delta_i \quad \textit{and} \quad y_i = \eta_i + \epsilon_i, \quad i = 1, \ldots, n \tag{6}$$

Assume that $\delta_i, \epsilon_i, \quad i = 1, \ldots, n$, all have finite variances, zero mean (without loss of generality), and are uncorrelated, i.e., $\mathrm{E}(\delta_i) = \mathrm{E}(\epsilon_i) = 0$, $\mathrm{var}(\delta_i) = \sigma_\delta^2$, $\mathrm{var}(\epsilon_i) = \sigma_\epsilon^2$ for all i, $\mathrm{cov}(\delta_i, \delta_j) = \mathrm{cov}(\epsilon_i, \epsilon_j) = 0$ for all $i \neq j$, $\mathrm{cov}(\delta_i, \epsilon_j) = 0$ for all i, j. Depending on the assumption about ξ_i, three different models are defined. If the ξ_i are unknown constants, then the model is known as a functional relationship. If the ξ_i are independent identically distributed (i.i.d.) random variables and independent of the errors, the model is called a structural relationship and we have: $E(\xi_i) = \mu$ and $\mathrm{var}(\xi_i) = \sigma^2$. A generalization of both models is the ultrastructural relationship which assumes that the ξ_i are independent random variables but not identically distributed, i.e. having possibly different means μ_i and common variance σ^2.

EIV regression looks like standard regression if one rewrites Eqs. (5-6) as

$$\beta_0 + x_i\beta_1 + \zeta_i = y_i \text{ with } \zeta_i \equiv \epsilon_i - \delta_i\beta_1, \quad i = 1, \ldots, n. \tag{7}$$

However, this is not the usual regression model, x_i is random and is correlated with the error term ζ_i: $\operatorname{cov}(x_i, \zeta_i) = -\beta_1\sigma_\delta^2$. This covariance is only zero when $\sigma_\delta^2 = 0$, which is the regression model, or when $\beta_1 = 0$, which is the trivial case. If one attempts to use ordinary regression estimates (least squares) on EIV regression modeled data, one obtains inconsistent estimates.

The seemingly minor change between model (4) and model (5)-(6) has important practical and theoretical consequences. One of the most important differences between both models concerns model identifiability. It is common to assume that all random variables in the EIV regression model are jointly normal. In this case, the structural and functional model are not identifiable [7]. Side conditions need to be imposed, the most common of which are the following: (1) the ratio of the error variances, $\lambda \equiv \sigma_\epsilon^2/\sigma_\delta^2$, is known; (2) σ_δ^2 is known; (3) σ_ϵ^2 is known; (4) both of the error variances, σ_δ^2 and σ_ϵ^2, are known. The first assumption is the most popular and is the one with the most published theoretical results, dating back to Adcock [2], [3]. It also leads to the commonly known Orthogonal Regression (OR) estimator. Indeed, if λ is known, the data can be scaled so that $\lambda = 1$. In this case, the maximum likelihood solution of the normal EIV regression problem is OR, which minimizes the sum of squares of the orthogonal distances from the data points to the regression line instead of the sum of squares of the vertical distances, as in standard regression (see Figure 1).

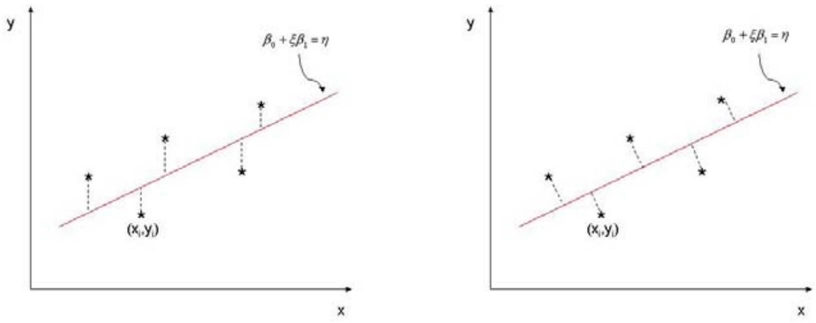

Figure 1: Standard regression (LS) Orthogonal regression (TLS)

2.2 Parameter estimation

Assume that the data have been properly scaled so that $\lambda = 1$. For the functional relationship, the likelihood function is $L(\beta_0, \beta_1, \sigma_\delta^2, \xi_1, \ldots, \xi_n) \propto$

$$\sigma_\delta^{-2n} \exp\left[\frac{-1}{2\sigma_\delta^2}\left\{\sum_{i=1}^{n}(x_i - \xi_i)^2 + (y_i - \beta_0 - \xi_i\beta_1)^2\right\}\right] \tag{8}$$

Note that $\delta_i = x_i - \xi_i$ and $\epsilon_i = y_i - \beta_0 - \xi_i\beta_1$ so that maximizing (8) requires minimizing $\sum(\delta_i^2 + \epsilon_i^2)$, which means that the sum of squares of the orthogonal distances from the data points to the line is minimized. Adcock [2], [3] considered the appropriate estimator to be orthogonal regression, which has been rediscovered many times during the first half of the 20th century. Lindley [23], however, considered a weighted least squares approach to the model (7) as follows. Estimate β_0, β_1 by taking both errors ϵ_i and δ_i into account to minimize a sum of weighted squared residuals, where the weights are proportional to the reciprocal of the variance of the errors ζ_i, i.e., $\sigma_\epsilon^2 + \sigma_\delta^2\beta_1^2$. Thus, one minimizes:

$$Q(\beta_0, \beta_1) = \frac{1}{n(\sigma_\epsilon^2 + \sigma_\delta^2\beta_1^2)}\sum_{i=1}^{n}(y_i - \beta_0 - \xi_i\beta_1)^2. \tag{9}$$

This minimization problem is solved when λ is known or both σ_ϵ^2 and σ_δ^2 are known. If $\lambda = 1$, the denominator reduces to $1 + \beta_1^2$ and amounts to orthogonal regression. Weighted least squares has drawn much attention in the literature; see [7] for references. Since Sprent [28], the name has standardized to generalized least squares. The success of generalized LS might give the impression that it is *the* LS method for the EIV regression model. Since generalized LS estimation only works for the no-equation-error model with the error covariance matrix known up to a scalar multiple, a unified approach for modifying LS to suit all different assumptions on the error covariance structure is called for. Modified LS is such an approach. The normality assumption on the errors (and on the true variables for the structural and ultrastructural relationships) is not needed, only the existence of second moments. From Eq. (7) it is clear that ζ_i are i.i.d. random variables with zero mean and variance $\sigma_\epsilon^2 + \sigma_\delta^2\beta_1^2$ regardless of the type of relationship. Cheng [7] developed modified LS estimators for β_0 and β_1 by minimizing an unbiased and consistent estimator of the appropriate unknown error variance. The estimators are a function of the residuals. Assuming λ known, an appropriate modified LS estimator for the unknown error variance σ_δ^2 is obtained by minimizing

$$Q(\beta_0, \beta_1) = \frac{1}{n(\lambda + \beta_1^2)}\sum(y_i - \beta_0 - \xi_i\beta_1)^2. \tag{10}$$

Minimizing Q with respect to β_0 and β_1 yields:

$$\hat{\beta}_0 = \bar{y} - \hat{\beta}_1 \bar{x} \quad \text{(where } \bar{v} \text{ denotes the mean of a vector } v\text{)} \tag{11}$$

$$\hat{\beta}_1 = \frac{s_{yy} - \lambda s_{xx} + [(s_{yy} - \lambda s_{xx})^2 + 4\lambda s_{xy}^2]^{\frac{1}{2}}}{2 s_{xy}}, \text{ provided } s_{xy} \neq 0 \tag{12}$$

with $s_{xx} = \frac{1}{n} \sum (x_i - \bar{x})^2$, $s_{yy} = \frac{1}{n} \sum (y_i - \bar{y})^2$ and $s_{xy} = \frac{1}{n} \sum (x_i - \bar{x})(y_i - \bar{y})$ the sample variances and covariance. In summary, the statistical approach seeks for estimators of the EIV regression model with optimal statistical properties (such as maximum likelihood, unbiasedness, consistency, etc.), mostly reflecting asymptotic behaviour as $n \to \infty$. If $p > 1$ explanatory variables ξ are considered, the problem formulation can be extended but the estimator β of dimension p can no longer be found analytically, as derived above, but via an eigenvalue-eigenvector approach [12, 13] or an SVD approach (see further).

3 TLS and EIV regression: a computational approach

3.1 Model formulation

In computational mathematics, measurement errors in linear models are tackled from a geometrical point of view, as explained in Section 1. To enlighten the difference with the statistical approach , we consider the univariate model and first assume that the intercept is zero, i.e. $\beta_0 = 0$. It is assumed that the true variables satisfy a compatible linear relationship, given by Eqs. (5)-(6). The TLS approach then aims to find minimal corrections (in a LS sense) $\hat{\delta}_i$ and $\hat{\epsilon}_i$ to the measured data x_i, y_i such that the corrected data $x_i - \hat{\delta}_i, y_i - \hat{\epsilon}_i$ satisfy exactly the unobserved relationship, i.e.

Definition 3.1 (Univariate TLS problem). *Given* $(x_i, y_i), i = 1, \ldots, n$ *satisfying Eqs. (5)-(6). Find corrections* $\hat{\delta}_i$ *and* $\hat{\epsilon}_i$ *and a slope estimate* $\hat{\beta}_1$ *by minimizing*

$$\min_{\hat{\delta}_i, \hat{\epsilon}_i, \hat{\beta}_1} \sum_{i=1}^{n} (\hat{\delta}_i^2 + \hat{\epsilon}_i^2) \text{ subject to } (x_i - \hat{\delta}_i)\hat{\beta}_1 = y_i - \hat{\epsilon}_i, \quad i = 1, \ldots, n \tag{13}$$

Solving this seemingly different minimization problem leads to the same slope estimator $\hat{\beta}_1$, called the TLS solution, as given in (12). If the underlying relationship is an intercept model, as given by Eqs. (5)-(6), the same TLS approach can be used provided the centered data $x_i - \bar{x}$ and $y_i - \bar{y}$ are used. Alternatively, a mixed LS-TLS approach [33] can be applied to the original data:

Definition 3.2 (Univariate mixed LS-TLS problem). *Given* (x_i, y_i), $i = 1, \ldots, n$ *satisfying Eqs. (5-6). Find corrections* $\hat{\delta}_i$ *and* $\hat{\epsilon}_i$, *an intercept* *estimate* $\hat{\beta}_0$ *and a slope estimate* $\hat{\beta}_1$ *by minimizing*

$$\min_{\hat{\delta}_i, \hat{\epsilon}_i, \hat{\beta}_0, \hat{\beta}_1} \sum_{i=1}^{n} (\hat{\delta}_i^2 + \hat{\epsilon}_i^2) \ \textit{subject to} \ \hat{\beta}_0 + (x_i - \hat{\delta}_i)\hat{\beta}_1 = y_i - \hat{\epsilon}_i, \quad i = 1, \ldots, n \quad (14)$$

This approach is called mixed LS-TLS because the underlying relationship between the true variables is equivalent with

$$\omega_i \beta_0 + \xi_i \beta_1 = \eta_i, \quad i = 1, \ldots, n \qquad (15)$$

where η_i, ξ_i are unobservable, as expressed by Eq. (6), and $\omega_i \equiv 1 \ \forall i$ is exactly known. Therefore, no corrections are needed for the observations ω_i in contrast to the corresponding observations x_i, y_i of ξ_i, η_i. Hence, the best estimates are found via a mixture of a LS and TLS approach, see [33]. Solving this mixed LS-TLS minimization problem leads to the same slope estimators $\hat{\beta}_0, \hat{\beta}_1$, called the mixed LS-TLS solution, as given in (11)-(12). Hence, for the univariate case, TLS in its simplest version is just orthogonal regression. For $p > 1$ explanatory variables, the TLS problem formulation is generalized as given in definition 1. Further extensions are discussed in Section 6.

3.2 Historical remarks

Although the name 'total least squares' appeared only recently in the literature [14], [15], this method of fitting is certainly not new and has a long history in the statistical literature where the method is known as orthogonal regression or errors-in-variables regression. Indeed, the univariate line fitting problem ($p = 1$) was already discussed since 1877 [2]. Some well-known contributors are Adcock [2], [3], Pearson [26], Koopmans [17], Madansky [24] and York [37] (see [4], [7] for a list of references). The method of orthogonal regression has been rediscovered many times, often independently. About thirty years ago, the technique was extended to multiple regression problems ($p > 1$) and later to multivariate problems which deal with more than one observation vector y, e.g., [29], [13].

More recently, the TLS approach to fitting also stimulated interest outside statistics. In the field of numerical analysis, this problem was first studied by Golub and Van Loan [14], [15]. Their analysis, as well as their algorithm, is strongly based on the SVD. Geometrical insight into the properties of the SVD brought Staar [30] independently to the same concept. Van Huffel and Vandewalle [32] generalized the algorithm of Golub and Van Loan to all cases in which their algorithm fails to produce a solution, described the properties of these so-called nongeneric TLS problems and proved that the proposed generalization still satisfies the TLS criteria if additional constraints are imposed on the solution space. This seemingly different linear algebraic approach is actually equivalent to the method of multivariate EIV regression analysis, studied by Gleser [13]. Gleser's method is based on an eigenvalue-eigenvector analysis, while the TLS method uses the SVD which is numerically more robust in the sense of algorithmic implementation. Furthermore, the TLS algorithm computes the minimum norm solution (called minimum norm TLS) whenever the TLS problem lacks a unique minimizer. These extensions are not considered by Gleser.

In engineering fields, e.g., experimental modal analysis, the TLS technique (more commonly known as the H_v technique), was also introduced about 20 years ago [21]. In the field of system identification, Levin [22] first studied the problem. His method, called the eigenvector method or Koopmans-Levin method [10], computes the same estimate as the TLS algorithm whenever the TLS problem has a unique solution. Compensated least squares was yet another name arising in this area: this method compensates for the bias in the estimator, due to measurement error, and is shown to be asymptotically equivalent to TLS [31]. Furthermore, in the area of signal processing, the minimum norm method was introduced and shown to be equivalent to minimum norm TLS [9]. Finally, the TLS approach is tightly related to the maximum likelihood Principal Component Analysis (PCA) method used in chemometrics [36].

4 Basic TLS algorithm and computational issues

We now analyze the TLS problem by making substantial use of the SVD.

Definition 4.1 (Singular Value Decomposition). *The singular value decomposition (SVD) of the $n \times (p+1)$ matrix $[X\ y]$ is defined by*

$$[X\ y] = U\Sigma V^T \tag{16}$$

where $U = [u_1, \ldots, u_n]$, $u_i \in \mathbb{R}^n$, $U^T U = I_n$ and $V = [v_1, \ldots, v_{p+1}]$, $v_i \in \mathbb{R}^{p+1}$, $V^T V = I_{p+1}$ contain respectively the left and right singular vectors, and $\Sigma = diag(\sigma_1, \ldots, \sigma_r)$, $r = \min\{n, p+1\}$, $\sigma_1 \geq \ldots \geq \sigma_r \geq 0$, are the singular values in decreasing order of magnitude.

To solve Eq. (2) with TLS, bring the set into the form:

$$[X\ y][\beta^T; -1]^T \approx 0 \tag{17}$$

If $\sigma_{p+1} \neq 0$, $[X\ y]$ is of rank $p+1$ and the space S generated by the rows of $[X\ y]$ coincides with $\mathbb{R}^{p+1}$. There is no nonzero vector in the orthogonal complement of S, hence the set of equations (17) is incompatible. In order to obtain a solution, the rank of $[X\ y]$ must be reduced to p. Using the Eckart-Young-Mirsky theorem [16], the best rank p TLS approximation $[\widehat{X}\ \widehat{y}]$ of $[X\ y]$, which minimizes the deviations in variance, is obtained by setting the smallest singular value σ_{p+1} of $[X\ y]$ to zero. The following theorem gives conditions for the **uniqueness** and **existence** of a TLS solution (v_{ij} denotes the (i, j)th entry of matrix V):

Theorem 4.1. Solution of the basic TLS problem $X\beta \approx y$.
Let(16) be the SVD of $[X\ y]$ *and* $\sigma_{\min}(X)$ *the smallest singular value of* X*. If* $\sigma_{\min}(X) > \sigma_{p+1}$*, the rank 1 TLS correction solves the TLS problem (3)*

$$[\Delta\widehat{X}\ \Delta\widehat{y}] = [X\ y] - [\widehat{X}\ \widehat{y}] = \sigma_{p+1}u_{p+1}v_{p+1}^T$$

with $[\widehat{X}\ \widehat{y}] = U\widehat{\Sigma}V^T$, $\widehat{\Sigma} = \mathrm{diag}(\sigma_1, \ldots, \sigma_p, 0)$ *and the TLS solution*

$$\widehat{\beta} = -\frac{1}{v_{p+1,p+1}}[v_{1,p+1}, \ldots, v_{p,p+1}]^T \tag{18}$$

exists and is the unique solution to $\widehat{X}\beta = \widehat{y}$.

Note the equivalence: $\sigma_{\min}(X) > \sigma_{p+1} \Leftrightarrow \sigma_p > \sigma_{p+1}$ and $v_{p+1,p+1} \neq 0$.

The following algorithm computes (if possible) a TLS solution $\widehat{\beta}$ of $X\beta \approx y$ such that $(X - \Delta\widehat{X})\widehat{\beta} = y - \Delta\widehat{y}$ and $\|[\Delta\widehat{X}\ \Delta\widehat{y}]\|_F$ is minimal.

Algorithm 4.1. Basic TLS solution of $X\beta \approx y$**.** Given $X \in \mathbb{R}^{n\times p}$, $y \in \mathbb{R}^n$.
Step 1: Compute the SVD (16), i.e. $[X\ y] = U\Sigma V^T$
Step 2: If $v_{p+1,p+1} \neq 0$ then $\widehat{\beta} = -\frac{1}{v_{p+1,p+1}}[v_{1,p+1}, \ldots, v_{p,p+1}]^T$

For the univariate case ($p = 1$), one easily proves, using the basic properties of eigenvalue and singular value decompositions, that the SVD based TLS solution, given by $\widehat{\beta}_1 = -v_{12}v_{22}^{-1}$, equals the analytical solution in Eq. (12).

The conditions $\sigma_{\min}(X) > \sigma_{p+1}$, or equivalently $\sigma_p > \sigma_{p+1}$ and $v_{p+1,p+1} \neq 0$, ensure that algorithm 4.1 computes the **unique** TLS solution of $X\beta \approx y$. These conditions are generically satisfied provided X is of full rank and the set $X\beta \approx y$ is not too conflicting. Hence, most TLS problems which arise in practice can be solved by means of algorithm 4.1, in which the TLS solution is obtained by a simple scaling of the right singular vector of $[X\ y]$ corresponding to its smallest singular value.

Extensions of this basic TLS problem to multivariate TLS problems $XB \approx Y$ having more than one right hand side vector, to problems in which the TLS solution is no longer unique or fails to have a solution altogether and to mixed LS-TLS problems that assume some of the columns of X to be error-free, are considered in detail in [33]. In addition, it is shown how to speed up the TLS computations directly by computing the SVD only partially or iteratively if a good starting vector is available. More recent advances, e.g. recursive TLS algorithms, neural based TLS algorithms, rank-revealing TLS algorithms, regularized TLS algorithms, TLS algorithms for large scale problems, etc., are reviewed in [34], [35].

5 TLS properties

Under specific conditions, the TLS solution, as introduced in numerical analysis, computes optimal parameter estimates in models with *only measurement* *error*, referred to as classical *errors-in-variables* (EIV) models. This is shown for the univariate case in Sections 2 and 3. These models are characterized by the fact that the true values of the observed variables satisfy one or more unknown but exact linear relations of the form (1). In particular, in case of one underlying linear relation, we define:

Definition 5.1 (Multiple EIV regression model). *Assume that the n measurements in X, y are related to p unknowns β by :*

$$\Xi\beta = \eta \qquad\qquad X = \Xi + \Delta \;\; \textit{and} \;\; y = \eta + \epsilon \tag{19}$$

where Δ, ϵ represent the measurement errors and all rows of $[\Delta\ \epsilon]$ are i.i.d. with zero mean and covariance matrix $\mathcal{C}$, known up to a scalar multiple σ_ν^2.

If additionally $\mathcal{C} = \sigma_\nu^2 I$ is assumed with I the identity matrix (i.e. Δ_{ij} and ϵ_i are uncorrelated random variables with equal variance) and $\lim_{n\to\infty} \frac{1}{n}\Xi^T\Xi$ exists and is positive definite, then it can be proven [12, 14] that the TLS solution $\widehat{\beta}_{TLS}$ of $X\beta \approx y$ estimates the *true* parameter values β, given by $(\Xi^T\Xi)^{-1}\Xi^T\eta$, *consistently*, i.e. $\widehat{\beta}_{TLS}$ converges to β as $n \to \infty$. This TLS property does not depend on any assumed distributional form of the errors. It should be noted that the TLS correction $[\widehat{\Delta}\ \widehat{\epsilon}]$, being of rank 1 as shown in Theorem 1, can not be considered as an appropriate estimator for the true measurement errors Δ and ϵ, added to the data [33], [15]. Note also that the LS estimates are inconsistent in this case. In these cases, TLS gives better estimates than does LS, as confirmed by simulations [33]. This situation may occur far more often in practice than is recognized. It is very common in agricultural, medical and economic science, in humanities, business and many other data analysis situations. Hence TLS should be a quite useful tool to data analysts. In fact, the keyrole and importance of LS in regression analysis is the same as that of TLS in EIV regression. Nevertheless, a lot of confusion exists in the fields of numerical analysis and statistics about the principle of TLS and its relation to EIV modeling. In particular, the name "Total Least Squares" is still largely unknown in the statistical community, while inversely the concept of EIV modeling did not penetrate sufficiently well in the field of computational mathematics and engineering. Roughly speaking, TLS is a special case of EIV estimation and, as such, TLS is reduced to a method in statistics but, on the other hand, TLS appears in many other fields, where mainly the data modification idea is used and explained from a geometric point of view, independently from its statistical interpretation.

Let us now discuss some of the main properties of the TLS method by comparing them with those of LS. First of all, a lot of insight can be gained by comparing their analytical expressions, given by:

$$\text{LS:} \quad \widehat{\beta}_{LS} = (X^TX)^{-1}X^Ty \tag{20}$$

$$\text{TLS:} \quad \widehat{\beta}_{TLS} = (X^TX - \sigma_{p+1}^2 I)^{-1}X^Ty \tag{21}$$

with X of full rank and σ_{p+1} the smallest singular value of $[X\ y]$.

From a numerical analyst's point of view, these formulas tell us that the TLS solution is more ill-conditioned than the LS solution since it has a higher condition number. This implies that errors in the data more likely affect the TLS solution than the LS solution. This is particularly true under worst case perturbations. Hence, TLS can be considered as a kind of *de*regularizing procedure. However, from a statistical point of view, these formulas tell us that TLS is doing the right thing in the presence of i.i.d. equally sized errors since it removes (asymptotically) the bias by subtracting the error covariance matrix (estimated by $\sigma_{p+1}^2 I$) from the data covariance matrix $X^T X$.

Secondly, while LS minimizes a sum of squared residuals, TLS minimizes a sum of *weighted* squared residuals, expressed as follows:

$$\text{LS:} \qquad \min_{\beta} \|X\beta - y\|^2 \tag{22}$$

$$\text{TLS:} \qquad \min_{z=[\beta^T \; -1]^T} \frac{\|[X \; y]z\|^2}{\|z\|^2} = \min_{\beta} \frac{\|X\beta - y\|^2}{\|\beta\|^2 + 1} \tag{23}$$

From a numerical analyst's point of view, we say that TLS minimizes the Rayleigh quotient. From a statistical point of view, we say that we weight the residuals by multiplying them with the inverse of the corresponding error covariance matrix (up to a scaling factor) to derive consistent estimates.

Other properties of TLS, which were studied in the field of numerical analysis, are its sensitivity in the presence of errors on all data [33]. Differences between the LS and TLS solution are shown to increase when the ratio $\sigma_p([X \; y])/\sigma_{\min}(X)$ is growing. This is the case when the set of equations $X\beta \approx y$ becomes less compatible, when the vector y is growing in length and when X tends to be rank-deficient. Assuming i.i.d. equally sized errors, the improved accuracy of the TLS solution compared to that of LS is maximal when the orthogonal projection of y is parallel with the pth singular vector of X, corresponding to $\sigma_{\min}(X)$. Additional algebraic connections and sensitivity properties of the TLS and LS problem, as well as many more statistical properties of the TLS estimators, based on knowledge of the distribution of the errors in the data, have been described, see [33], [34] for an overview.

6 TLS extensions

The statistical model that corresponds to the basic TLS approach is the no-equation-error EIV regression model with the restrictive condition that the measurement errors on the data are i.i.d. with zero mean and common error covariance matrix, equal to the identity matrix up to an unknown scalar. Most published TLS algorithms just handle this case while other more useful EIV regression estimators did not receive enough attention in computational mathematics. To relax these restrictions, several extensions of the TLS problem have been investigated. In particular, the *mixed LS-TLS* problem formulation allows to extend consistency of the TLS estimator in EIV models, where some of the variables ξ_i are measured without error. The *data least* *squares* problem refers to the special case in which all variables except η are measured with error and was introduced in the field of signal processing by DeGroat and Dowling [8] in the mid nineties. Whenever the errors are independent but *unequally* sized, *weighted TLS* problems should be considered using appropriate diagonal scaling matrices in order to maintain consistency. If, additionally, the errors are also correlated, then the *generalized TLS* problem formulation allows to extend consistency of the TLS estimator in EIV models, provided the corresponding error covariance matrix is known up to a factor of proportionality (see definition 7). More general problem formulations, such as *restricted TLS*, which also allow the incorporation of equality constraints, have been proposed, as well as equivalent problem formulations using other $\mathrm{L_p}$ norms and resulting in the so-called *Total* $\mathrm{L_p}$ *approximations* (see [33] for references). The latter problems proved to be useful in the presence of outliers. Robustness of the TLS solution is also improved by adding regularization, resulting in the *regularized TLS* methods [11], [27], [35]. In addition, various types of bounded uncertainties have been proposed in order to improve robustness of the estimators under various noise conditions and algorithms are outlined [34], [35].

Furthermore, *constrained TLS* problems have been formulated. Arun [5] addressed the unitarily constrained TLS problem, i.e., $XB \approx Y$, subject to the constraint that the solution matrix B should be unitary. He proved that this solution is the same as the solution to the orthogonal Procrustes problem [16, p.582]. Abatzoglou et al [1] considered yet another constrained TLS problem, which extends the classical TLS problem (3) to the case where the errors $[\Delta\ \epsilon]$ in the data $[X\ y]$ are algebraically related. However, if there is a linear dependence among the error entries in $[\Delta\,\epsilon]$, then the TLS solution no longer has optimal statistical properties (e.g. maximum likelihood in case of normality). This happens, for instance, in dynamic system modeling, e.g., in system identification when we try to estimate the impulse response of a system from its input and output by discrete deconvolution. In these so-called *structured TLS* problems, the data matrix $[X\ y]$ is structured, typically block Toeplitz or Hankel. In order to preserve maximum likelihood properties and consistency of the solution [1], [18], the TLS problem formulation, given in definition 1, must be extended with the additional constraint that any (affine) structure of X or $[X\ y]$ must be preserved in $\widehat{\Delta}$ or $[\widehat{\Delta}\ \widehat{\epsilon}]$, where $\widehat{\Delta}$ and $\widehat{\epsilon}$ are chosen to minimize the error in the discrete L_1, L_2 and L_∞ norm. For L_2 norm minimization, various computational algorithms have been presented, as surveyed in [34], [35], and shown to reduce the computation time by exploiting the matrix structure in the computations. In addition, it is shown how to extend the problem and solve it, if latency or equation errors are included. Recently, robustness of the structured TLS solution has been improved by adding regularization, see e.g. [25].

Yet, another important extension is the *elementwise-weighted TLS* (EW-TLS) estimator, which computes consistent estimates in linear EIV models, where the measurement errors are elementwise differently sized or, more generally, where the corresponding error covariance matrices may differ from row to row. Some of the variables are allowed to be exactly known (observable) [19], [35]. Mild conditions for weak consistency of the EW-TLS estimator are given and an iterative procedure to compute it is proposed.

Finally, we mention the important extension to *nonlinear EIV* models, nicely studied in the book of Caroll, Ruppert and Stefanski [6]. In these models, the relationship between the variables ξ_i and η is assumed to be nonlinear. It is important to notice here that the close relationship between nonlinear TLS and EIV stops to exist. Indeed, consider the bilinear EIV model $XBG \approx Y$, in which X, G, and Y are affected by measurement errors. Applying TLS to this model leads to the following bilinear TLS problem:

$$\min_{\widehat{\Delta}_X, \widehat{\Delta}_G, \widehat{\Delta}_Y, B} \|[\widehat{\Delta}_X \ \widehat{\Delta}_G \ \widehat{\Delta}_Y]\|_F^2 \, \text{s.t.} \, (X - \widehat{\Delta}_X)\, B\, (G - \widehat{\Delta}_G) = Y - \widehat{\Delta}_Y$$

However, solving this problem yields inconsistent estimates of B [12]. A consistent estimate can be obtained [20] using the adjusted LS estimator (the full rank case is considered here for reasons of simplicity):

$$\widehat{B}_{ALS} = (X^T X - V_X)^{-1} (X^T Y G^T)(G G^T - V_G)^{-1} \tag{24}$$

with $V_X = E(\Delta_X^T \Delta_X)$, $V_G = E(\Delta_G \Delta_G^T)$ and Δ_X and Δ_G represent the errors on X and G respectively. Corrections for small samples have been derived and shown to give superior performance for small sized problems. Various other types of nonlinear EIV models, including bilinear, polynomial, nonlinear functional, semi-linear and Cox's proportional Hazards models, have been considered and consistent estimators are derived, see [35] for an overview.

7 Applications in engineering fields

Since the publication of the SVD based TLS algorithm [15], many new TLS algorithms have been developed and, as a result, the number of applications in TLS and EIV modeling has increased exponentially in the last decade, because of its emergence in new fields such as computer vision, image reconstruction, speech and audio processing, and its gain in popularity in fields as signal processing, modal and spectral analysis, system identification and astronomy. In [34], [35], the use of TLS and errors-in-variables models in the most important application fields, such as signal processing and system identification, are surveyed and new algorithms that apply the TLS concept to the model characteristics used in those fields are described. In these fields, the structured TLS approach is important. In particular, a lot of common problems in ststem identification and signal processing can be reduced to special types of structured TLS problems, including block Hankel or Toeplitz matrix structures, the essence of which is the LS approximation of a given matrix by a rank-deficient one. For example, in system identification the well-known Kalman filtering is extended to the errors-in-variables context in which noise on the inputs as well as on the outputs is taken into account thereby improving the filtering performance. In the field of signal processing, in particular in-vivo magnetic resonance spectroscopy and audio coding, new state-space based methods have been derived by making use of the TLS approach for spectral estimation with extensions to decimation and multichannel data quantification. In addition, it has been shown how to extend the least mean squares (LMS) algorithm to the EIV context for use in adaptive signal processing and various noise environments. Finally, TLS applications also emerge in other fields, including information retrieval, image reconstruction, multivariate calibration, astronomy, and computer vision. It is shown in [35] how the TLS approach and its generalizations, including structured, regularized and generalized TLS, can be successfully applied.

This list of applications of TLS and EIV modeling is certainly not exhaustive and clearly illustrates the increased interest of TLS and EIV modeling in engineering over the past 20 years.

8 Conclusions

The basic principle of TLS is that the noisy data $[X\ y]$, while not satisfying a linear relation, are modified with minimal effort, as measured by the Frobenius norm, in a 'nearby' matrix $[\widehat{X}\ \widehat{y}]$ which is rank-deficient so that the set $\widehat{X}\beta = \widehat{y}$ is compatible. This matrix $[\widehat{X}\ \widehat{y}]$ is a rank-one modification of the data matrix $[A\ b]$. The solution to the TLS problem can be determined from the SVD of the matrix $[X\ y]$. A simple algorithm outlines the computations of the solution of the basic TLS problem. By 'basic' is meant that only one right-hand side vector y is considered and that the TLS problem is solvable (generic) and has a unique solution. Extensions of this basic TLS problem are discussed. Much of the literature concerns the classical TLS problem $X\beta \approx y$, in which all columns of X are subject to errors, but more general TLS problems, as well as other problems related to classical TLS, have been proposed and are briefly overviewed here.

Engineering applications of the Total Least Squares (TLS) technique have been overviewed. TLS has its roots in statistics where it can be defined as a special case of classical Errors-in-Variables (EIV) regression in which all measurement errors on the data are i.i.d. with zero mean and equal variance. Due to the development of a powerful algorithm based on the SVD in computational mathematics the method became very popular in engineering applications. This is a nice example of interdisciplinary work. However, the danger exists that researchers will focus their attention on the wrong problems which are either unreasonable from a statistical point of view (e.g. biased, inconsistent, not efficient) or not practically useful from an engineering point of view (e.g. assumptions never satisfied). This paper invites any reader to open the frontiers of its own discipline and look over the border into neighbouring areas so that the any engineering problem, dealing with measurement error, is studied in a correct way.

BINARY DATA IN THE PRESENCE OF MISCLASSIFICATIONS

Jorge Alberto Achcar, Edson Zangiacomi Martinez and Francisco Louzada-Neto

Key words: Binary data, sensitivity and specificity, Bayesian analysis.

COMPSTAT 2004 section: Bayesian methods.

Abstract: This contribution concentrates on the sensitivity and specificity of medical tests in the presence of misclassifications

1 Introduction

In many applications of binary data, we have the presence of covariates and misclassifications (see, for example, Geng and Asano [5], or Soares and Paulino [8]). As a special situation, we could have the presence of false positives or false negatives in diagnostic medical tests. In medical terminology, we denote sensitivity as the probability of positive test given that the patient really has the disease and specificity as the probability of a negative test given that the patient has not the disease. Let p be the prevalence of disease in the population and D the disease status, where $D = 1$ (or simply, D) denotes an individual with the disease and $D = 0$ (or $\overline{D}$) denotes a free-disease individual. Thus, $p = P(D)$. Let T be a random variable related to the diagnostic test results, where $T = 1$ (or T) denotes a positive test and $T = 0$ (or $\overline{T}$) denotes a negative test. The sensitivity of the diagnostic test is given by $S_E = P(T|D)$ and the specificity is given by $S_P = P(\overline{T}|\overline{D})$. Observe that $1 - S_E$ and $1 - S_P$ are the probabilities of misclassifications. In the presence of a vector of covariates $\mathbf{X}_i' = (X_{0i}, X_{1i}, \ldots, X_{Li})$, the probability of a positive test (sucess) is given by $\eta_i = p_i S_E + (1 - p_i)(1 - S_P)$, where $i = 1, \ldots, n$. Different parametric choices for p_i could be considered. We assume a logistic regression model given by $e^{\mathbf{x}'\beta} / \left(1 + e^{\mathbf{x}'\beta}\right)$. Observe that we also could assume S_E and S_P dependent on the covariates.

2 Bayesian analysis, all individuals are unverified

Let us assume that all individuals are unverified about the real disease status after an application of a medical test. Assuming a Bernoulli distribution for the test result t_i with sucess probability given by η_i, let $D_i = (t_i, \mathbf{x}_i)$, $i = 1, \ldots, n$ be the data where $t_i = 1$ (T) or 0 ($\overline{T}$) and $\mathbf{X}_i$ is a covariate vector associated to each individual. Also assume the logit link for the probability of prevalence of disease for the individual in the population. The likelihood function for $\theta' = (S_E, S_P, \beta_{p0}, \beta_{p1}, \ldots, \beta_{pL})$ is given by

$$L(\theta) = \prod_{i=1}^{n} \left[p_i S_E + (1 - p_i)(1 - S_P)\right]^{t_i} \left[p_i (1 - S_E) + (1 - p_i) S_P\right]^{1 - t_i}. \tag{1}$$

For a Bayesian analysis of the model, let us assume the following prior distributions for S_E, S_P and $\beta_p' = (\beta_{p0}, \beta_{p1}, \ldots, \beta_{pL}) : S_E \sim Beta(a,b)$, $S_P \sim Beta(c,d)$, $\beta_{pj} \sim N(e_j; f_j^2)$, a, b, c, d, e_j, f_j known, where $j = 0, 1, \ldots, L$, $Beta(a,b)$ denotes a Beta distribution with mean $a/(a+b)$ and variance $ab/\left[(a+b)^2(a+b+1)\right]$ and $N(\mu, \sigma^2)$ denotes a normal distribution with mean μ and variance σ^2. We also assume prior independence among the parameters. To obtain better performance for the Gibbs sampling algorithm (see, for example, Gelfand and Smith [4]), we introduce latent variables given by $\mathbf{D}_i^* = (\mathbf{D}_{i1}^*, \mathbf{D}_{i2}^*)$ where $\mathbf{D}_{i1}^* = (D_{i1}^*, \overline{D}_{i1}^*)$ given $T_i = 1$ and $\mathbf{D}_{i2}^* = (D_{i2}^*, \overline{D}_{i2}^*)$ given $T_i = 0$ for $i = 1, \ldots, n$. That is,

(a) $\mathbf{D}_{i1}^* = (D_{i1}^*, \overline{D}_{i1}^*)$ given $T_i = 1$ where $D_{i1}^* + \overline{D}_{i1}^* = 1$ and D_{i1}^* is a random variable (disease status) with a Bernoulli distribution with sucess probability given by $h_{1i} = P\left(D_{i1}^* | T_i\right) = p_i S_E \left[p_i S_E + (1-p_i)(1-S_P)\right]^{-1}$.

(b) $\mathbf{D}_{i2}^* = (D_{i2}^*, \overline{D}_{i2}^*)$ given $T_i = 0$ where $D_{i2}^* + \overline{D}_{i2}^* = 1$ and D_{i2}^* is a random variable (disease status) with a Bernoulli distribution with sucess probability given by $h_{2i} = P\left(D_{i2}^* | T_i\right) = p_i\left(1 - S_E\right)\left[p_i\left(1 - S_E\right) + \left(1 - p_i\right) S_P\right]^{-1}$.

In this way, the joint posterior distribution for θ is given by

$$\begin{aligned}\Pi\left(\theta | \mathbf{t}, \mathbf{d}^*\right) \quad \propto \quad & S_E^{a+\sum_{i=1}^n t_i d_{i1}^* - 1} \left(1 - S_E\right)^{b + \sum_{i=1}^n (1-t_i) d_{i2}^* - 1} \times \\ & \times S_P^{c + \sum_{i=1}^n (1-t_i)(1-d_{i2}^*) - 1} \left(1 - S_P\right)^{d + \sum_{i=1}^n t_i (1 - d_{i1}^*) - 1} \times \\ & \times \prod_{j=0}^L \exp\left[-\left(2 f_j^2\right)^{-1} \left(\beta_{pj} - e_j\right)^2\right] \times \\ & \times \prod_{i=1}^n p_i^{t_i d_{i1}^* + (1-t_i) d_{i2}^*} \left(1 - p_i\right)^{t_i (1 - d_{i1}^*) + (1-t_i)(1-d_{i2}^*)}. \quad (2)\end{aligned}$$

The conditional distributions for the Gibbs sampling algorithm are given by

$$S_E | \theta_{(S_E)}, \mathbf{t}, \mathbf{d}^* \sim Beta\left(a + \sum_{i=1}^n d_{i1}^* t_i, b + \sum_{i=1}^n d_{i2}^* \left(1 - t_i\right)\right), \quad (3)$$

$$S_P | \theta_{(S_P)}, \mathbf{t}, \mathbf{d}^* \sim Beta\left(c + \sum_{i=1}^n \left(1 - d_{i2}^*\right)\left(1 - t_i\right), d + \sum_{i=1}^n t_i \left(1 - d_{i1}^*\right)\right), \quad (4)$$

$$\Pi\left(\beta_{pj} | \theta_{(\beta_{pj})}, \mathbf{t}, \mathbf{d}^*\right) \propto \exp\left[-\left(2 f_j^2\right)^{-1} \left(\beta_{pj} - e_j\right)^2\right] \psi(\theta), \quad (5)$$

where

$$\psi(\theta) = \exp\left\{\beta_{pj} \sum_{i=1}^n x_{ji} \left[t_i d_{i1}^* + \left(1 - t_i\right) d_{i2}^*\right] - \sum_{i=1}^n \ln\left(1 + e^{\sum_{j=0}^L \beta_{pj} x_{ji}}\right)\right\},$$

$x_{0i} = 1$, $i = 1, \ldots, n$ and $\theta_{(r)} = \left(\theta_1, \ldots, \theta_{r-1}, \theta_{r+1}, \ldots, \theta_L\right)$. Observe that we should simulate samples for β_{pj}, $j = 0, 1, \ldots, L$ considering the Metropolis-Hastings algorithm. Starting with initial values $\theta^{(0)}$, we simulate samples of the joint posterior distribution (2) following the steps:

(i) generate a sample of $\mathbf{D}^*_{i1} = (D^*_{i1}, \overline{D}^*_{i1})$, $i = 1, \ldots, n$, from the conditional Bernoulli distribution with success probability h_{1i} given $T_i = 1$;

(ii) generate a sample of $\mathbf{D}^*_{i2} = (D^*_{i2}, \overline{D}^*_{i2})$, $i = 1, \ldots, n$, from the conditional Bernoulli distribution with success probability h_{2i} given $T_i = 0$;

(iii) generate a sample from the conditional distributions
$\Pi\left(\theta_1|\theta_{(\theta_1)}, \mathbf{t}, \mathbf{d}^*\right), \ldots, \Pi\left(\theta_L|\theta_{(\theta_L)}, \mathbf{t}, \mathbf{d}^*\right)$.

A special case is given when we do not have the presence of covariates [7]. In this case, we assume the same Beta prior distributions for S_E and S_P and a Beta distribution for p with hyperparameters e and f considering e and f known. Also assuming the introduction of the latent variables $\mathbf{D}^*_{i1}$ given $T_i = 1$ and $\mathbf{D}^*_{i2}$ given $T_i = 0$, the conditional posterior distributions for the Gibbs sampling algorithm are given by (3), (4) and $p|\theta_{(p)}, \mathbf{t}, \mathbf{d}^*$ has a Beta distrbution with parameters $e + \sum_{i=1}^n d^*_{i1} t_i + \sum_{i=1}^n d^*_{i2}\left(1 - t_i\right)$ and $f + \sum_{i=1}^n t_i\left(1 - d^*_{i1}\right) + \sum_{i=1}^n\left(1 - t_i\right)\left(1 - d^*_{i2}\right)$.

3 Model formulation assuming verified and unverified individuals

In medical applications, if we consider only the verified cases (see for example, Begg [1]; Begg and Greenes [2] or Zhou [9], we could obtain biased estimators for S_E and S_P. This occurs when only part of the sampled individuals are verified about their real disease status by a procedure generically denominated by "gold standard". Let V be a random variable related to the verification by a gold standard, where $V = 1$ (or V) denotes a verified individual and $V = 0$ (or $\overline{V}$) denotes an unverified individual. In Table 1, we have the probabilities in the cross-tabulation of the variables V, D and T considering verified and unverified individuals by a gold standard.

	verified (V)		
	D	$\overline{D}$	unverified $(\overline{V})$
T	$p\lambda_{11}S_E$	$(1-p)\,\lambda_{01}\,(1-S_P)$	$p\,(1-\lambda_{11})\,S_E+$ $+\,(1-p)\,(1-\lambda_{01})\,(1-S_P)$
$\overline{T}$	$p\lambda_{10}\,(1-S_E)$	$(1-p)\,\lambda_{00}S_P$	$p\,(1-\lambda_{10})\,(1-S_E)+$ $+\,(1-p)\,(1-\lambda_{00})\,S_P$

Table 1: Probabilities in the cross-tabulation of the variables V, D and T.

Let us assume that D and V are independent random variables. In Table 1, we have $\lambda_{11} = P\left(V|TD\right)$, $\lambda_{01} = P\left(V|T\overline{D}\right)$, $\lambda_{10} = P\left(V|\overline{T}D\right)$, $\lambda_{00} = P\left(V|\overline{TD}\right)$, $S_E = P(T|D)$ and $S_P = P(\overline{T}|\overline{D})$. For the calculation of the probabilities of Table 1, observe that $P\left(T = 1, D = 1, V = 1\right) = P\left(TDV\right) = P\left(D\right)P\left(V|TD\right)P\left(T|D\right) = P\lambda_{11}S_E$. In the same way, we find the other probabilities given in Table 1. Considering the data given by $\mathcal{D}_i = \left(d_i, t_i, v_i\right)$, $i = 1, \ldots, n$, where $d_i = 1$ (D) or 0 $(\overline{D})$; $t_i = 1$ (T) or 0 $(\overline{T})$, and $v_i = 1$ (V) or 0 $(\overline{V})$, the likelihood function for $\theta'_1 = (\lambda_{11}, \lambda_{10}, \lambda_{01}, \lambda_{00}, S_E, S_P, p)$ is

$$\begin{aligned} L\left(\theta_1\right) \;=\; & \prod\nolimits_{i=1}^{n}\left(p\lambda_{11}S_E\right)^{d_i t_i v_i}\left[p\lambda_{10}\left(1-S_E\right)\right]^{d_i(1-t_i)v_i}\times \\ & \times\left[(1-p)\,\lambda_{01}\left(1-S_P\right)\right]^{(1-d_i)t_i v_i}\left[(1-p)\,\lambda_{00}S_P\right]^{(1-d_i)(1-t_i)v_i}\times \\ & \times\left[p\left(1-\lambda_{11}\right)S_E+(1-p)\left(1-\lambda_{01}\right)\left(1-S_P\right)\right]^{t_i(1-v_i)}\times \\ & \times\left[p\left(1-\lambda_{10}\right)\left(1-S_E\right)+(1-p)\left(1-\lambda_{00}\right)S_P\right]^{(1-t_i)(1-v_i)}. \qquad (6) \end{aligned}$$

In the presence of a vector of covariates $\mathbf{X}_i' = (X_{0i}, X_{1i}, \ldots, X_{Li})$, let us assume the logit links for p_i, S_{E_i}, S_{P_i}, λ_{11_i}, λ_{01_i}, λ_{10_i}, and λ_{00_i} given by $\upsilon_{l_i} = \exp\left(\sum_{j=0}^{L}\beta_{lj}x_{ji}\right)\left[1+\exp\left(\sum_{j=0}^{L}\beta_{lj}x_{ji}\right)\right]^{-1}$, for $l = 1, 2, \ldots, 7$; $X_{0i=1}$; $\upsilon_{1_i} = p_i$; $\upsilon_{2_i} = S_{E_i}$; $\upsilon_{3_i} = S_{P_i}$; $\upsilon_{4_i} = \lambda_{11_i}$; $\upsilon_{5_i} = \lambda_{01_i}$; $\upsilon_{6_i} = \lambda_{10_i}$ and $\upsilon_{7_i} = \lambda_{00_i}$, $i = 1, \ldots, n$. In this way, we have a vector of parameters given by $\theta_2' = (\beta_1, \beta_2, \ldots, \beta_7)$, where $\beta_1' = (\beta_{10}, \beta_{11}, \ldots, \beta_{1L})$, $\beta_2' = (\beta_{20}, \beta_{21}, \ldots, \beta_{2L})$,..., $\beta_7' = (\beta_{70}, \beta_{71}, \ldots, \beta_{7L})$.

4 A Bayesian analysis in the presence of covariates

Let us assume the model given in Table 1 assuming the verified and the unverified cases and the presence of a vector of covariates $\mathbf{X}_i'$, $i = 1, \ldots, n$, associated to each individual. Assuming prior independence among the parameters, consider normal $N\left(a_{lj}, b_{lj}^2\right)$ prior distributions for β_{lj}, where a_{lj}, b_{lj} known, $l = 1, 2, \ldots, 7$ and $j = 0, 1, \ldots, L$. We also assume the introduction of latent variables $\mathbf{D}_i^* = (\mathbf{D}_{i1}^*, \mathbf{D}_{i2}^*)$ (see Section 2) where $\mathbf{D}_{i1}^* = (D_{i1}^*, \overline{D}_{i1}^*)$ given $V_i = 0$ and $T_i = 1$ and $\mathbf{D}_{i2}^* = (D_{i2}^*, \overline{D}_{i2}^*)$ given $V_i = 0$ and $T_i = 0$, $i = 1, \ldots, n$. That is,

(a) $\mathbf{D}_{i1}^* = (D_{i1}^*, \overline{D}_{i1}^*)$ given $V_i = 0$ and $T_i = 1$ where $D_{i1}^* + \overline{D}_{i1}^* = 1$, $i = 1, \ldots, n$, and D_{i1}^* is a random variable with a Bernoulli distribution with success probability given by

$$h_{1i} = P\left(D_{i1}^* | \overline{V}_i T_i\right) = \frac{p_i\left(1-\lambda_{11_i}\right)S_{E_i}}{p_i\left(1-\lambda_{11_i}\right)S_{E_i} + \left(1-p_i\right)\left(1-\lambda_{01_i}\right)\left(1-S_{P_i}\right)}. \qquad (7)$$

(b) $\mathbf{D}_{i2}^* = (D_{i2}^*, \overline{D}_{i2}^*)$ given $V_i = 0$ and $T_i = 0$ where $D_{i2}^* + \overline{D}_{i2}^* = 1$, $i = 1, \ldots, n$, and D_{i2}^* is a random variable with a Bernoulli distribution with success probability given by

$$h_{2i} = P\left(D_{i2}^* | \overline{V}_i \overline{T}_i\right) = \frac{p_i\left(1-\lambda_{10_i}\right)\left(1-S_{E_i}\right)}{p_i\left(1-\lambda_{10_i}\right)\left(1-S_{E_i}\right) + \left(1-p_i\right)\left(1-\lambda_{00_i}\right)S_{P_i}}. \qquad (8)$$

The joint distribution for $\theta_2' = (\beta_1, \beta_2, \ldots, \beta_7)$ is given by

$$\begin{aligned}
&\Pi\left(\theta_2|\mathcal{D},\mathbf{t},\mathbf{d}^*\right) \propto \Pi\left(\theta_2\right)\left[\prod\nolimits_{i=1}^{n} \lambda_{00_i}^{r_i^{(001)}}\left(1-\lambda_{00_i}\right)^{s_{2_i}^{(000)}}\right] \times \\
&\times\left[\prod\nolimits_{i=1}^{n} \lambda_{10_i}^{r_i^{(101)}}\left(1-\lambda_{10_i}\right)^{s_{2_i}^{(100)}}\right]\left[\prod\nolimits_{i=1}^{n} \lambda_{01_i}^{r_i^{(011)}}\left(1-\lambda_{01_i}\right)^{s_{1_i}^{(010)}}\right] \times \\
&\times\left[\prod_{i=1}^{n} \lambda_{11_i}^{r_i^{(111)}}\left(1-\lambda_{11_i}\right)^{s_{1_i}^{(110)}}\right]\left[\prod_{i=1}^{n} S_{P_i}^{r_i^{(001)}+s_{2_i}^{(000)}}\left(1-S_{P_i}\right)^{r_i^{(011)}+s_{1_i}^{(010)}}\right] \times \\
&\times\left[\prod\nolimits_{i=1}^{n} S_{E_i}^{r_i^{(111)}+s_{1_i}^{(110)}}\left(1-S_{E_i}\right)^{r_i^{(101)}+s_{2_i}^{(100)}}\right] \times \\
&\times\left[\prod\nolimits_{i=1}^{n} p_i^{r_i^{(111)}+r_i^{(101)}+s_{1_i}^{(110)}+s_{2_i}^{(100)}}\left(1-p_i\right)^{r_i^{(011)}+r_i^{(001)}+s_{1_i}^{(010)}+s_{2_i}^{(000)}}\right], \quad (9)
\end{aligned}$$

where $\Pi\left(\theta_2\right)$ is the joint prior distribution for θ_2, $r_i^{(111)} = d_i t_i \upsilon_i$, $r_i^{(011)} = \left(1-d_i\right) t_i \upsilon_i$, $r_i^{(101)} = d_i\left(1-t_i\right)\upsilon_i$, $r_i^{(001)} = \left(1-d_i\right)\left(1-t_i\right)\upsilon_i$, $s_{1_i}^{(110)} = d_{i1}^* t_i \times \times\left(1-\upsilon_i\right)$, $s_{1_i}^{(010)} = \left(1-d_{i2}^*\right) t_i\left(1-\upsilon_i\right)$, $s_{2_i}^{(100)} = d_{i2}^*\left(1-t_i\right)\left(1-\upsilon_i\right)$, $s_{2_i}^{(000)} = \left(1-d_{i2}^*\right)\left(1-t_i\right)\left(1-\upsilon_i\right)$, $i = 1,\ldots,n$. We simulate samples from the joint distribution for $\theta_2' = \left(\beta_1,\beta_2,\ldots,\beta_7\right)$ using the Metropolis-Hastings algorithm.

In the situation where we do not have the presence of covariates, we have a vector of parameters given by $\theta_1' = (\upsilon_1,\upsilon_2,\ldots,\upsilon_7)$, where $\upsilon_1 = p$, $\upsilon_2 = S_E$, $\upsilon_3 = S_P$, $\upsilon_4 = \lambda_{11}$, $\upsilon_5 = \lambda_{01}$, $\upsilon_6 = \lambda_{10}$ and $\upsilon_7 = \lambda_{00}$. Assuming prior independence among the parameters, let us consider $Beta\left(a_{1j},b_{1j}\right)$ prior distributions for υ_j, $j = 1,\ldots,7$, with a_{1j} and b_{1j} known hyperparameters. Also considering the introduction of the latent variables $\mathbf{D}_{i1}^* = (D_{i1}^*,\overline{D}_{i1}^*)$, $i = 1,\ldots,n$, the joint posterior distribution for θ_1 is given by

$$\begin{aligned}
&\Pi\left(\theta_1|\mathcal{D},\mathbf{t},\mathbf{d}^*\right) \propto p^{a_{11}+T_1-1}(1-p)^{b_{11}+T_2-1} S_E^{a_{12}+T_3-1}(1-S_E)^{b_{12}+T_4-1} \times \\
&\times S_P^{a_{13}+T_5-1}(1-S_P)^{b_{13}+T_6-1}\lambda_{01}^{a_{14}+T_7-1}(1-\lambda_{01})^{b_{14}+T_8-1}\lambda_{10}^{a_{15}+T_9-1} \times \\
&\times(1-\lambda_{10})^{b_{15}+T_{10}-1}\lambda_{00}^{a_{16}+T_{11}-1}(1-\lambda_{00})^{b_{16}+T_{12}-1} \times \\
&\times\lambda_{11}^{a_{17}+T_{13}-1}(1-\lambda_{11})^{b_{17}+T_{14}-1}, \qquad (10)
\end{aligned}$$

where $T_1 = \sum_{i=1}^n d_i\upsilon_i + \sum_{j=1}^2\sum_{i=1}^n(1-\upsilon_i)d_{ij}^*$, $T_2 = \sum_{i=1}^n\left(1-d_i\right)\upsilon_i + \sum_{j=1}^2\sum_{i=1}^n(1-\upsilon_i)\left(1-d_{ij}^*\right)$, $T_3 = \sum_{i=1}^n d_i t_i\upsilon_i + \sum_{i=1}^n t_i(1-\upsilon_i)d_{i1}^*$, $T_4 = \sum_{i=1}^n d_i\left(1-t_i\right) + \sum_{i=1}^n(1-t_i)(1-\upsilon_i)d_{i2}^*$, $T_5 = \sum_{i=1}^n\left(1-d_i\right)\left(1-t_i\right)\upsilon_i + \sum_{i=1}^n\left(1-t_i\right)\left(1-\upsilon_i\right)\left(1-d_{i2}^*\right)$, $T_6 = \sum_{i=1}^n\left(1-d_i\right)t_i\upsilon_i + \sum_{i=1}^n t_i(1-\upsilon_i)\times \times\left(1-d_{i1}^*\right)$, $T_7 = \sum_{i=1}^n\left(1-d_i\right)t_i\upsilon_i$, $T_8 = \sum_{i=1}^n t_i(1-\upsilon_i)\left(1-d_{i1}^*\right)$, $T_9 = \sum_{i=1}^n d_i\left(1-t_i\right)\upsilon_i$, $T_{10} = \sum_{i=1}^n(1-t_i)(1-\upsilon_i)d_{i2}^*$, $T_{11} = \sum_{i=1}^n\left(1-d_i\right) \times \times\left(1-t_i\right)\upsilon_i$, $T_{12} = \sum_{i=1}^n\left(1-t_i\right)\left(1-\upsilon_i\right)\left(1-d_{i2}^*\right)$, $T_{13} = \sum_{i=1}^n d_i t_i\upsilon_i$, and $T_{14} = \sum_{i=1}^n t_i\left(1-\upsilon_i\right)d_{i1}^*$. Considering that, for instance, $\theta_{(p)}$ is the vector θ_1 without the parameter p, the conditional distributions for the Gibbs sampling algorithm are given by

$$\begin{aligned}
p|\theta_{(p)},\mathcal{D},\mathbf{d}^* &\sim Beta\left(a_{11}+T_1,b_{11}+T_2\right),\\
S_E|\theta_{(S_E)},\mathcal{D},\mathbf{d}^* &\sim Beta\left(a_{12}+T_3,b_{12}+T_4\right),\\
S_P|\theta_{(S_P)},\mathcal{D},\mathbf{d}^* &\sim Beta\left(a_{13}+T_5,b_{13}+T_6\right),\\
\lambda_{01}|\theta_{(\lambda_{01})},\mathcal{D},\mathbf{d}^* &\sim Beta\left(a_{14}+T_7,b_{14}+T_8\right),\\
\lambda_{10}|\theta_{(\lambda_{10})},\mathcal{D},\mathbf{d}^* &\sim Beta\left(a_{15}+T_9,b_{15}+T_{10}\right),\\
\lambda_{00}|\theta_{(\lambda_{00})},\mathcal{D},\mathbf{d}^* &\sim Beta\left(a_{16}+T_{11},b_{16}+T_{12}\right) \text{ and}\\
\lambda_{11}|\theta_{(\lambda_{11})},\mathcal{D},\mathbf{d}^* &\sim Beta\left(a_{17}+T_{13},b_{17}+T_{14}\right). \qquad (11)
\end{aligned}$$

5 An example

Aiming to get estimates for the measures of the performance of cervical cytology (Papanicolaou test) and hybrid capture II (HC-II) in detecting neoplastic and pre-neoplastic cervical lesions, without a gold standard, a study was conducted using a sample of 807 women who visited two different public health units in Campinas, Brazil. Table 2 displays how these test results were distributed among study participants. Considering that smoking is a known risk factor for the disease, Table 2 shows also the frequency distribution of test outcomes by smoking status.

tests			smoking status (*)		
cervical cytology	hybrid capture II	total	1	2	3
negative	negative	653	408	126	119
positive	negative	21	13	5	3
negative	positive	102	68	24	10
positive	positive	31	17	11	3

(*) 1: was never a smoker; 2: current smoker; 3: smoker in the past

Table 2: Frequency distribution of tests findings by smoking status.

Using the proposed methodology, we estimated the sensitivity and specificity measures of cervical cytology and HC-II, without a reference test (gold standard). In this model, X is a covariate related to smoking status, coded as “was never a smoker”, “current smoker” or “was a smoker in the past”. To to introduce this variable in the model, we use a set of dummy variables X_1 and X_2, where X_1 and X_2 are both equal to zero when a woman was never a smoker; X_1 is equal to 1 and X_2 is equal to 0 when a woman is a current smoker; and when a woman was a smoker in the past, we used $X_1 = 0$ and $X_2 = 1$. From the respective conditional posterior distributions we generated a chain of 100,000 iterations, and in order to diminish some effect of the initial parameters values, we discarted the first 20,000 elements of each chain. For each parameter we considered every 50^{th} draw. The results for a Bayesian analysis without the covariate.are provided in Table 3. The choice of hyperparameter values for the prior distributions of $S_{E_1}, S_{E_2}, S_{P_1}$ and S_{P_2} were based in results introduced in articles from the medical literature. The hyperparameter values for the prior distributions of p were subjectively choosen, and a small sensitivity analysis was made by choosing other hyperparameter values, but their choice do not modify substantially the results presented below and the correspondent results are omitted here.

		posterior summaries		95% credible

β_{52}	−0.33981	0.36796	−1.05416	0.36621

Table 4: Posterior summaries (S.D.: standard deviation).

Table 4 shows the posterior summaries for the parameters in the Bayesian model that considers the smoking status as a covariate. The parameters β_{11} to β_{51} are related to category “current smoker” versus “was never a smoker”, and the parameters β_{12} to β_{52} are associated to category “was a smoker in the past” versus “was never a smoker”. We note that the 95% credible intervals for β_{11} to β_{51} and β_{12} to β_{52} included the value 0, suggesting that the effect of smoking status on the S_{E_1}, S_{E_2}, S_{P_1}, S_{P_2} and p measures is not important. Posterior mean estimates of S_{E_1}, S_{E_2}, S_{P_1}, S_{P_2} and p, calculated from simulated values for the vector θ_2, are given by: (1) (was never a smoker)

$\widehat{S_{E_1}} = 0.495$, $\widehat{S_{E_2}} = 0.979$, $\widehat{S_{P_1}} = 0.828$, $\widehat{S_{P_2}} = 0.895$ and $\widehat{p} = 0.088$; (2) (current smoker) $\widehat{S_{E_1}} = 0.540$, $\widehat{S_{E_2}} = 0.977$, $\widehat{S_{P_1}} = 0.829$, $\widehat{S_{P_2}} = 0.890$ and $\widehat{p} = 0.127$; and (3) (was a smoker in the past) $\widehat{S_{E_1}} = 0.499$, $\widehat{S_{E_2}} = 0.979$, $\widehat{S_{P_1}} = 0.811$, $\widehat{S_{P_2}} = 0.929$ and $\widehat{p} = 0.067$. These results suggest again that the smoking status is not related to prevalence of cervical lesions and the performance measures of the tests. We used the software SAS (proc IML) to perform all the simulations. The convergence of the Gibbs samples was monitored by standard existing methods [6] available in CODA package [3].

COMPSTAT'2004 Symposium

MULTIPLE CORRESPONDENCE SPLINE ANALYSIS FOR GRAPHICALLY REPRESENTING NONLINEAR RELATIONSHIPS BETWEEN VARIABLES

Koichi Adachi

Key words: Multiple correspondence analysis, principal component analysis inter-variable nonlinear relationships, trajectories of variables, smoothing splines.

COMPSTAT 2004 section: Data visualization.

Abstract: To deal with difficulties which may arise when multiple correspondence analysis (MCA) or principal component analysis (PCA) is used for finding inter-variable nonlinear relationships, we propose a variant of MCA. In this method, variables are represented as trajectories in a low-dimensional space, where the trajectories are defined using smoothing splines. In a simulation study, the proposed method was found to recover true trajectories better than MCA and PCA.

1 Introduction

We often encounter data including variables related nonlinearly to each other. Such a data set is illustrated in Table 1(A). There, the first variable, though correlated linearly to the second, has nonlinear relation to the third variable, showing that cakes of medium sweet are preferred, but less sweet or too sweet cakes are not preferred. To represent such nonlinear relationships graphically in a low-dimensional space, we propose a variant of MCA (multiple correspondence analysis) in this paper. This proposal is motivated by noting difficulties which may arise when MCA or PCA (principal component analysis) is used for exploring inter-variable nonlinear relations. To describe this motivation, we begin with formulating PCA and MCA within a common framework.

Let $\mathbf{X} = [\tilde{\mathbf{x}}_1, \ldots, \tilde{\mathbf{x}}_m]$ denote an n-objects by m-variables data matrix and the mutually different K_j values in $\tilde{\mathbf{x}}_j$ be collected into $\mathbf{y}_j{}' = [y_{j1}, \ldots, y_{jK_j}]$: for example, $\mathbf{y}_1{}' = [10, 25, 40]$ for $\tilde{\mathbf{x}}_1$ in Table 1(A). Let $\mathbf{G}_j = (g_{ijk})(n \times K_j)$ be the indicator matrix transformed from $\tilde{\mathbf{x}}_j$ as illustrated in Table 1(B): g_{ijk} (the ikth element of $\mathbf{G}_j$) takes one if $x_{ij} = y_{jk}$ and zero otherwise, with x_{ij} the ith element of $\tilde{\mathbf{x}_j}$. We further let $\mathbf{J} = \mathbf{I}_n - n^{-1}\mathbf{1}_n\mathbf{1}_n'$ be the $n \times n$ centering matrix with $\mathbf{I}_n$ the $n \times n$ identity matrix and $\mathbf{1}_n$ the $n \times 1$ vector of ones.

According to Gifi [3], PCA for centered data matrix $\mathbf{JX}$ is formulated as minimizing

(A) Data matrix $\mathbf{X}$

Cake	Sales $\tilde{\mathbf{x}}_1$	Name value $\tilde{\mathbf{x}}_2$	Sweet $\tilde{\mathbf{x}}_3$	...
1	10	1	5	...
2	10	1	1	...
3	25	2	1	...
4	40	3	3	...
5	40	4	3	...

(B) Matrix $\mathbf{G}$ transformed from $\mathbf{X}$

	Sales $\mathbf{G}_1$			Name value $\mathbf{G}_2$				Sweet $\mathbf{G}_3$		...
10	25	40	1	2	3	4	1	3	5	
1			1						1	...
1				1			1			...
	1				1				1	...
		1			1			1		...
		1				1		1		...

$$LP(\mathbf{F}, \mathbf{A}) = \sum_{j=1}^{m} \left\| \mathbf{F} - \mathbf{J}\tilde{\mathbf{x}}_j \mathbf{a}_j' \right\|^2 \tag{1}$$

over $\mathbf{F} = [\mathbf{f}_1, \ldots, \mathbf{f}_n]'$($n$-objects by p-dimensions) and $\mathbf{A} = [\mathbf{a}_1, \ldots, \mathbf{a}_m]'$($m \times p$) under the following normalization conditions.

$$\mathbf{F} = \mathbf{JF}. \tag{2}$$

$$n^{-1}\mathbf{F}'\mathbf{F} = \mathbf{I}_p. \tag{3}$$

In MCA, a value in a data set, i.e., y_{jk} is treated not as a quantity but just as a nominal category to be given score vector, which we express as $\mathbf{w}_{jk}(p \times 1)$. To obtain score vectors $\mathbf{W}_j = [\mathbf{w}_j 1, \ldots, \mathbf{w}_{jkj}]'$($K_j$-categories by p-dimensions),

$$LM(\mathbf{F}, \mathbf{W}) = \sum_{j=1}^{m} \|\mathbf{F} - \mathbf{G}_j \mathbf{W}_j\|^2 \tag{4}$$

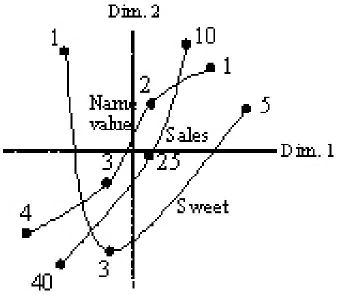
is minimized over $\mathbf{W} = [\mathbf{W}_1{}', \ldots, \mathbf{W}_m{}']'(\sum_{j=1}^{m} K_j \times p)$ and $\mathbf{F}(n \times p)$ subject to (2) and (3) [3]. Loss function (4) is derived from the following principle.

> *Homogeneity principle.* Let k_{ij}^* denote the category associated with object i for variable j, with $x_{ij} = y_{j,k_{ij}^*}$ (e.g., $k_{31}^* = 2$ and $x_{31} = y_{12} = 25$ in Table 1). Then, $\mathbf{w}_{j,k_{ij}^*}$ (the score vector of the category for object i) should be close (or homogeneous) to $\mathbf{f}_i$ (the vector of object i).

The departure from this principle can be expressed as $\sum_i \sum_j \|\mathbf{f}_i - \mathbf{w}_{k,k^*_{ij}}\|^2$, which equals (4).

Noticing that $\mathbf{D}_j = \mathbf{G}'_j\mathbf{G}_j$ is the diagonal matrix having category frequencies on the diagonal, $\mathbf{D}_j\mathbf{1}_{K_j} = \mathbf{G}'_j\mathbf{1}_n, \mathbf{G}_j\mathbf{1}_{K_j} = \mathbf{1}_n$, and $\tilde{\mathbf{x}}_j = \mathbf{G}_j\mathbf{y}_j$, we find $\mathbf{J}\mathbf{G}_j = \mathbf{G}_j\mathbf{E}_j$ and $\mathbf{J}\tilde{\mathbf{x}}_j = \mathbf{J}\mathbf{G}_j\mathbf{y}_j = \mathbf{G}_j\mathbf{E}_j\mathbf{y}_j$ with $\mathbf{E}_j = \mathbf{I}_{K_j} - n^{-1}\mathbf{1}_{K_j}\mathbf{1}'_{K_j}\mathbf{D}_j$. Thus (1) is rewritten as

$$LP(\mathbf{F}, \mathbf{A}) = \sum_{j=1}^{m} \|\mathbf{F} - \mathbf{G}_j\mathbf{E}_j\mathbf{y}_j\mathbf{a}'_j\|^2. \tag{5}$$



Comparing this with (4), we can find that PCA is a constrained version of MCA with $\mathbf{W}_j = \mathbf{E}_j\mathbf{y}_j\mathbf{a}'_j$.

For the data in Table 1, MCA might yield a result illustrated in Figure 1. There, a trajectory associated with variable j connects the score vectors $\mathbf{w}_{jk}$ and $\mathbf{w}_{j,k+1}$ which are represented as points labeled with the corresponding y_{jk} and $y_{j,k+1}$. This configuration allows us easily to grasp inter-variable correlations: nonlinear relations of variable "sweet" to the others are found by the curved trajectory for "sweet". Such relations cannot be found in results of PCA, since $\mathbf{W}_j$ is constrained as $\mathbf{W}_j = \mathbf{E}_j\mathbf{y}_j\mathbf{a}'_j$, i.e., $\mathbf{w}_{jk} = z_{jk}\mathbf{a}_j$ with z_{jk} the kth element of $\mathbf{z}_j = \mathbf{E}_j\mathbf{y}_j$, and PCA yields straight trajectories extending in the direction of vector $\mathbf{a}_j$. Nishisato [5] has illustrated the above advantage of MCA with a numerical example. This advantage owes to that y_{jk} is regarded just as a category "k" to be given score vector $\mathbf{w}_{jk}$.

However, MCA may not work well if K_j is large, since the number of unknown parameters $\mathbf{w}_{jk}$ increases so that the resulting $\mathbf{w}_{jk}$ may be unstable and give too zigzag trajectories. As a remedy for this difficulty, Nishisato [5] has suggested classifying $y_{j1}, \ldots, y_{jK_j}$ into a fewer categories. However, how to classify them has not been clarified. In this paper, we consider another method, in which trajectories are required to be smooth. This requirement is attained by defining a loss function as

$$L(\mathbf{F}, \mathbf{W}) = LM(\mathbf{F}, \mathbf{W}) + s \times LS(\mathbf{W}), \tag{6}$$

i.e., by combing (4) and $LS(\mathbf{W})$ expressing loss of the smoothness of trajectories, with s a positive constant.

Function $LS(\mathbf{W})$ and minimization of (6) are detailed in section 2. A simulation study is described in section 3 and the method is compared with related techniques in the final section.

2 Proposed method

We regard the trajectory for variable j (illustrated in Figure 1) as a function of continuous variable Y_j and express this function as $\mathbf{w}_j(Y_j)$ with its lth element $w_{jl}(Y_j)$. According to this notation, score vector $\mathbf{w}_{jk}$ is expressed as $\mathbf{w}_{jk} = \mathbf{w}_j(y_{jk})$, that is, $\mathbf{w}_j(y_{jk})$ is the point at $Y_j = y_{jk}$ on trajectory $\mathbf{w}_j(Y_j)$. We require $w_{jl}(Y_j)$ to change smoothly with Y_j. The departure from the smoothness can be expressed as the integral of the squared second derivative of $w_{jl}(Y_j)$:

$$LS_{jl} = \int \left(\frac{d^2 w_{jl}(Y_j)}{dy^2} \right)^2 dY_j. \tag{7}$$

We define $LS(\mathbf{W})$ in (6) as the sum of (7) over variables j and dimensions l.

It is known that (7) takes a lower value when $w_{jl}(Y_j)$ is the smoothing spline (natural cubic spline) function of Y_j with knots $y_{j1}, \ldots, y_{jK_j}$, than when $w_{jl}(Y_j)$ is any other functional [6]. We thus let $w_{jl}(Y_j)$ be the smoothing spline. Then, integral (7) can be rewritten in the form $LS_{jl} = \tilde{\mathbf{w}}'_{jl}\mathbf{Q}_j\mathbf{R}_j^{-1}\mathbf{Q}'_j\tilde{\mathbf{w}}_{jl}$ (e.g., Green and Silverman [4]). Here, $\tilde{\mathbf{w}}_{jl}$ is the l-th column of $\mathbf{W}_j$, and $\mathbf{Q}_j$ and $\mathbf{R}_j$ are $K_j \times (K_j - 2)$ and $(K_j - 2) \times (K_j - 2)$ tridiagonal matrices, respectively, defined using $h_{jk} = y_{j,k+1} - y_{jk}$ as follows. With $q_{jkk'}$ the kk'th elements of $\mathbf{Q}_j$, its non-zero elements are expressed as $q_{jkk} = h_{jk}^{-1}, q_{j,k+1,k} = -h_{jk}^{-1} - h_{j,k+1}^{-1}$, and $q_{j,k+2,k} = -h_{j,k+1}^{-1}$ for $k = 1, \ldots, K_j - 2$. With $r_{jkk'}$ the kk'th elements of $\mathbf{R}_j$, its non-zero elements are defined as $r_{jkk} = 3^{-1}(h_{jk} + h_{j,k+1})$ for $k = 1, \ldots, K_j$ and $r_{j,k-1,k} = r_{j,k,k-1} = 6^{-1}h_{jk}$ for $k = 2, \ldots, K_j - 2$. The sum of (7) is thus written as

$$LS(\mathbf{W}) = \sum_{j=1}^{m}\sum_{l=1}^{p} LS_{jl} = \sum_{j=1}^{m} \mathrm{tr}\, \mathbf{W}'_j\mathbf{Q}_j\mathbf{R}_j^{-1}\mathbf{Q}'_j\mathbf{W}_j. \tag{8}$$

Substituting (7) and (8) into (6), we have

$$L(\mathbf{F}, \mathbf{W}) = \sum_{j=1}^{m} \left(\|\mathbf{F} - \mathbf{G}_j\mathbf{W}_j\|^2 + s \times \mathrm{tr}\, \mathbf{W}'_j\mathbf{Q}_j\mathbf{R}_j^{-1}\mathbf{Q}'_j\mathbf{W}_j \right). \tag{9}$$

This is minimized over $\mathbf{W}$ and $\mathbf{F}$ subject to (2) and (3), for given p and $s > 0$. We refer to this method as multiple correspondence spline analysis (MCSA) in this paper.

Loss function (9) is rewritten as

$$L(\mathbf{F}, \mathbf{W}) = nmp = \mathrm{tr} \sum_{j=1}^{m} \left(\mathrm{tr}\, \mathbf{W}'_j\mathbf{C}_j\mathbf{W}_j - 2\mathrm{tr}\, \mathbf{F}'\mathbf{J}\mathbf{G}_j\mathbf{W}_j \right). \tag{10}$$

Here, (2) and (3) are used and $\mathbf{C}_j = \mathbf{D}_j + s\mathbf{Q}_j\mathbf{R}_j^{-1}\mathbf{Q}_j'$. We supposed $\mathbf{D}_j$ to be positive definite. Then, $\mathbf{C}_j$ is also positive definite, since $\mathbf{Q}_j\mathbf{R}_j^{-1}\mathbf{Q}_j'$ is nonnegative definite and $s > 0$. Solving $\partial L(\mathbf{FW})/\partial \mathbf{W}_j = \mathbf{0}$ (with $\mathbf{0}$ denoting a null matrix or vector of an appropriate size), we find that the optimal $\mathbf{W}_j$ satisfies

$$\hat{\mathbf{W}}_j = \mathbf{C}_j^{-1}\mathbf{G}_j'\mathbf{J}\mathbf{F}. \tag{11}$$

The substitution of (11) into $\mathbf{W}_j$ in (10) yields

$$L(\mathbf{F}, *) = nmp - \operatorname{tr} \mathbf{F}'\mathbf{JGC}^{-1}\mathbf{G}'\mathbf{JF}$$

with $\mathbf{G} = [\mathbf{G}_1, \ldots, \mathbf{G}_m]$ $(n \times \sum_{j=1}^m K_j)$ and $\mathbf{C}$ the $(\sum_{j=1}^m K_j) \times (\sum_{j=1}^m K_j)$ block diagonal matrix whose jth diagonal block is $\mathbf{C}_j$. Minimizing $L(\mathbf{F}, *)$ subject to (2) and (3) is attained using the SVD (singular value decomposition) $\mathbf{JGC}^{-\frac{1}{2}} = \mathbf{NTM}'$. Here, $\mathbf{N}'\mathbf{N} = \mathbf{M}'\mathbf{M} = \mathbf{I}_g$ with g the rank of $\mathbf{JGC}^{-\frac{1}{2}}$ and $\mathbf{T}$ is the diagonal matrix whose lth diagonal element is the lth largest singular value of $\mathbf{JGC}^{-\frac{1}{2}}$. Let $\mathbf{T}_p$ be the first $p \times p$ diagonal block of $\mathbf{T}$, and $\mathbf{N}_p$ and $\mathbf{M}_p$ contain the first p columns of $\mathbf{N}$ and $\mathbf{M}$, respectively, with $p \le g$. The optimal $\mathbf{F}$ is then given by $\hat{\mathbf{F}} = n^{\frac{1}{2}}\mathbf{N}_p$. Substituting this and the above SVD into (11), we find the optimal $\mathbf{W}$ is given by $\hat{\mathbf{W}} = n^{\frac{1}{2}}\mathbf{C}^{-\frac{1}{2}}\mathbf{M}_p\mathbf{T}_p$. That is, the solution is given explicitly using SVD.

However, we may encounter cases where the size of $\mathbf{JGC}^{-\frac{1}{2}}$ to be decomposed, i.e., n or $\sum_{j=1}^m K_j$, is so large that we cannot obtain solution easily. We thus use another algorithm without the decomposition of large-sized matrices. This is an alternating least squares algorithm, in which the following two steps are iterated alternately until $L(\mathbf{F}, \mathbf{W})$ is judged to converge to its minimum.

Step 1. Given $\mathbf{F}, L(\mathbf{F}, \mathbf{W})$ is minimized over $\mathbf{W} = [\mathbf{W}_1', \ldots, \mathbf{W}_m']'$. The optimal $\mathbf{W}$ is obtained with (11).

Step 2. Given $\mathbf{W}, L(\mathbf{F}, \mathbf{W})$ is minimized over $\mathbf{F}$ subject to (2) and (3). The optimal $\mathbf{F}$ is given by $\hat{\mathbf{F}} = n^{\frac{1}{2}}\mathbf{KL}'$ with $\mathbf{JGW} = \mathbf{KSL}'$ the SVD of $\mathbf{JGW}(n \times p)$. $\mathbf{K}$ and $\mathbf{L}$ can be obtained with the eigenvalue-decomposition of $\mathbf{V} = \mathbf{W}'\mathbf{G}'\mathbf{JGW}$. This size is of $p \times p$, and p is usually far smaller than n or $\sum_{j=1}^m K_j$.

3 Simulation

To evaluate the proposed method MCSA, we performed a small simulation study, in which artificial data synthesized from true scores were used for assessing how well they are recovered by the method.

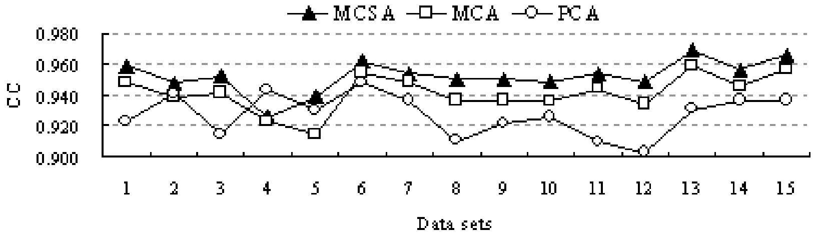
Setting $p = 2,\ n = 200,\ m = 10,\ K_j = 10$, and $y_{jk} = k$ for $j = 1, \ldots, m$, we had different fifteen sets of true scores and data matrices, i.e., 15 sets of $\{\mathbf{F}, \mathbf{W}$ and $\mathbf{X}$ (or $\mathbf{G}$)$\}$. Each set was generated through the following three stages.

Stage 1. $\mathbf{f}_i$ $(i = 1, \ldots, n)$ were sampled independently from the bivariate normal distribution with mean vector $\mathbf{0}$ and covariance matrix $\mathbf{I}_2$. This sampling allows the resulting $\mathbf{F}$ approximately to satisfy (2) and (3), but not exactly.

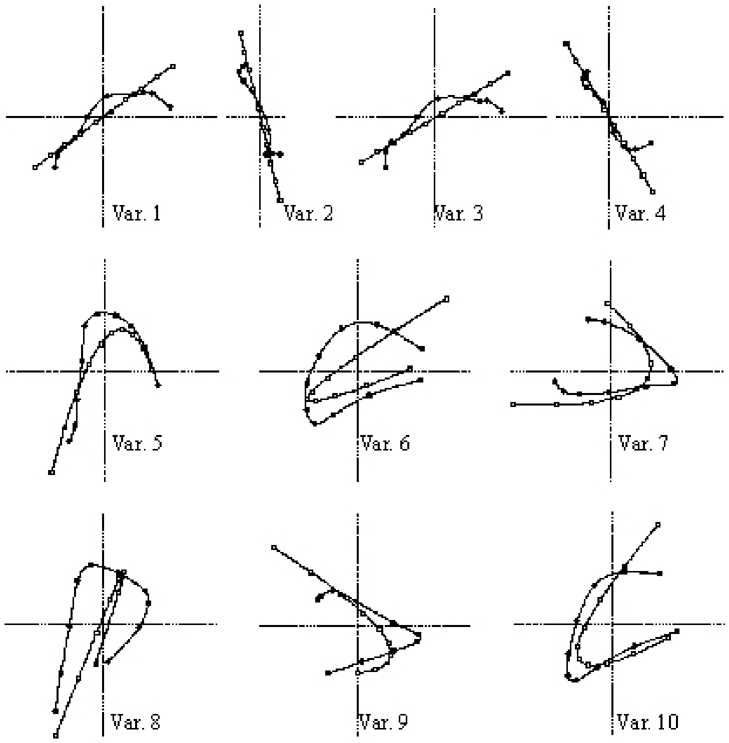
Stage 2. To obtain true trajectories $\mathbf{w}_j(Y_j)$ which are linear for $j \leq 4$ and quadratic for $j \geq 5$ (see Figure 3), we first generated *raw* trajectories $\mathbf{w}^*_j(Y_j)$ and then transformed them into $\mathbf{w}_j(Y_j)$ which yield true score vectors $\mathbf{w}_{jk} = \mathbf{w}_j(y_{jk})$. Using orthogonal polynomials, the lth element of $\mathbf{w}^*_j(Y_j)$ was chosen as $w^*_{jl} = b_{0l}u_{1j}(Y_j)$ for $j \leq 4$ and $w^*_{jl}(Y_j) = b_{1l}u_{1j}(Y_j) + b_{2l}u_{2j}(Y_j)$ for $j \geq 5$, where $u_{1j}(Y_j) = 1-2Y_j/(K_j-1), u_{2j}(Y_j) = 1-6Y_j/(K_j-1)+6Y_j(Y_j-1)/[(K_j-1)(K_j-2)]$, and b_{0l}, b_{1l} and b_{2l} were independently sampled from the uniform distribution ranging from -1 to 1. Then, $w^*_{jl}(Y_j)$ was linearly transformed into $w_{jl}(Y_j)$ so that the average and the variance of $w_{jl}(y_{jk})$ over $k = 1, \ldots, K_j$ became zero and unit, respectively. This standardization allows the distribution of score vectors to be similar to that of $\mathbf{f}_i$.

Stage 3. We generated data $\mathbf{X} = (x_{ij})$ in such a manner that they are consistent to the homogeneity principle which implies that k^*_{ij} (a category to be associated with object i) should be the category whose score vector is close to $\mathbf{f}_i$. That is, we set $k^*_{ij} = \arg\min_{1 \leq k \leq K_j} \|\mathbf{f}_i - \mathbf{w}_{jk}\|$ to generate $x_{ij} = y_{j,k_ij^*}$. This is simplified as $x_{ij} = \arg\min_k \|\mathbf{f}_i - \mathbf{w}_{jk}\|$, since of $y_{jk} = k$, in this simulation.

Each of the $15\mathbf{X}'s$ or the corresponding $\mathbf{G}'s$ is analyzed by MCSA, MCA and PCA. In order to assess the recovery of score vectors, we obtained a congruence coefficient (CC). This is defined as the cosine between $100 \times 99/2$ dimensional vectors $\mathbf{d}$ and $\hat{\mathbf{d}}$, where $\mathbf{d}$ contains the distances between the 100(= 10 variables $\times$10 categories) true $\mathbf{w}_{jk}$'s and $\hat{\mathbf{d}}$ contains the corresponding distances for the resulting $\hat{\mathbf{w}}_{jk}$. At the highest CC takes one which shows complete recovery. The results are shown in Figure 2. There, the CC's for MCSA are found higher than those of PCA and MCA for 14 data sets (excluding the fourth set), which shows the superiority of MCSA in recovering score vectors.



To illustrate the recovery of true trajectories by MCSA, the result for the third data set giving the median CC = 0.952 over CC's for 15 sets, is shown in Figure 3. There, the pair of the true and resulting trajectories for each variable is depicted separately in each panel, for ease of grasping recovery. Though the resulting trajectories deviate somewhat from true ones, the recovery is thought satisfactory in that we can find true inter-variable relationships from the result fairly well.



4 Final remarks

In order to represent inter-variable relations graphically in a low-dimensional configuration, we proposed a variant of MCA named MCSA. In MCSA, variables are represented as trajectories defined using smoothing splines and the objective function to be minimized is formed by combining the loss function for MCA with the loss of the smoothness of trajectories.

A fixed effect curvilinear model (FECM) proposed by Besse and Ferraty [2] is related to MCSA, in that FECM is an extension of the nonmetric PCA that is a variant of MCA [3] and smoothing splines are also used in FECM. According to our notation, the loss function for FECM may be written as

$$LF(\mathbf{F}, \mathbf{A}, \mathbf{Y}) = \sum_{j=1}^{m} \|\mathbf{G}_j \mathbf{E}_j \mathbf{y}_j - \mathbf{F}\mathbf{a}_j\|^2 + \sum_{j=1}^{m} s_j \mathbf{y}_j' \mathbf{Q}_j \mathbf{R}_j^{-1} \mathbf{Q}_j \mathbf{y}_j, \qquad (12)$$

which is minimized over $\mathbf{F}, \mathbf{A}$ and $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_m]$ under normalization conditions (2), (3) and $\mathbf{y}_j \mathbf{E}_j' \mathbf{D}_j \mathbf{E}_j \mathbf{y}_j = n$, for given $s_j > 0$. Note that $\mathbf{y}_j$ is unknown in (12). Since the minimization of $\|\mathbf{G}_j \mathbf{E}_j \mathbf{y}_j - \mathbf{F}\mathbf{a}_j\|^2$ is found equivalent to that of $\|\mathbf{F} - \mathbf{G}_j \mathbf{E}_j \mathbf{y}_j \mathbf{a}_j'\|^2$ under the normalization conditions, FECM can also be formulated as minimizing

$$LF(\mathbf{F},\mathbf{A},\mathbf{Y}) = \sum_{j=1}^{m} \|\mathbf{F} - \mathbf{G}_j\mathbf{E}_j\mathbf{y}_j\mathbf{a}_j'\|^2 + \sum_{j=1}^{m} s_j\mathbf{y}_j'\mathbf{Q}_j\mathbf{R}_j^{-1}\mathbf{Q}_j\mathbf{y}_j. \qquad (13)$$

The first term in the right side of (13) is identical to (5) and can thus be viewed as a constrained version of (4) with $\mathbf{W}_j = \mathbf{E}_j\mathbf{y}_j\mathbf{a}_j'$. It shows that, differently than our method, FECM yields linear trajectories of variables extending in the direction of $\mathbf{a}_j$. However, $\mathbf{y}_j$ is unknown in FECM, which differs from PCA.

A variant of MCA with smoothing splines has also been presented by Adachi [1]. However, in this method splines are used for the smoothing on **F** (the scores of objects), while they are used for **W** (variables) in our MCSA.

In the simulation study, we chose one as the value of s, i.e., as the weight for the loss of smoothness. However, another choice might yield a better result. It thus remains for future study to consider a method for choosing the optimal value of s.

MODELLING SHORT TERM VARIABILITY INTERACTIONS IN ECG: QT VERSUS RR

Rute Almeida, Ana Paula Rocha, Paules E. Pueyo, Juan Pablo Martínez and Pablo Laguna

Key words: Parametric modelling, QT variability, HRV.

COMPSTAT 2004 section: Time series analysis.

Abstract: QT and RR series interactions were explored by a dynamic linear approach using AR and ARARX models with automatic orders selection. Validation with simulated data and application to real records are presented. An important QTV fraction was found to be not linearly driven by HRV.

1 Introduction

The electrocardiogram (ECG) analysis is extensively used as a diagnostic tool to provide information on the heart function. Each cardiac beat (Figure 1) is typically associated to a sequence of five principal waves denoted by P, Q, R, S and T, whose characteristics are clinically relevant. In particular, the time interval between the onset of the QRS complex and the T wave end, known as QT interval, is considered to express the duration of ventricular repolarization. Abnormal QT values have been associated with ventricular pro-arrythmicity and its beat-to-beat variations are, to some extent, driven by the autonomic nervous system through the RR interval (measured as the time interval between consecutive beats). However it has not been yet clearly quantified which fraction of QT variability (QTV) is effectively correlated with RR beat-by-beat variations (Heart Rate Variability - HRV).

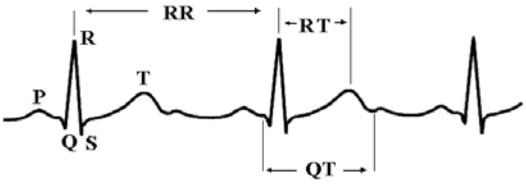

Figure 1: Schematic representation of relevant information in a cardiac beat.

The determination of RR and QT sequences requires the detection and delineation of ECG waves and limits. A wavelet transform based delineation system has proven to be quite robust against noise and morphological variations [3], even in the problematic T wave. Problems in delineation of T end lead to uncertainty in QTV measures which, allied to its smaller amplitude compared to HRV, represents the main difficulties in exploring this relation.

Many authors used alternative measures such as the RT interval (time between the peaks of the R and T waves); however, in spite of being easier to measure, the RT presents even shorter length than QT interval, additionally penalising the variability measures. A linear dynamic parametric approach was proposed by Porta et al [7] to express the interactions between the RR and RT intervals and allowing to quantify the fraction of the RT variability driven by RR. In previous work [1] we used a linear low order model similar to the one proposed by Porta to explore the short term HRV and QTV relations. A generalized and improved version of that model including automatic orders selection is now proposed and validated, defining an approach to quantify the fraction of QTV not driven by HRV.

2 Methods

2.1 Model formulation

Our approach, based on Porta [7], expresses RR and QT variability interactions in an open loop linear model (Figure 2) where A_{11}, A_{12}, A_{22} and D are polynomials in z^{-1} with coefficients $a_{11}[k]$, $a_{12}[k]$, $a_{22}[k]$ and $d[k]$, respectively. The series $W_{RR}[n]$ and $W_{QT}[n]$ are uncorrelated stationary zero-mean white noises with variances λ^2_{RR} and λ^2_{QT} and n denotes beat number.

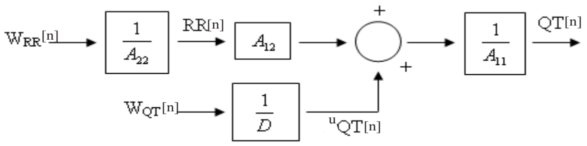

Figure 2: Schematic representation of the QTV versus HRV model.

$RR[n]$ series was modelled as an AR_p stationary random process given by

$$RR[n] = -\sum_{k=1}^{p} a_{22}[k]RR[n-k] + W_{RR}[n] \tag{1}$$

The QT was assumed to result from two uncorrelated sources, one driven by heart rate and other resulting of an exogenous input ($ARARX_q$ model [2])

$$\begin{aligned} QT[n] &= \sum_{k=0}^{q} a_{12}[k]RR[n-k] - \sum_{k=1}^{q} a_{11}[k]QT[n-k] +^u QT[n], \\ {}^uQT[n] &= -\sum_{k=1}^{q} d[k]\,{}^uQT[n-k] + W_{QT}[n] \end{aligned} \tag{2}$$

Therefore, the model accounts for the possible dependence on its past values and those of the RR interval (as shown in recent studies [8]). For simplicity, the same order q was assumed for all ARARX model polynomials, while a possible different order p is allowed for the AR model. This is a generalization from previous approaches [1], [7] where the same order was considered for all polynomials in the model. In fact there is no reason to constrain the QT and RR sequences to the same memory of its own past.

The assumption of uncorrelated sources allows to compute the Power Spectral Density (PSD) of QT ($S_{QT}(f)$) as the sum of the partial spectra that express each one of the contributions

$$S_{QT/W_{RR}}(f) = \overline{RR}\lambda_{RR}^2 \left| \frac{A_{12}(z)}{A_{11}(z)A_{22}(z)} \right|^2_{z=\exp(j2\pi f\overline{RR})} \tag{3}$$

$$S_{QT/W_{QT}}(f) = \overline{RR}\lambda_{QT}^2 \left| \frac{1}{A_{11}(z)D(z)} \right|^2_{z=\exp(j2\pi f\overline{RR})} \tag{4}$$

where f is the frequency in Hz. As both $QT[n]$ and $RR[n]$ series are unevenly sampled the mean RR interval ($\overline{RR}$) was used as sampling rate for estimating the PSD functions, what has been shown acceptable for low frequencies far from the Nyquist frequency [4]. As usual in HRV studies, the spectral energy within each frequency band (*band*) was measured taking the areas (P^{band}) below the spectra, S,

$$P_E^{band} = \int_{f\in band} S_E(f)df; \tag{5}$$

with $E \in \{QT, QT/W_{QT}, QT/W_{RR}\}$. The ratios between $P_{QT/W_{QT}}^{band}$ and in total power P_{QT}^{band} represent the relative contribution of the QTV not driven by RR in the frequency band *band*.

2.2 Model identification and order selection

From the $RR[n]$ and $QT[n]$ interval series corrected from the mean, the polynomial A_{11} was estimated using least squares, while the ARARX model parameters were iteratively obtained using a generalized least squares methodology [2]. For adequate orders the convergence to white noise residual W_{QT} is expected in a reasonable small number of iterations and a large enough SNR guarantees that the minima of the square residue are global [2].

From $p, q \in \{6, 8, 10, 12, 14, 16, 18\}$, an order was considered to be adequate for modelling a given segment of data if the normalized autocorrelations of the residual ($W_{RR}[n]$ or $W_{QT}[n]$) satisfied a 5% significance bilateral test, both in lags lower than 40 beats and considering all lags. The optimal p and q were automatically selected from the adequate orders as the ones that better satisfied a common criteria such as FPE or AIC [2]. The uncorrelation between $W_{RR}[n]$ and $W_{QT}[n]$ was also verified for the same 5% significance.

2.3 Simulation set-up and performance evaluation

The validation of the model was based on simulated $RR[n]$ and $QT[n]$ series with known QTV fraction correlated with RR ($QT_{W_{RR}}$).

The $RR[n]$ sequences were simulated using a model IPFM (integral pulse frequency modulation) [4] following a AR_{10} modulating signal. Two models (RR1 and RR2) with different main frequency components (Figure 3) were used to simulate uncorrelated RR series realizations.

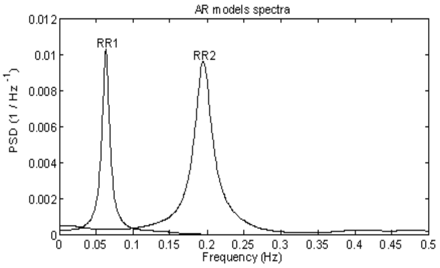

Figure 3: Spectra of the AR_{10} models used to generate data.

To obtain realistic QT series from RR sequences we considered a constant QT value qt_0, extracted from a real beat, and used the classical $Bazett's$ formula as a static relation between a QT and the previous RR [8]: $QTj[n] = qt_0\sqrt{RRj[n]}$, for $j = 1, 2$. The test data was defined considering 3 cases:

A: QT and RR correlated: $RR1_i[n]$ vs $QT1_i[n]$ and $RR2_i[n]$ vs $QT2_i[n]$;

B: QT and RR uncorrelated: $RR1_i[n]$ vs $QT2_i[n]$ and $RR2_i[n]$ vs $QT1_i[n]$;

C: Mixture of the dependencies: $RR1_i[n]$ vs $QT1_i[n]+QT2_i[n]-\overline{QT2_i}$ and $RR2_i[n]$ vs $QT1_i[n]+QT2_i[n]-\overline{QT1_i}$; were $\overline{QTj_i} = (\sum_{n=0}^{N} QTj_i[n])/N$.

were i denotes realization. The $QT[n]$ fraction linearly driven by $RR[n]$ is denoted as $QT_{RR}[n]$ and calculated for each pair of test data as the projection of ($QT_i[n]$-$\overline{QT_i}$) over the subspace generated by the corresponding ($RR_i[n]$-$\overline{RR_i}$) and its delayed vectors up to order 10 (in accordance with RR simulation). The ratio between the power variability measures of this projection and of the total QTV corresponds to the fraction correlated with HRV. The reference variability measures $\tilde{P}_E^{band}$ were obtained from AR_{10} spectral model, analogously as P_E^{band} and the errors calculated as $P_E^{band} - \tilde{P}_E^{band}$.

After identification of the model (figure 2), from the estimated coefficients and the residues $W_{RR}[n]$ and $W_{QT}[n]$, we calculated explicitly the signals $QT_{W_{RR}}[n]$ and $QT_{W_{QT}}[n]$ corresponding to the two uncorrelated driving sources in QT ($QT[n] - \overline{QT} = QT_{W_{QT}}[n] + QT_{W_{RR}}[n]$). The similarity of $QT_{W_{RR}}[n]$ and the reference projection $QT_{RR}[n]$ was evaluated from the coherence between them and the same was applied to $QT_{W_{QT}}[n]$ versus the difference between ($QT[n] - \overline{QT}$) and the reference projection (corresponding to the QTV fraction uncorrelated to HRV). Both spectral coherences were calculated using an non parametric approach (Welch method with a Hanning window).

2.4 Real data set

ECG recordings of young normal subjects from POLI/MEDLAV and Politecnico Ca' Granda databases [6] were used in this study (3 leads at 500 Hz) and each lead was processed by the delineation system in [3]. Only segments with minimum length of 315 consecutive beats with valid RR and QT intervals were considered in the subsequent analysis: anomalies in RR series were identified [5] and QT intervals out of a 3-standard deviation band were rejected as possible outliers. Longer segments were carved up respecting the minimum length admitted, what allowed to obtain 29 segments from POLI/MEDLAV database and 135 segments from Politecnico Ca' Granda database, with a mean length of 415 and 402 beats (≈ 292.46 and 329.24 sec), respectively.

3 Results and discussion

The methods were implemented using MATLAB and the facilities of the System Identification Toolbox. All the results are relative to the orders chosen by FPE but analogous ones were obtained using AIC. To evaluate whether the uncorrelated fraction differed for different frequencies, the measures were estimated considering separately low frequency (band = LF: 0.04-0.15 Hz) and high frequency (band = HF: 0.15-0.4Hz), frequency bands typically used in HRV studies. Total power (band = TP) was considered as the band from 0.04 Hz to the highest frequency present in each spectrum.

3.1 Simulated data

We simulated 50 uncorrelated RR realizations ($i = 1, ..., 50$) with 348 beats at 500 Hz, resulting on a test data of 300 pairs of RR vs QT series.

As expected the orders selected (figure 4, left) were mainly the lowest, as an AR_{10} was used to generated $RR[n]$ series and the IPFM model does not change revelantly the frequency components, for the considered frequency bands [4]. The errors in the calculated ratios between $P^{band}_{QT/W_{QT}}$ and P^{band}_{QT} were lower than 5% for more than 75% of the series in LF and HF frequency bands and for about 96% of the segments considering TP. In the right panel of figure 4 are presented the distribution of the errors for each case.

The mean and standard deviation of the errors in the estimated QTV fraction uncorrelated to RR can be found in the table below, for each case of simulated series and for all the data set, considering each frequency band.

Considering all data sets, the mean errors were lower that 4% for all

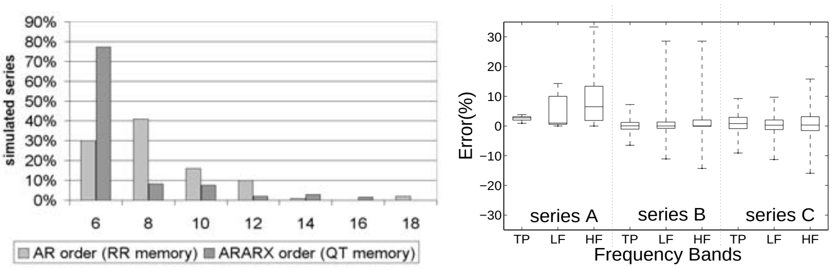

Figure 4: Simulated data: left) selected orders; right) box and whisker plots of errors in the ratios between $P^{band}_{QT/W_{QT}}$ and P^{band}_{QT}.

	series A	series B	series C	all data sets
$P^{TP}_{QT/W_{QT}}$	2.53 ± 0.76	-0.06 ± 2.11	0.88 ± 3.12	1.12 ± 2.46
$P^{LF}_{QT/W_{QT}}$	4.56 ± 5.21	1.01 ± 5.99	0.63 ± 3.22	2.07 ± 5.24
$P^{HF}_{QT/W_{QT}}$	9.45 ± 8.89	1.46 ± 7.10	0.55 ± 4.48	3.82 ± 8.10

Table 1: Errors in ratios over simulated data ($\%, mean \pm std$).

bands. The increased error found in series A is due to the very low power of RR1 and QT1 series in HF band and of RR2 and QT2 in LF band (as illustrated in Fig. 2), resulting in a small absolute error on the estimated PSD measures holding a high percent importance. Eliminating the series A the mean results became lower that 1%, with a relevant decrease on std values (0.41 ± 2.70 for TP, 0.82 ± 4.80 for LF and 1.00 ± 5.94 for HF).

The gain (evaluated as the squared absolute value) and phase (angle) of the complex spectral coherence γ between the model estimated $QT_{W_{RR}}[n]$ and the projection $QT_{RR}[n]$ used as reference are presented in the table below, for each frequency band. The high gains reflect the degree of similarly between the variability distribution shapes and thus $QT_{W_{RR}}[n]$ has frequency contents close to $QT_{RR}[n]$ both in power as in location of peaks. The lower gains relative to $QT_{W_{QT}}[n]$ are partially related with the very low power in some regions of the simulated spectra (case A). Excluding these series the mean gain increase to 0.87 (TP), 0.93 (LF) and 0.86 (HF). The very low phases reflect the no existence of delays in the model.

	$QT_{W_{QT}}[n]$		$QT_{W_{RR}}[n]$	
	γ gain	γ phase (rad)	γ gain	γ phase (rad)
TP	0.98	0.01	0.76	-0.01
LF	0.99	-0.02	0.80	-0.01
HF	0.90	0.01	0.75	-0.01

Table 2: Mean spectral coherence between QTV fractions and the references.

3.2 Real data

We obtained adequate models for 28 segments in POLI/MEDLAV and 132 in Politecnico Ca' Granda database and in 4 cases for which we did not found an adequate order to the AR model part.

In the left panel of figure 5 the orders selected by FPE for each model part are presented. Lower orders are more frequent for the ARARX model than for AR, reflecting different dependence of QT from its own past (memory) and past RR intervals. This can also be seen in simulated signals (left side of figure 4) validating that the QT intervals were realistically simulated.

The fraction uncorrelated with HRV was found to be higher than 40% for 98% of the segments in TP and HF band and for 91% in LF suggesting that other factors rather than RR could drive an important part of QTV. The values found for the ratios (%) between the measures on uncorrelated fraction and total QTV spectrum were very high, as illustrated in Figure 5. It is worthwhile to remark that in this study we aimed to estimate the fraction of QTV that is not correlated with HRV. The uncorrelation between that part of QTV and HRV does not imply that there is not any physiological dependence between them, since non-linear effects are not taken into account.

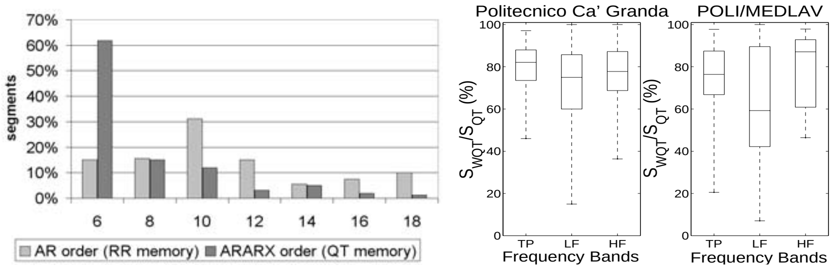

Figure 5: Real data: left) selected orders; right) box and whisker plots of the ratios between $P^{band}_{QT/W_{QT}}$ and P^{band}_{QT}.

4 Concluding remarks

This work discusses the characterization of the short term QT versus RR variabilities by applying a linear open loop model that includes an approach for order selection in each part of the model. The methodology was validated with simulated data and applied to real records. The orders selected for the RR model part are generally higher than for QT what can be associated to differences in the memory of the signals. The results point out that an important part of QTV (more than 40%) is not linearly driven by RR.

The study of the QT versus RR interactions is a complex problem. A deeper characterization requires the incorporation of additional information on the model. Identification and interpretation of the sources non-correlated with RR are the driving force for future studies.

THE THRESHOLD ARMA MODEL AND ITS AUTOCORRELATION FUNCTION

Alessandra Amendola, Marcella Niglio
and Cosimo Damiano Vitale

Key words: SETARMA model, indicator process, autocorrelation.

COMPSTAT 2004 section: Time series analysis.

Abstract: This paper considers the autocorrelation function of a particular family of threshold structure, the Self Exciting AutoRegressive Moving Average (SETARMA) model. Its is initially presented in the original form and some properties of the process which regulates the switching among the regimes are shown. An alternative representation of the SETARMA structure is then proposed and its autocorrelation function is exactly derived.

1 Introduction

The statistical and econometric literature has given an increasing attention to threshold models and different structures have been proposed in the years.

In the present paper the attention has been focused on a particular class of threshold models, the Self Exciting Threshold AutoRegressive Moving Average [4], whose dependence structure has been investigated. In particular the aim of the paper is to derive the analytic expression of the autocorrelation function of the SETARMA models which can be used to compute well known indexes to evaluate how far the process is from the linearity.

In Section 2 the SETARMA model has been shown in its traditional form and the main properties of the process which regulates the switching in a two regimes structure are discussed. An alternative representation of the model is further proposed under well defined conditions on the generating process. In Section 3 the exact form of the autocorrelation function of the model under analysis is presented and its expression for a SETARMA(2; 1,1; 1,1) is shown and discussed. Some concluding remarks are given in the final section.

2 The model under analysis

The Self-Exciting Threshold AutoRegressive Moving Average process [4] of order $(k; p_1, \ldots, p_k; q_1, \ldots, q_k)$ is defined as:

$$X_t = \sum_{i=1}^{k} \left[\phi_0^{(i)} + \sum_{j=1}^{p_i} \phi_j^{(i)} X_{t-j} + \sigma_i \left(e_t - \sum_{w=1}^{q_i} \theta_w^{(i)} e_{t-w} \right) \right] I(X_{t-d} \in R_i) \quad (1)$$

where $\sigma_i e_t \sim WN(0, \sigma_i^2)$, for $i = 1, \ldots, k$, $R_i = [r_{i-1}, r_i)$ forms a partition of the real line such that $-\infty = r_0 < r_1 < r_2 < \ldots < r_k = +\infty$ with r_i the threshold values, d is the threshold delay, p_i and q_i are non negative integers, $\phi_j^{(i)}$ and $\theta_w^{(i)}$ are unknown parameters with $j = 1, 2, \ldots, p_i$ and $w = 1, 2, \ldots, q_i$ and $I(\cdot)$ is a Bernoulli random process.

In the following, in order to easily show the results on the autocorrelation function and to avoid an heavy notation, a SETARMA $(2; p_1, p_2; q_1, q_2)$ model with threshold delay d and threshold value r, such that $R_1 = [r, \infty)$, $R_2 = (-\infty, r)$, is considered. In this case the switching between the two regimes is regulated by the indicator process $I_{t-d} = I(X_{t-d} \in R_1)$ that, given its dichotomy, can be written as:

$$I_{t-d} = \begin{cases} 1 & \text{if} \quad X_{t-d} \geq r \\ 0 & \text{if} \quad X_{t-d} < r \end{cases} \tag{2}$$

for $t = 1, 2, \ldots$, and $d > 0$.

I_{t-d} has a relevant role in the dynamic structure of X_t and it is characterized by some interesting properties shown in the next section.

2.1 The indicator process $\mathrm{I}_{\mathrm{t-d}}$

The process I_{t-d} in (2), which controls the switch between the two regimes of the SETARMA model, satisfy four main properties which are strictly related to its dichotomy:

a) $E[I_{t-d}] = P(I_{t-d} = 1) = P(X_{t-d} \geq r)$
b) $I_{t-d}^v = I_{t-d}$ and $(1 - I_{t-d})^s = 1 - I_{t-d}$
c) $I_{t-d}^v (1 - I_{t-d})^s = 0 \qquad \text{for} \quad v, s = 1, 2, 3, \ldots$
d) $I_{t-d} \cdot I_{t-d-k} = \begin{cases} 1 & \text{if} \;\; X_{t-d} \geq r \;\text{ and }\; X_{t-d-k} \geq r \\ 0 & \text{otherwise} \end{cases} \qquad \text{with} \quad k \in N$

In order to focus the attention on some properties of the process $\{I_{t-d}\}$, $t = d + 1, d + 2, \ldots$, the following assumption is fixed:

[A1.] *The process I_{t-d} is second order stationary and ergodic.*

which implies that:

- $E(I_{t-d}) = p$
- $var(I_{t-d}) = p(1 - p) \qquad t = d + 1, d + 2, \ldots$
- $cov(I_{t-d}, I_{t-d-k}) = \gamma_I(k) = p_k - p^2$

where:

$$p_k = E[I_{t-d} I_{t-d-k}] \qquad \text{for } k = 1, 2, \ldots .$$

It further follows that the double random variable (I_{t-d}, I_{t-d-k}) has the probability distribution shown in Table 1, where p and p_k have to satisfy the inequalities:

I_{t-d}/I_{t-d-k}	**0**	**1**	
0	$1-2p+p_k$	$p-p_k$	$1-p$
1	$p-p_k$	p_k	p
	$1-p$	p	1

Table 1: Probability distribution of the random variable (I_{t-d}, I_{t-d-k}).

$$p_k \leq p \leq \frac{1+p_k}{2} \qquad \text{and} \qquad \max(0, 2p-1) \leq p_k \leq p \tag{3}$$

It implies that:

$$\sum_{k=0}^{\infty} |\gamma_I(k)| = p(1-p) + \sum_{k=1}^{\infty} |p_k - p^2| < \infty \tag{4}$$

where, recalling that $p_0 = E(I_{t-d}^2) = p$, $\gamma_I(0) = p_0 - p^2 = p(1-p)$.

The estimate of the probabilities p and p_k can be obtained taking advantage of the properties of the Bernoulli process I_{t-d}. In particular, given the assumption [A1.], a consistent estimate in probability for p and p_k is given respectively by:

$$\hat{p} = \frac{\#(x_{t-d} \geq r)}{T-d} \qquad\qquad \hat{p}_k = \frac{\#(x_{t-d} \geq r, x_{t-d-k} \geq r)}{T-d} \tag{5}$$

where $x_1, x_2, \ldots, x_T$ is the time series of length T generated from the stochastic process X_t.

2.2 An alternative representation for the SETARMA model

A SETARMA model can be seen as a direct generalization, in the non-linear domain, of the ARMA model of Box and Jenkins [1]. In particular, under well defined conditions, some results reached in the linear context can be properly extended to this class of nonlinear models and alternative representations of them can be derived.

Given these further two assumptions on X_t:

[A2.] *all the roots of the autoregressive polynomials* $\phi_{p_i}(B) = 1 - \sum_{j=1}^{p_i} \phi_j^{(i)} B^j$, *lie outside the unit cycle, (for* $i = 1, 2$*)*;

[A3.] *given the SETARMA model* $X_t = X_t^{(1)} I_{t-d} + X_t^{(2)}(1 - I_{t-d})$, *with* $X_t^{(i)} \sim ARMA(p_i, q_i)$ *for* $i = 1, 2$, *the joint process* $\mathbf{X_t} = (X_t^{(1)}, X_t^{(2)}, I_{t-d})$ *is strict stationary and ergodic*;

model (1), with $k = 2$, can be alternatively written as:

$$X_t = \left[c_0^{(1)} + \sigma_1 \sum_{j=0}^{\infty} \psi_j^{(1)} B^j e_t \right] I_{t-d} + \left[c_0^{(2)} + \sigma_2 \sum_{j=0}^{\infty} \psi_j^{(2)} B^j e_t \right] (1 - I_{t-d}) \quad (6)$$

where

- $c_0^{(i)} = \frac{\phi_0^{(i)}}{1 - \sum_{j=1}^{p_i} \phi_j^{(i)}}$ is the mean value of regime i, for $i = 1, 2$;
- $\sum_{j=1}^{\infty} |\psi_j^{(i)}| < \infty$, with $\psi_0^{(i)} = 1$ and $i = 1, 2$;
- and the weights $\psi_j^{(i)}$ (for $i = 1, 2$ and $j = 0, 1, 2, \ldots$) are computed as:

$$\psi_j^{(i)} = \begin{cases} 1 & \text{when} \quad j = 0 \\ \sum_{s=0}^{j-1} \psi_s^{(i)} \phi_{j-s}^{(i)} - \theta_j^{(i)} & \text{when} \quad j \geq 1 \end{cases} \quad (7)$$

with $\phi_j^{(i)} = 0$, for $j > p_i$, and $\theta_j^{(i)} = 0$, for $j > q_i$.

Model (6) allows to derive, in an easier form, the results in Section 3 and therefore is used as shown in the following pages.

3 The autocorrelation

The autocorrelation coefficient $\rho(k)$, given as:

$$\rho(k) = \frac{cov(X_t, X_{t \pm k})}{[Var(X_t) Var(X_{t \pm k})]^{1/2}} \qquad k = 0, 1, 2, \ldots, N \quad (8)$$

is a remarkable tool for the analysis of linear time series to study the dependence among the random variables and to identify the ARMA models in the Box and Jenkins [1] approach.

When nonlinear models are under analysis, $\rho(k)$ is not sufficient to investigate the relation among the X_t's ($t = 1, 2, \ldots, N$) even if it can give useful practical indications to evaluate how the generating mechanism of $\{X_t\}$ is closed to the linearity. In this context Tong [5] proposes an *index of linearity* based on the use of the square autocorrelations; more recently Nielsen and Madsen [3] generalize some traditional tools, such as the global and partial autocorrelation function, for the identification of nonlinear models. Their use imply the knowledge of the autocorrelation of nonlinear models in order to evaluate their applicability. For example, no advantages can be reached using $\rho(k)$ when the data generating process is related to a purely bilinear model [2] where the autocorrelation is shown to be zero, with the exception of few and well defined representations of the model.

When instead $X_t \sim$ SETARMA$(2; p_1, p_2; q_1, q_2)$, its local linearity naturally lead to investigate on $\rho(k)$.

Starting from the denominator of (8), the stationarity assumed for X_t allows to write $[Var(X_t)Var(X_{t\pm k}]^{1/2} = Var(X_t)$ and using model (6):

$$Var(X_t) = p\sigma_1^2 \sum_{j=0}^{\infty} \left(\psi_j^{(1)}\right)^2 + (1-p)\sigma_2^2 \sum_{j=0}^{\infty} \left(\psi_j^{(2)}\right)^2 + p(1-p)[c_0^{(1)} - c_0^{(2)}]^2 \quad (9)$$

where $c_0^{(1)}$ and $c_0^{(2)}$ are the two regimes constants.

The numerator of (8) instead involves more detailed investigation as shown in the following proposition.

Proposition 3.1. *If* $X_t \sim \mathrm{SETARMA}(2; p_1, p_2; q_1, q_2)$ *and the assumptions [A.2] and [A.3] are satisfied,* [so that the SETARMA model can be written in the alternative form (6)], *the autocovariance of* X_t *at lag* k*, with* $k = 0, 1, \ldots, N$*, is:*

$$\begin{aligned}\gamma(k) \quad &= \quad \sum_{j=0}^{\infty} \Big[p_k \sigma_1^2 \psi_j^{(1)} \psi_{k+j}^{(1)} + (1-2p+p_k)\sigma_2^2 \psi_j^{(2)} \psi_{k+j}^{(2)} + (p-p_k)\sigma_1\sigma_2 \cdot \\ &\quad \cdot \left(\psi_j^{(1)}\psi_{k+j}^{(2)} + \psi_{k+j}^{(1)}\psi_j^{(2)}\right)\Big] + (p_k - p^2)(c_0^{(1)} - c_0^{(2)})^2 \qquad (10)\end{aligned}$$

with $p_k = E[I_{t-d}I_{t-d-k}]$.

Proof. The assumption of stationarity implies the symmetry of the autocovariance of X_t, such that $cov(X_t, X_{t-k}) = cov(X_t, X_{t+k})$ and so the proof can be limited to the case $\gamma(k) = cov(X_t, X_{t-k})$.

Starting from the definition of $\gamma(k)$:

$$\begin{aligned}\gamma(k) \quad &= \quad cov(I_{t-d}X_t^{(1)}, I_{t-d-k}X_{t-k}^{(1)}) + cov(I_{t-d}X_t^{(1)}, (1-I_{t-d-k})X_{t-k}^{(2)}) + \\ &+ \quad cov((1-I_{t-d})X_t^{(2)}, I_{t-d-k}X_{t-k}^{(1)}) + cov((1-I_{t-d})X_t^{(2)}, \qquad (11) \\ &\qquad (1-I_{t-d-k})X_{t-k}^{(2)})\end{aligned}$$

each term of (11) is given as:

a) $cov(I_{t-d}X_t^{(1)}, I_{t-d-k}X_{t-k}^{(1)}) = p_k\gamma_1(k) + (p_k - p^2)(c_0^{(1)})^2$

b) $cov(I_{t-d}X_t^{(1)}, (1-I_{t-d-k})X_{t-k}^{(2)}) = (1-2p+p_k)\gamma_2(k) + (p_k - p^2)(c_0^{(2)})^2$

c) $cov((1-I_{t-d})X_t^{(2)}, I_{t-d-k}X_{t-k}^{(1)}) = (p-p_k)\gamma_{12}(k) - (p_k - p^2)c_0^{(1)}c_0^{(2)}$

d) $cov((1-I_{t-d})X_t^{(2)}, (1-I_{t-d-k})X_{t-k}^{(2)}) = (p-p_k)\gamma_{21}(k) - (p_k - p^2)c_0^{(1)}c_0^{(2)}$

with $E[(1-I_{t-d})(1-I_{t-d-k})] = 1-2p+p_k$ and $E[(1-I_{t-d})I_{t-d-k}] = p-p_k$.

Substituting the results a)-d) in (11), $\gamma(k)$ becomes:

$$\begin{aligned}\gamma(k) \quad &= \quad p_k\gamma_1(k) + (1-2p+p_k)\gamma_2(k) + (p-p_k)[\gamma_{12}(k) + \gamma_{21}(k)] + \\ &\quad +(p_k - p^2)(c_0^{(1)} - c_0^{(2)})^2 \qquad (12)\end{aligned}$$

where

- $\gamma_i(k) = \sigma_i^2 \sum_{j=0}^{\infty} \psi_j^{(i)} \psi_{k+j}^{(i)}$, for $i = 1, 2$;
- $\gamma_{12}(k) = \sigma_1 \sigma_2 \sum_{j=0}^{\infty} \psi_j^{(1)} \psi_{k+j}^{(2)}$;
- $\gamma_{21}(k) = \sigma_1 \sigma_2 \sum_{j=0}^{\infty} \psi_{k+j}^{(1)} \psi_j^{(2)}$;

which lead to the result (10). ◇

The combination of (9) and (10) in (8) allows to obtain $\rho(k)$ for model (6) which assumes different forms when the orders p_i and q_i of the two regimes are selected.

For example when a SETARMA(2; 1,1; 1,1) with no intercepts is chosen, the numerator (12) of the autocorrelation is such that:

$$\begin{aligned}
\gamma_i(k) &= cov(X_t^{(i)} X_{t-k}^{(i)}) = \sigma_i^2 \left(\phi_1^{(i)}\right)^{k-1} \frac{(1-\phi_1^{(i)}\theta_1^{(i)})(\phi_1^{(i)} - \theta_1^{(i)})}{1 - \left(\phi_1^{(i)}\right)^2}, \\
& \quad \text{for} \quad i = 1, 2; \\
\gamma_{12}(k) &= cov(X_t^{(1)} X_{t-k}^{(2)}) = \frac{\sigma_1 \sigma_2}{1 - \phi_1^{(1)} \phi_1^{(2)}} \\
& \left[\left(\phi_1^{(1)}\right)^{k-1} \left(\phi_1^{(1)} - \theta_1^{(1)}\right) \left(1 - \phi_1^{(1)} \theta_1^{(2)}\right) \right] \\
\gamma_{21}(k) &= cov(X_{t-k}^{(1)} X_t^{(2)}) = \frac{\sigma_1 \sigma_2}{1 - \phi_1^{(1)} \phi_1^{(2)}} \\
& \left[\left(\phi_1^{(2)}\right)^{k-1} \left(\phi_1^{(2)} - \theta_1^{(2)}\right) \left(1 - \phi_1^{(2)} \theta_1^{(1)}\right) \right]
\end{aligned}$$

whereas the variance at the denominator is:

$$Var(X_t) = p\sigma_1 \frac{1 + \left(\theta_1^{(1)}\right)^2 - 2\phi_1^{(1)}\theta_1^{(1)}}{1 - \left(\phi_1^{(1)}\right)^2} + (1-p)\sigma_2 \frac{1 + \left(\theta_1^{(2)}\right)^2 - 2\phi_1^{(2)}\theta_1^{(2)}}{1 - \left(\phi_1^{(2)}\right)^2}$$

From the previous results it can be shown that $\rho(k)$ of the SETARMA(2; 1,1; 1,1) model is null as k diverges, that is:

$$\lim_{k \to \infty} \rho(k) = 0$$

and so the autocorrelation between X_t and $X_{t \pm k}$ is zero as the temporal lag $|k|$ grows.

These results can be graphically observed in Figure 1 [frame (b)] where the correlogram of the series generated from a SETARMA(2; 1,1; 1,1) model is considered, with X_t given as:

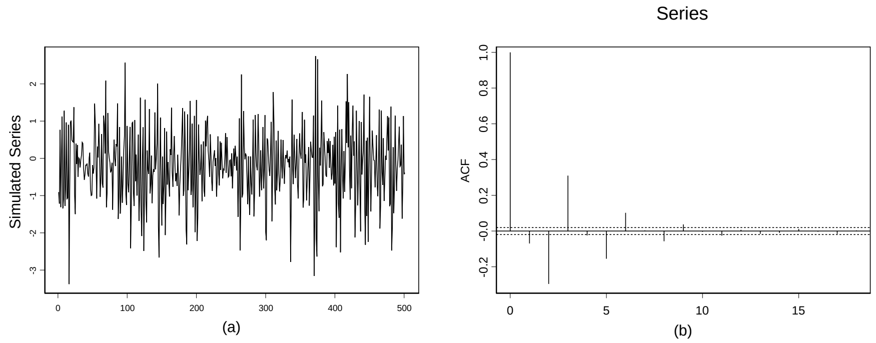

Figure 1: (a): Sample of the generated series of length 500; (b):Correlogram of the complete generated series.

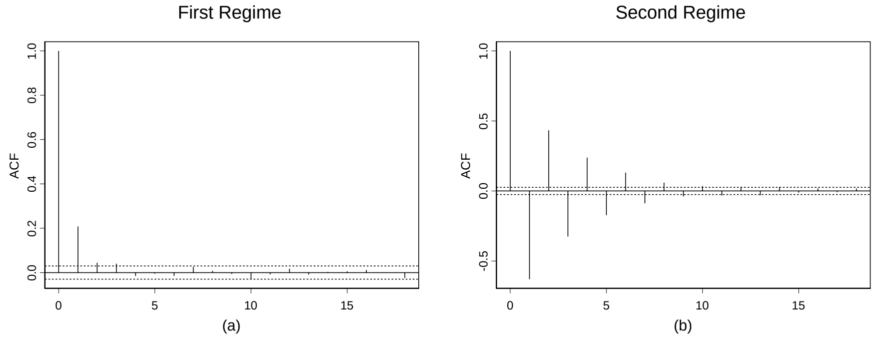

Figure 2: Correlograms of the generated data which belong to the first and second regime [frames (a) and (b) respectively].

$$X_t = \begin{cases} 0.6X_{t-1} + e_t^{(1)} - 0.4e_{t-1}^{(1)} & X_{t-1} \geq 0 \\ -0.6X_{t-1} + e_t^{(2)} + 0.4e_{t-1}^{(2)} & X_{t-1} < 0 \end{cases} \tag{13}$$

where $e_t^{(1)} = e_t$, $e_t^{(2)} = 0.5e_t$ and $\{e_t\}$ is a white noise process with $e_t \sim N(0,1)$, for $t = 1, 2, \dots, 10000$.

In particular the sample autocorrelation decreases exponentially to zero and give useful information about the dependence structure of the series under analysis. As widely discussed in [5], this can be considered a first step to investigate the dependence among the X_t's which needs to be further evaluated with more sophisticated instruments in order to avoid model misspecification. It is even informative for the identification of the two regimes when the threshold delay d and the threshold value r are known and therefore the correlograms of the values which belongs to each regime can be constructed [frames (a) and (b) in Figure 2].

4 Concluding remarks

In time series analysis the autocorrelation function is often used to study the dependence among data and to evaluate which approach to follow to model them. In fact numerous instruments based on its application have been proposed in literature and most of them have been successfully applied.

In this context the exact form of the SETARMA autocorrelation function $\rho(k)$ have been derived in order to investigate some aspects of the dependence structure of this family of process and to show how it changes with respect to the regimes orders and to the lag length between X_t and X_{t-k}.

The results obtained further highlight that some tools, based on $\rho(k)$, which evaluate how the generating process is far from the linearity, can be properly applied in the SETARMA context.

Key words: Classification, functional data analysis, maximum penalised likelihood, microarray, radial basis function.

COMPSTAT 2004 section: Functional data analysis.

Abstract: We introduce functional logistic discriminant analysis (FLDA) which is an extension of the classical method of logistic discriminant analysis to data where predictor variables are functions or curves. FLDA approach can effectively classify functions into two distinct classes by imposing smoothness constraint on the predictor functions and coefficient function by radial basis function expansion and regularization. In order to select the value of a smoothing parameter, we derive an information criterion which enables us to evaluate model estimated by regularization. The proposed method is illustrated through the analysis of yeast cell cycle microarray data. It is shown that FLDA performs well especially in terms of prediction ability.

1 Introduction

Classification or discrimination technique is one of the most widely used statistical tools in various fields of natural and social sciences. In recent years, several techniques have been proposed for analyzing multivariate observations with complex structure (see, for example, [3]).

The focus in the present paper will be on the problem of classifying functions, where each observation can be interpreted as a discretized realization of a function evaluated at possibly differing time points. Recently, Cardot et al. [2] used functional approaches for estimating land use based on the temporal evolution of remote sensing data.

Our motivation arises from the analysis of yeast cell cycle gene expression data which provide inference about how gene expression levels evolve in time and how genes are dependent during a given biological process [10] and [5]. Classification of genes enables us to predict functions of unknown genes and to identify the set of co-regulated genes. In the yeast cell cycle data analysis, one wish to classify genes based on the cDNA microarray time series data.

We introduce functional discriminant analysis using Gaussian radial basis function networks with help of regularization. It is designed to construct a decision rule based on data given as a set of functions. We first transfer the vector valued observations to a set of functions. Secondly, functional logistic model is constructed by using Gaussian radial basis functions and then estimation is by regularized maximum likelihood method. In order to select smoothing parameters, we derive model selection criterion within the framework of functional data analysis by developing the generalized information criterion due to [4].

The paper is organized as follows. In Section 2 we describe the radial basis expansion smoothing technique which converts discrete raw data into underlying smooth functional form. In Section 3 the new method, functional logistic discriminant analysis, is set out and the details of its implementation are described. Section 4 presents an application of the proposed method to yeast cell cycle gene expression data collected by [10].

2 Radial basis smoothing techniques

In the context of functional data analysis [9], individual data should be considered to have a functional form in nature even though observed data are usually recorded discretely. In addition, those discrete raw data which are supposed to have functional form may contain observational error. Therefore, converting raw data into underlying smooth functional form requires efficient smoothing techniques.

The typical functional data analysis approach is to fit each curve individually using expansion in basis functions. Common basis functions for smoothing functional data are B-spline basis and Fourier expansions. In our model, we use Gaussian radial basis function with hyperparameter [1]. An advantage of this basis expansion is that it controls the amount of overlapping among basis functions and adopts the information of the desired outputs. For background about radial basis function networks, we refer to [7], [8].

Suppose we have N independent observations $\{(x_i, t_i);\ t_i \in \mathcal{T},\ i = 1, 2, \cdots, N\}$, where x_i are random response variables and t_i are explanatory variables, assuming that they are drawn from the Gaussian nonlinear regression model

$$x_i = u(t_i) + \epsilon_i, \qquad i = 1, \cdots, N, \tag{1}$$

where $u(t)$ is a smooth function to be estimated, and the errors ϵ_i are independently, normally distributed with mean zero and variance σ^2. We consider the function $u(t)$ that can be expanded in the form of the radial basis function network taking the following form;

$$u(t; \boldsymbol{\omega}) = \sum_{k=1}^{m} \omega_k \phi_k(t) + \omega_0, \tag{2}$$

where $\boldsymbol{\omega} = (\omega_0, \omega_1, \cdots, \omega_m)^T$ and $\phi_k(t)$ are a set of Gaussian radial basis functions with hyperparameter ν given as

$$\phi_k(t; \mu_k, \sigma_k^2) = \exp\left\{ -\frac{(t - \mu_k)^2}{2\nu\sigma_k^2} \right\}, \qquad k = 1, \cdots, m, \tag{3}$$

where μ_k is a scalar determining the location of the kth basis function, σ_k is the width, ν is a hyperparameter. The function $\hat{u}(t) \equiv x(t)$ which is estimated from the observed data $\{(x_i, t_i); i = 1, \cdots, N\}$ is called 'functional data', and is proceeded to further analysis.

The nonlinear function $u(t)$ is estimated in two-stage procedure; position the centers and determine the dispersions first, then calculate the weights using an appropriate optimization schemes. This two stage learning is reported to solve the problem of convergence and the identification problem. Among several strategies, k-means clustering method algorithm is used to determine the centers μ_k and the dispersion parameters σ_k^2 of the basis functions. More precisely, observation points $\{t_1, \cdots, t_N\}$ are grouped into m clusters $\{C_1, \cdots, C_m\}$, where m is a given number of radial basis functions. Then the centers and the dispersion parameters are determined by

$$c_k = \frac{1}{n_k} \sum_{t_i \in C_k} t_i, \qquad s_k^2 = \frac{1}{n_k} \sum_{t_i \in C_k} (t_i - c_k)^2,$$

where n_k represents the number of data which belong to the cluster C_k. We define the basis function $\phi_k(t; c_k, s_k^2)$ using those estimates as $\phi_k(t)$. Hence it follows that the nonlinear regression model based on the radial basis function network can be written as

$$f(x_i | t_i; \boldsymbol{\omega}, \sigma^2) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp\left[-\frac{\left\{x_i - \boldsymbol{\omega}^T \boldsymbol{\phi}(t_i)\right\}^2}{2\sigma^2} \right], \tag{4}$$

where $\boldsymbol{\phi}(t_i) = (1, \phi_1(t_i), \cdots, \phi_m(t_i))^T$.

In fitting data with complex structure, the maximum likelihood method does not yield satisfactory results, since it often occurs overfitting and yields unstable parameter estimates. Moreover, in smoothing functional data, all individual data should be fitted by using the common basis functions in our model. In other words, the number of basis functions is fixed even though the amount of smoothness imposed on a set of discrete data will be differ from each other. Therefore the unknown weights and the error variances are estimated by regularization method. Regularization allows us to adjust individual differences by a smoothing parameter. In addition, implementing the hyperparameter and adjusting the smoothing parameter capture the structure in the data flexibly.

The regularization method maximizes the penalized log-likelihood function

$$l_\gamma(\boldsymbol{\omega}, \sigma^2) = \sum_{i=1}^{N} \log f(x_i | t_i; \boldsymbol{\omega}, \sigma^2) - \frac{N\gamma}{2} \boldsymbol{\omega}^T D_2^T D_2 \boldsymbol{\omega}, \tag{5}$$

where $D_2^T D_2$ is the second order difference matrix and γ is called a smoothing parameter which adjusts the amount of smoothness and also avoids ill-posed problem. The maximum penalized likelihood estimates are

$$\hat{\boldsymbol{\omega}} = (\Phi^T\Phi + N\beta D_2^T D_2)^{-1}\Phi^T \boldsymbol{x}, \quad \hat{\sigma}^2 = \frac{1}{N}\sum_{i=1}^{N}\{x_i - \hat{\boldsymbol{\omega}}^T \boldsymbol{\phi}(t_i)\}^2, \tag{6}$$

where $\Phi = (\boldsymbol{\phi}(t_1), \boldsymbol{\phi}(t_2), \cdots, \boldsymbol{\phi}(t_N))^T$, $\beta = \gamma\sigma^2$ and $\boldsymbol{x} = (x_1, \cdots, x_N)^T$.

The number of basis functions m, the adjusted parameters ν and γ are determined by using an information criterion given by [1]. Thus the observed discrete data $\{(x_i, t_i); t_i \in \mathcal{T}, i = 1, \cdots, N\}$ are smoothed by the method described above and we have a functional data given by $x(t)$;

$$\hat{u}(t) = \sum_{k=1}^{m} \hat{\omega}_k \phi_k(t) + \hat{\omega}_0 \equiv x(t), \qquad t \in \mathcal{T}. \tag{7}$$

Marx and Eilers [6] used B-splines expansion with regularization, called P-splines, and applied the procedure to medical diagnosis and phoneme recognition.

3 Functional logistic discrimination

Suppose we have n independent observations $\{(x_\alpha(t),\ g_\alpha);\ \alpha = 1, \cdots, n\}$, where $x_\alpha(t)$ are functional predictor variables and g_α are indicators of the group membership. For example, we consider two-class classification, i.e. $k = 1$ or 2, $g_\alpha = k$ implies that it belongs to class G_k. A set of functions smoothed by the Gaussian radial basis function smoothing method are given by

$$x_\alpha(t) = \boldsymbol{w}_\alpha^T \boldsymbol{\phi}(t), \qquad \alpha = 1, \cdots, n, \tag{8}$$

where $\boldsymbol{w}_\alpha$ are estimated parameter vectors and $\boldsymbol{\phi}(t)$ is a vector of Gaussian basis functions given in equation (3).

A Bayes rule of allocation is to assign $x_\alpha(t)$ to group $G_k (k = 1, 2)$ with the maximum posterior probability $\Pr(g = k|x_\alpha(t))$. We consider the log-odds of the posterior probability given in the following form;

$$\log\left\{\frac{\Pr(g = 1|x_\alpha(t))}{\Pr(g = 2|x_\alpha(t))}\right\} = \beta_a + \int_{\mathcal{T}} \beta(t) x_\alpha(t) dt. \tag{9}$$

By making use of the same Gaussian radial basis function $\boldsymbol{\phi}(t)$ as in (8), we expand the functional parameter as $\beta(t) = \beta_0 + \sum_{i=1}^{m} \beta_i \phi_i(t) = \boldsymbol{\beta}^T \boldsymbol{\phi}(t) (\in \mathcal{T})$, where $\boldsymbol{\beta} = (\beta_0, \beta_1, \cdots, \beta_m)^T$. We denote the posterior probability $\Pr(g = 1|$ $x_\alpha(t)) = \pi(x_\alpha(t))$, so that $\Pr(g = 2|x_\alpha(t)) = 1 - \pi(x_\alpha(t))$. Then the log-odds model (9) can be expressed as

$$\log\left\{\frac{\pi(x_\alpha(t))}{1 - \pi(x_\alpha(t))}\right\} = \boldsymbol{Z}_\alpha^T \boldsymbol{\beta}, \tag{10}$$

where Z is an $n \times (m + 2)$ matrix given by

$$Z^T = \begin{bmatrix} 1 & 1 & \cdots & 1 \\ \Phi^T \boldsymbol{w}_1 & \Phi^T \boldsymbol{w}_2 & \cdots & \Phi^T \boldsymbol{w}_n \end{bmatrix} \tag{11}$$

with $(m+1) \times (m+1)$ matrix Φ having $\phi_{jk} = \int \phi_j(t)\phi_k(t)dt$ as the (j,k)-th element.

We define the binary variable y_α coded as either 0 or 1 to indicate the group membership of a sample, where $y_\alpha = 1$ if $g_\alpha = 1$ and $y_\alpha = 0$ if $g_\alpha = 2$. The log-likelihood function is

$$l(\boldsymbol{\beta}) = \sum_{\alpha=1}^{n} \left[y_\alpha \log \pi(x_\alpha(t)) + (1 - y_\alpha) \log\{1 - \pi(x_\alpha(t))\} \right], \tag{12}$$

where $\pi(x_\alpha(t)) = \exp(\boldsymbol{Z}_\alpha^T \boldsymbol{\beta})/\{1 + \exp(\boldsymbol{Z}_\alpha^T \boldsymbol{\beta})\}$. We estimate the parameter vector $\boldsymbol{\beta}$ by maximizing the penalized log-likelihood function

$$l(\boldsymbol{\beta}) - \frac{n\lambda}{2} \boldsymbol{\beta}^T D_2^T D_2 \boldsymbol{\beta}. \tag{13}$$

This is because regularization method yields estimates with lower variances, even though they are biased. Therefore we obtain the solution $\hat{\boldsymbol{\beta}}_\lambda$ by the iterative algorithm like Newton-Raphson algorithm.

The crucial issue on regularization method is the choice of the optimal value of smoothing parameter λ. We obtain an information-theoretic criterion within the framework of functional data analysis. An information criterion for evaluating functional logistic discrimination model estimated by regularization is of the form

$$\mathrm{GIC_F} = -2 \log l(\hat{\boldsymbol{\beta}}_\lambda) + 2\mathrm{tr} Q^{-1} R, \tag{14}$$

where Q and R are $(m+2) \times (m+2)$ matrices given by the first and second derivatives of equation (13). We choose the smoothing parameter λ to minimize $\mathrm{GIC_F}$.

4 Real data example

In this section we show the effectiveness of the proposed method through the analysis of the yeast cell cycle gene expression data collected by [10]. Gene expressions for all 6,178 genes in the yeast genome were measured by cDNA microarrays over time during about two cell cycles. These data contain 77 microarrays and consist of two short time-courses (two time points) and four medium time-courses (18, 24, 17 and 14 time points). Spellman et al. [10] identified 800 genes as cell cycle related genes based on the clustering analysis, and also grouped these genes into five classes, G1, S, G2, M, and M/G1, by considering peaks in the expression patterns. Figure 1 shows the expression patterns of the 800 genes in the five classes.

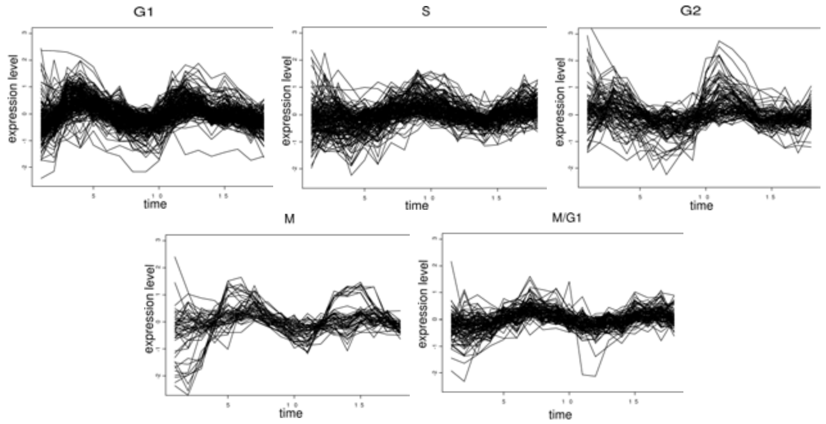

Figure 1: Raw gene expression patterns during the yeast synchronization experiment.

In our analysis, we concentrate on the time-course "α factor-based synchronization experiment data" (18 time points), for simplicity excluding the genes containing missing values. That is, the expression patterns of 612 genes out of 800 cell cycle related genes are used in our analysis, and those expression data are considered as a discretized realization of 612 expression curves evaluated at 18 time points. Note that microarray data usually contain observational noise. Therefore, the smoothing that we will first perform has an important role to remove the observational noise from expression data. In addition, since the gene expression pattern of each cell cycle related gene can be considered as a function of time, the proposed method is appropriate for analyzing time course gene expression data.

We carried out two-class logistic discrimination for all possible combinations. In order to evaluate the effectiveness of our FLDA model, the genes in each class were randomly assigned into training data and test data. That is, the FLDA model is estimated by using the training data, and the predictive ability of the estimated model is evaluated by the test data.

We first performed the Gaussian radial basis smoothing method described in Section 2 to the time-course expression data $\{(t_i, x_{ij});\ i = 1, \ldots, 18;\ j = 1, \ldots, 612\}$, where t_i is the i-th time point and x_{ij} is the expression value of j-th gene at time t_i. In the functional discrimination analysis, each smoothing step has to be carried out by using the same number of basis functions. Hence the differences of the degree of smoothness between different gene expression patterns can be adjusted by the smoothing parameters. However, since there are various gene expression patterns in the same group, adjusting their smoothness by using only the smoothing parameter might not be enough. In such a case, the proposed radial basis function smoothing method with the hyperparameter works efficiently in practice.

Figure 2 shows examples of two G1-grouped genes with the Gaussian ra-

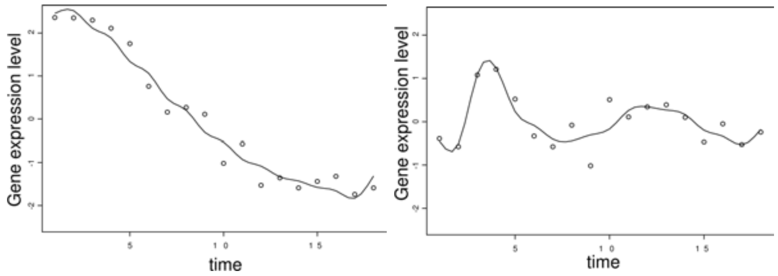

Figure 2: Smoothed gene expression patterns by the Gaussian radial basis function networks with hyperparameter.

dial basis smoothing curves. Although there are various types of expression patterns in the same class, we succeeded in extracting the effective expression curves that are possibly close to the real expression patterns. We observe that the hyperparameter allows flexible curve fitting, and the smoothing parameter adjusts the differences of gene expression patterns effectively.

The linear discriminant analysis (LDA) and the quadratic discriminant analysis (QDA) are the most popular classical method for discriminant analysis. We compare FLDA evaluated by the criterion $\mathrm{GIC}_{\mathrm{F}}$ with LDA and QDA which analyze discretized data directly. For almost all combinations of the classes, the proposed method yields a lower test error. We suggest investigating genes that were classified in the opposite group with high posterior probability, since they may have been misclassified by [10].

5 Conclusion

The functional logistic discriminant analysis proposed in this paper appears to be a useful tool for classifying functions or curves. An advantage of our method is that one could treat the samples as a set of functions, hence the problems of the observational point difference and highly correlated data are overcome. Also the model selection criterion enables us to evaluate models subjectively. Potential research would be extending our modeling strategy to the case of sampled surface for multi-group classification.

COMPSTAT 2004 section: Data visualisation.

Abstract: This paper shows how to use differential branches of mathematics (mathematical analysis, theory of differential equations, theory of probability etc.) and informatics (object-oriented analysis and designing, imitative modelling, visual programming etc.) to model the real phenomena. The modelling of the size of population is be demonstrated by the factors of birth and death.

1 Introduction

When exploring real phenomena, the choice of a model is the most significant aspect of applied research. The same real phenomenon may be described from different points of view. This enables to create many abstract conceptions concerning the reality to explore. In order to develop and explore models, different branches of mathematics (mathematical analysis, theory of differential equations, theory of probability etc.) and informatics (object-oriented analysis and designing, imitative modelling, visual programming etc.) are used. The only possible way, how to acquire the modelling, is to demonstrate different phenomena and different models, describing them. Interrelationships among plants and animals and between them and their environment are the significant issue to be explored. The modelling of the number of population is determined by the factors of birth and death.

2 Maltus' model

Maltus' model is one of the first models of the dynamics of population number. It is named after its author and is expressed by $\frac{dx}{dt} = \alpha x$. The integration of equation provides solution $x = x_0 e^{\alpha t}$, where x_0 – the threshold value of x. Maltus' equation models the hypothesis "The change of the number of population is proportional to the number of already existing individuals". Variable x indicates the number of a particular biological population type within at a certain moment. Constant α (Maltus' constant) indicates the coefficient of the increase of population number. Maltus' discreet model we can obtain from the continuous model by means of conceiving the separate interval of time. The birth of new individuals occurs after the interval, equal to one unit. According to the derivative function

$$\frac{x(t+\Delta t) - x(t)}{\Delta t} = \frac{\Delta x}{\Delta t} \overset{\Delta t \to 0}{\to} \frac{dx}{dt} \,.$$

If we introduce symbol: $\Delta t = 1$, $x_n = x(t)$, $x_{n+1} = x(t + \Delta t) = x(t + 1)$, then discreet model will be expressed by:

$$\begin{cases} x_0 = \text{const} \\ x_{n+1} = x_n + \alpha x_n \end{cases} .$$

Maltus' discreet model of the unlimited increase of population means that the number x_{n+1} of every next generation consists of the number x_n of the previous generation and the number αx_n of new-born individuals. If x_0 is the given threshold number of individuals of population, the model provides the answer to the question – how many individuals will be in the biological population after certain discreet period of time.

3 Fractal visualization of Maltus' discreet model

If we formally replace the real symbols by complex numbers, we can view Maltus' discreet model in the complex plane. Maltus' discreet model in the complex plane C is the formal replacement of real variables, constants and coefficients by corresponding complex variables, constants and coefficients.

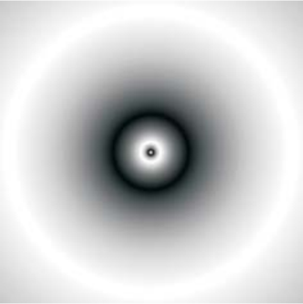

Figure 1:

Then the model

$$\begin{cases} Z_0 = C \\ Z_{n+1} = Z_n + AZ_n \end{cases}$$

may be viewed as iteration in the complex plane, but the results of such process may be described as a fractal portrait. The fractal portrait of iterative process $Z_{n+1} = Z_n + AZ_n$ is made in rectangular discrete area of a complex plane. For each point $Z_0 = C$ from this area process $Z_{n+1} = Z_n + AZ_n$ before performance of one of two conditions repeats. The first condition – whether it the new point Z_{n+1} has left the set area $|Z_{n+1}| < R$ of visibility whether or not. The second condition is a restriction on amount of iterations $n < N$. These two conditions guarantee the ending of iterative process. Or process will leave area of visibility, or process is conditionally infinite and it interrupts. The received number n is accepted for color value in a point

$Z_0 = C$, with which iterative process began. The fractal portrait is a set of integers n which are calculated in each point in rectangular discrete area of a complex plane. Thus, modulating the received digital values n in what or a color palette, the color image of fractal portrait is made. Change of ratio of color components of a palette allows considering features of process $Z_{n+1} = Z_n + AZ_n$.

4 Fractal visualization of Verhulst's model

According to Maltus' law, the number of population should increase exponentially. If we take into consideration that the population lives within the limited space (territory, resources etc.) and among the individuals there exists competition concerning the space, then we should take this factor into account within the model. Verhulst imparts the factor of the population number decrease to Maltus' model. Addend $(-\beta x^2)$ models the hypothesis "the decrease of the population number is proportional to the frequency of cases, when individuals meet each other". Then the equation of population number is expressed by

$$\frac{dx}{dt} = \alpha x - \beta x^2 \,.$$

If we take out of the brackets, we obtain Verhulst's equation

$$\frac{dx}{dt} = x(\alpha - \beta x \,,$$

where β – coefficient of the population decrease. Verhulst's discreet model is described by the recurrent ratio

$$\begin{cases} x_0 = \text{const} \\ x_{n+1} = x_n + x_n(\alpha - \beta x) \end{cases}$$

in the space of real numbers and

$$\begin{cases} Z_0 = C \\ Z_{n+1} = Z_n + Z_n \cdot (A - B \cdot Z_n) \end{cases}$$

in the space of complex numbers. Iteration of the reflection of Verhulst's model, if there are given different complex coefficients A and B, provides the set of fractals, corresponding to Julia's set. The solution of Verhulst's model is called logical function. Many models of birth and death in biology, economics, sociology are described by means of these functions. Perhaps, fundamental principles of increase enabled to reflect the likeness of the logical fractal portrait and the spirals of sun-flower, split into opposite directions, by means of Verhulst's model. Iterative process $Z_{n+1} = Z_n + Z_n \cdot (A - B \cdot Z_n)$ begins in a point $Z_0 = C$.

Amount of such computing processes is equal to amount of complex points on fractal portrait. The purpose of each process is calculation n of amount of

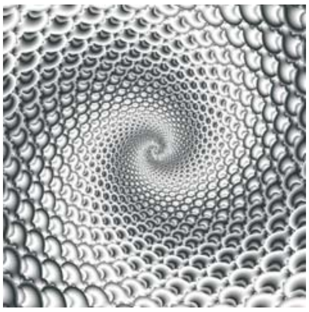

Figure 2:

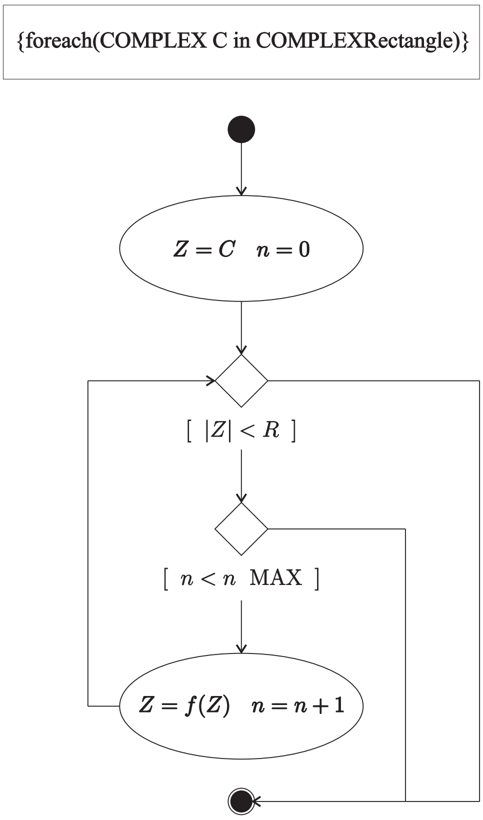

{foreach(COMPLEX C in COMPLEXRectangle)}
$Z = C \quad n = 0$
[$|Z| < R$]
[$n < n$ MAX]
$Z = f(Z) \quad n = n + 1$

Figure 3:

iterations. If iterative process constantly generates points Z_{n+1} in the field of visibility $|Z_n + Z_n \cdot (A - B \cdot Z_n)| < R$, then such process is considered infinite and the variable $n = N$ gives conditionally big number. If iterative process leaves area of visibility, that is at some value $n < N$ the condition $R \leq |Z_n + Z_n \cdot (A - B \cdot Z_n)|$ is true, then the variable n gives number of the executed iterations be satisfied. The integer n received thus sets color value of fractal portrait in a point $Z = C$ of a complex plane.

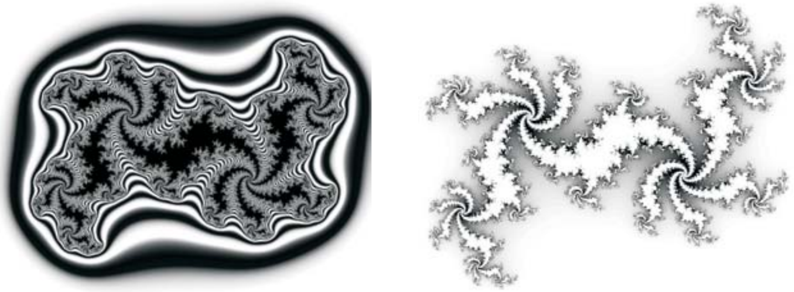

Figure 4: This is a fractal portrait and Julia's set of Verhulst's complex model with the given coefficients A=(0.283;1) and B=(0.5;0.5).

5 Fractal portrait of Volterra model

In Voltera model the problem becomes two-dimensional. There are two populations in the space – predators and their preys. Variable x indicates the number of preys, but variable y indicates the number of predators within the system. Equation of variable x – the number of preys is expressed by:

$$\frac{dx}{dt} = \alpha x - \beta x y\,.$$

The first addend αx, like in Maltus' model, means that the increase of the number of individuals is proportional their amount at a certain moment.

The second addend $(-\beta x y)$ means that the decrease of the population number is proportional to the frequency of cases, when the preys meet predators. If we take x out of the brackets, we obtain the equation for preys:

$$\frac{dx}{dt} = x(\alpha - \beta x)\,.$$

Equation of variable y – the number of dead predators is expressed by:

$$\frac{dy}{dt} = -\gamma y + \delta x y\,.$$

The first addend $(-\gamma y)$, means that the predators die if there is lack of prey. The second addend $\delta x y$ means that the increase of the population of predators is proportional to the number of cases, when the predator meets the prey. If we take out of the brackets, we obtain the equation for predators:

$$\frac{dy}{dt} = -y(\gamma - \delta x)\,.$$

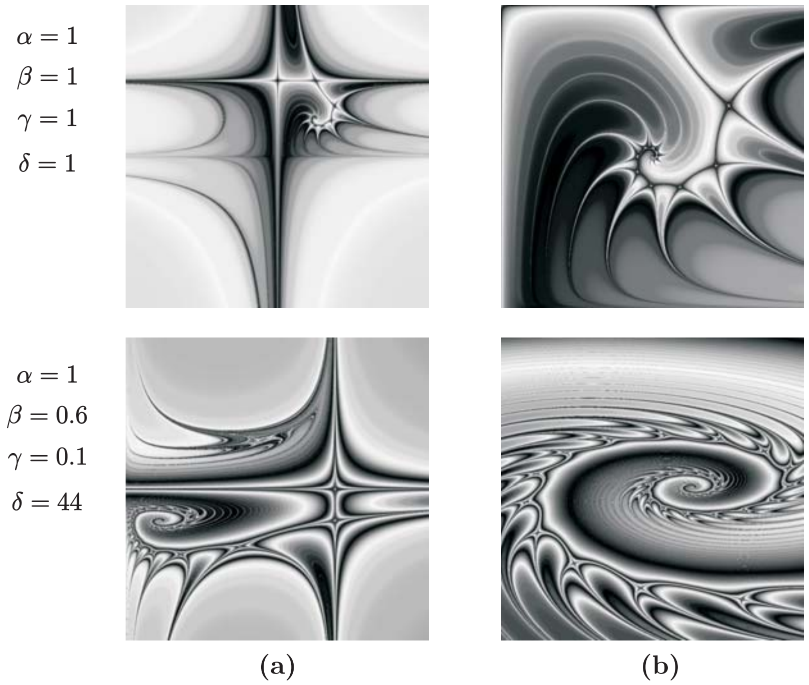

Figure 5: **(a)** Fractal portrait of Volterra model with the given parameters. **(b)** The enlarged centre of the spiral of left portrait.

Thus we obtain the non-linear system of differential equations:

$$\begin{cases} \frac{dx}{dt} = x(\alpha - \beta x) \\ \frac{dy}{dt} = -y(\gamma - \delta x)\,, \end{cases}$$

where α – the increase coefficient of the prey population number, β – the decrease coefficient of the prey population number, when the preys are eaten by the predators, γ – the decrease coefficient of the predators population number if there is a lack of preys. δ – the increase coefficient of the predators population number, when the predators eat preys. We obtain Volterra discreet model by replacing the derivative function by its discreet analogue and assuming that the period of time is a unit:

$$\begin{cases} x_0 = c_x \\ y_0 = c_y \\ x_{n+1} = x_n + x_n(\alpha - \beta x_n) \\ y_n = y_n - y_n(\gamma - \delta y_n) \end{cases}$$

Volterra model may be viewed as the one-dimensional reflection of complex plane in relation to oneself:

$$\begin{cases} Z_0 = C \\ Z_{n+1} = f(Z_n) = f(Z_n)\,, \end{cases}$$

where $Z_n = (x_n; y_n)$ and $C = (c_x; c_y)$ are the points in the complex plane.

Julia's set is the result of iteration of the complex plane reflections and enables to visualise the behaviour of the non-linear dynamic systems, developing a series of fractal portraits.

6 Conclusions

The present paper deals with some examples of the models of the populations dynamics and shows corresponding fractal portraits of systems. Some fractal portraits of systems include Julia's set. Some Julia's sets have a regular boarder, but some sets are structured fractually. The basic peculiarity of the fractal portraits of dynamic systems is the fact that the recursive procedure of the development of fractals naturally arise from the recurrent interrelations of corresponding discreet models. Therefore it is common to analyse the phase's portraits of systems together with their fractal peculiarities.

THE PROBLEM OF CHOOSING STATISTICAL HYPOTHESES IN APPLIED STATISTICS

Irina Arhipova and Signe Balina

Key words: Statistical methods, hypotheses.

COMPSTAT 2004 section: Teaching statistics.

Abstract: Based on our experience at Latvia University of Agriculture and University of Latvia, we would like to present views on how to teach statistics for undergraduate students in economics, management science and related disciplines. The approach of designing statistics' course depends both on the type of the course and on the students. Teaching statistics to graduate students or others, certain balances have to be observed and maintained. One of them is the balance between the theory and practice, because if theoretical materials take up too much time and energy the students will lose interest. Therefore there should be another balance - the balance between mathematical statistics, subject of statistical modelling and software usage. The goal of the statistical course for graduate is to acquaint students with a variety of problems with which they might encounter in their studies during which each problem requires students to collect "real-world" data and to combine several statistical methods. The interrelation of the statistical methods and statistical hypothesis had been considered in the statistics' course.

1 The tasks of teaching statistics at universities

The statisticians have three tasks at universities: teaching statistics, carrying out research in statistics and consulting in statistics. In this paper we discuss the task of teaching. It is very difficult for students to become familiar with a wide range of the statistical methods and statistical hypotheses. The one of the problems in the teaching process is how to show classification of the statistical methods and interrelation of statistical hypotheses. The first step is the identification of the number of variables and their scale. The next step is the definition of dependent and independent variables. The four possibilities according to the type and measurement scale of variables are as follows:

- The number of independent variables – one or more than one.
- The number of dependent variables – one or more than one.
- The type of measurement scale used for the dependent variables (i.e. metric or non-metric).
- The type of measurement scale used for the independent variables (i.e. metric or non-metric).

The third step is the definition of appropriate hypothesis (null and alternative) and the choosing of appropriate statistical method.

Introducing this classification there is no problem to define univariate and multivariate methods in teaching. For example, for one non-metric independent variable and one metric dependent variable the appropriate method is t-test but for more than one non-metric independent variable and one metric dependent variable the appropriate method is analysis of variance (ANOVA). At the same time for one metric independent variable and one metric dependent variable the appropriate method is regression analysis. And for more than one metric independent variable and one metric dependent variable the appropriate method is multivariate regression analysis.

However there are such data sets for which it is impossible to conceptually designate which set of variables is dependent, and which - independent. For these types of data sets the objectives are to identify how and why the variables are related among themselves. Statistical methods for analysing these types of data sets are called *interdependence methods*, for example, cluster analysis, factor analysis for more than two metric variables and multiway contingence tables for more than two non-metric variables.

Only after the regularities of statistical hypotheses have been acquired, the statistical software packages can be used in problem solving, because the unsophisticated use of the applied statistical packages hinders students' deep acquisition of the statistics.

2 Interrelation of statistical hypotheses

Teaching statistics different topics are taught separately without emphasising the fact that all the methods are closely interrelated, and, if the number or the types of the variables change, the method to be applied also changes. The students usually have difficulties to classify the methods accordingly to the information provided by the "real-world" problem and consequently they also have difficulties to choose the hypothesis to be verified. Teaching a new topic it is indispensable to show the link between the already acquired methods and this new topic. The interrelations between statistical methods are easy to show, if one "real-world" problem is used and developed. The first step is to word the null and alternative hypotheses of the problem, the second – to transform the hypotheses into mathematical symbols.

Let us consider the interrelation of statistical hypothesis using the hypotheses about the population mean. The first of them is T-*test* $H_0 : \mu = \mu_0$ versus $H_1 : \mu \neq \mu_0$. For example, suppose that statistician is interested in determining, whether the mean salary per month for inhabitants of Latvia is equal to EUR 500 or not: $H_0 : \mu = 500$ versus $H_1 : \mu \neq 500$.

The extension of these hypotheses is two-population hypothesis test $H_0 : \mu_1 = \mu_2$ versus $H_1 : \mu_1 \neq \mu_2$. For example, suppose you need to compare the equality of the mean salaries per month for inhabitants at the age below and over 40 years: $H_0 : \mu_{<40} = \mu_{>40}$ versus $H_1 : \mu_{<40} \neq \mu_{>40}$.

Let us suppose you need to compare the mean salary per month for inhabitants in the following groups of age: below 25 years, from 26 to 40 years, from 41 to 55 years, over 55 years. In this case more than two population means must be compared, and the method of one-way analysis of variance (ANOVA) is appropriate: $H_0 : \mu_1 = \mu_2 = \mu_3 = \cdots = \mu_a$ versus H_1: *not all populations have the same mean*, where a is the number of groups, or: $H_0 : \mu_{<25} = \mu_{(25-40)} = \mu_{(41-55)} = \mu_{>55}$ versus H_1: *not all mi are equal*.

This ANOVA test is the same as F-test: $H_0 : F = 0$ versus $H_1 : F > 0$, where $F = \frac{s_a^2}{s_e^2}$ and s_a^2 is between method estimate of σ^2 and s_e^2 – within method estimate of σ^2. The null hypothesis means that the factor (age) is not significant, and the alternative hypothesis – that the factor is significant.

Let us consider the age factor as the continuous factor. In this case the factor significance must be analysed by correlation analysis or one-factor regression analysis. Using the hypotheses: $H_0 : \rho = 0$ versus $H_1 : \rho \neq 0$ the correlation between depended and independent variables can be defined, in our case, between salary and age. Either the hypotheses $H_0 : \rho = 0$ versus $H_1 : \rho \neq 0$ or $H_0 : \beta_1 = 0$ versus $H_1 : \beta_1 \neq 0$ are the same for one-factor correlation and regression analysis, where β_1 is the slope coefficient of the linear regression model. The first hypothesis states that there is no correlation between age and salary. The second hypothesis states that if a regression line is fitted to the population salary – age data, this line will be horizontal, i.e., it will have a slope of zero. In others words, salary and age have no correlation in the population. If one of these hypotheses is true, the other also is. In fact, if these two null hypotheses are tested separately, t statistic and test conclusions will be the same.

Another key statistics in regression analysis, the F statistics, is used to test the null hypothesis that the sample regression equation does not explain a significant percentage of the dependent variable's variance. The null and alternative hypotheses are $H_0 : \rho^2 = 0$ versus $H_1 : \rho^2 > 0$.

Thus, the F test can be used to determine the existence of a linear relationship between independent and dependent variables. In the simple linear regression, this test is equivalent to the t test: $H_0 : \beta_1 = 0$ versus $H_1 : \beta_1 \neq 0$.

Therefore, for one factor regression analysis, you may conduct either F test or t test. The results of the two tests will lead to the same conclusions. The statistical methods and hypotheses interrelation is shown in figure 1.

Let us suppose that a new variable – inhabitants' work experience (in years) – has been added to the problem. Thus a hypothesis to be verified is set up – whether the salary depends on the inhabitant's age and work experience. The most appropriate method to verify the chosen hypothesis is the multiple regression. Because there is more than one explanatory variable, the null and alternative hypotheses can be set up as follows: $H_0 : \beta_1 = \beta_2 = 0$ versus H_1: at least one $\beta_j \neq 0$ where null hypothesis means that there is no linear relationship between the salary and explanatory variables (age and

\end{tikzcd}$$

Figure 1: The interrelation of statistical hypotheses.

work experience), but alternative hypothesis means that there is a linear relationship between the salary and at least one of the explanatory variables.

Let us add a new variable – inhabitant's gender – to the data base. Thus a new hypothesis to be verified is set up – whether the salary depends on the gender, age and work experience. In the particular case there are both qualitative and quantitative variables are among the independent variables. The chosen hypothesis can be verified by means of CANOVA (covariance analysis of variance), which is a combination of the regression analysis and the analysis of variance. If the goal of the problem is to verify, whether the salary depends on gender and age, the simple linear covariance model is valid: $Y_{ij} = \mu+\alpha_i+\beta X_{ij}+\varepsilon_{ij}$ where μ is the overall mean effect, α_i is the true effect of the gender and β is a slope parameter associated with the independent factor of age. If the goal of the problem is to verify, whether the salary depends on gender, age and work experience, the multiple linear covariance model is valid: $Y_i = \mu + \alpha_i + \beta_1 X_{1ij} + \beta_2 X_{2ij} + \varepsilon_{ij}$ where β_1 is a slope parameter associated with the age and β_2 is a slope parameter associated with the work experience. If the goal of the problem is to verify, whether the salary and work experience depend on gender, then the appropriate method is the multivariate analysis of variance (MANOVA) that combines results from the several ANOVAs.

Besides, if the goal of the problem is to analyse, whether the salary and work experience depend on gender and age, then the appropriate method is the multivariate covariance analysis of variance (MCANOVA). As we see, it is possible to show different methods and their interrelation on the basis of a particular example.

$$\begin{tikzcd}
 & \text{ANOVA} & & \text{MANOVA} \\
T\text{-test} \arrow[ur, Rightarrow] \arrow[dr, Rightarrow] & \arrow[r, Rightarrow] & \text{CANOVA} \arrow[ur, Rightarrow] \arrow[dr, Rightarrow] & \\
 & \text{Regression} & & \text{MCANOVA}
\end{tikzcd}$$

Figure 2: The example of the interrelation of statistical methods.

In order to help the students to classify the methods accordingly to the information provided by the problem, the classification of the statistical methods is provided in the table below.

			Dependent variable			
			One		**More than one**	
			Quantitative	**Qualitative**	**Quantitative**	**Qualitative**
Independent variable	**One**	**Quantitative**	**Univariate methods**			
			Simple regression	Two-group discriminant analysis	Canonical correlation	Multi-group discriminant analysis
		Qualitative	T-test	Discrete discriminant analysis	Multivariate analysis of variance	Discrete multi-group discriminant analysis
	More than one	**Quantitative**	Multiple regression	Two-group discriminant analysis	Canonical correlation	Multi-group discriminant analysis
		Qualitative	Analysis of variance, ANOVA	Discrete discriminant analysis	Multivariate analysis of variance	Discrete multi-group discriminant analysis

Table 1: The classification of the statistical methods.

3 The problem-orientated statistical method choice

For the illustration let us consider the typical problem in statistics' course, namely, let us consider data about average gross wages per month by sex and occupation in Latvia. The problems can be defined as follows:

- Is there a significant difference in the average gross wages for males and females?
- Is there a significant difference in the average gross wages for the various categories of occupation?
- Is there a significant relation between male and female gross wages?

Students should define the independent and dependent variables and their scale. For example, in the first problem factor sex is qualitative independent variable with two categories, and gross wages is quantitative dependent variable. In this case the t-test is the appropriate method for the statistical hypothesis for the proving the significant difference between the average wages for males and females. For the second problem factor occupation is qualitative independent variable with various categories, and gross wages is quantitative dependent variable. So, the analysis for variance (ANOVA) is appropriate method for the statistical hypothesis for proving the difference between the average wages for the various categories of occupation. For the last problem there are two quantitative variables: male's wage and female's wage, where the simple regression analysis allows defining a relation between wages of males and females.

4 The use of statistical packages in teaching statistics

After the acquisition of theoretical course, the students are ready to use the acquired knowledge to solve a problem, using ready-made statistical software, for example, SPSS, Minitab and Microsoft Excel Data Analysis Tools. The general linear model (GLM) is flexible statistical model which incorporates analyses involving normally distributed dependent variables and combinations of categorical and continuous factor variables. The SPSS GLM procedure can accommodate univariate models (one dependent variable) involving:

- Categorical predictors only (ANOVA)
- Continuous predictors only (Regression)
- Combinations of categorical predictors and continuous predictors (CANOVA)

as well as multivariate versions (two or more dependent variables) of all of these models (MANOVA and MCANOVA). Categorical predictors are referred to as factors, while continuous predictors are called covariates. The application of statistical packages allows the students to obtain the result quickly, as well as help them better understand the interrelation between the statistical hypotheses. Unfortunately, the simple data processing without profound understanding and interpretation of obtained results does not allow achieving a real result in problem solving.

Therefore teaching statistics much attention should be paid to the methodology of statistical analysis:

- The definition of a hypothesis.
- The specification of the hypothesis mathematical model.
- The specification of the statistical model.
- Data obtaining.
- The evaluation of the statistical model parameters.
- The verification of hypotheses.
- The interpretation of obtained results.

REDUCING THE BIAS OF THE LOG-PERIODOGRAM REGRESSION IN PERTURBED LONG MEMORY SERIES

Josu Arteche

Key words: Long memory, log periodogram, stochastic volatility.

COMPSTAT 2004 section: Time series analysis.

Abstract: This paper proposes an extension of the log periodogram regression which explicitly accounts for the added noise in Long Memory in Stochastic Volatility (LMSV) and other perturbed long memory time series. Contrary to the non linear log periodogram regression of [8], no linear approximation of the logarithmic term which accounts for the noise is used. This produces a reduction of the bias and increases the asymptotic efficiency in long memory signal plus noise series. Asymptotic and finite sample properties of the estimator are analyzed. Finally an application to the Spanish stock index Ibex35 is included.

1 Introduction

The estimation of the memory parameter in perturbed long memory series has become a subject of increasing interest motivated especially by the strong persistence found in the volatility of many financial and economic series. Alternatively to the different extensions of ARCH and GARCH models, the Long Memory in Stochastic Volatility (LMSV) has proved a useful tool to model such a strong persistent volatility. Estimation of the memory parameter of the volatility component in LMSV corresponds to a problem of estimation in a long memory signal plus noise model.

The perturbed long memory series recently considered in the literature are of the form,

$$z_t = \mu + y_t + u_t \tag{1}$$

where μ is a finite constant, y_t is a long memory (LM) process such that its spectral density satisfies

$$f_y(\lambda) = C\lambda^{-2d}(1 + O(\lambda^{\alpha})) \qquad \text{as } \lambda \to 0 \tag{2}$$

for a positive finite constant C, $\alpha \in [1, 2]$ and $0 < d < 0.5$, and u_t is a weakly dependent process. The condition of positive memory $0 < d < 0.5$ guarantees the asymptotic equivalence between spectral densities of y_t and z_t.

The version of [6] of the log periodogram regression estimator (LPE) in a fully observable LM series is based on the least squares regression $\log I_{yj} = a + d(-2\log\lambda_j) + v_j$, $j = 1, \ldots, m$, where $I_{yj} = I_y(\lambda_j) = |\sum_{t=1}^{n} y_t \exp(-i\lambda_j t)|^2/(2\pi n)$ is the periodogram of the series y_t, $t = 1, \ldots, n$, at

Fourier frequency $\lambda_j = 2\pi j/n$ and m is the bandwidth such that at least $m^{-1} + mn^{-1} \to 0$ as $n \to \infty$. The motivation of this estimator is the log linearization in (2) such that

$$\log I_{yj} = a + d(-2\log\lambda_j) + U_{yj} + O(\lambda_j^{\alpha}), \quad j = 1, 2, \ldots, m, \tag{3}$$

where $a = \log C - c_0$, $c_0 = 0.5772\ldots$ is Euler's constant and $U_{yj} = \log(I_{yj} f_y^{-1}(\lambda_j)) + c_0$. The bias of the least squares estimate of d is dominated by the $O(\lambda_j^{\alpha})$ term which is not explicitly considered in the regression such that a bias of order $O(\lambda_m^{\alpha})$ arises [4].

The main rival semiparametric estimator of the LPE is the local Whittle or Gaussian semiparametric estimator (GSE) of [7] which has the computational disadvantage of requiring nonlinear optimization but it is more efficient than the log periodogram regression. However both share important affinities. In particular the bias is in both cases of order $O(\lambda_m^{\alpha})$.

Both estimators preserve the consistency and asymptotic normality when applied to perturbed long memory series [3] and [1]. In this case

$$f_z(\lambda) = C\lambda^{-2d}\left(1 + \frac{f_u(\lambda)}{C}\lambda^{2d} + O(\lambda^{\alpha})\right) \quad \text{as } \lambda \to 0 \tag{4}$$

with $f_u(\lambda)$ positive and bounded. The leading term of the bias is in both estimators $f_u(\lambda)C^{-1}\lambda^{2d}$ which is the dominant part not considered explicitly in the estimation. Then the bias is of order $O(\lambda_m^{2d})$ which can be quite severe, especially if d is low. Correspondingly the asymptotic normality requires at least $m^{1+4d}n^{-4d} \to 0$ as $n \to \infty$ which limits the size of the bandwidth and consequently the asymptotic efficiency of both estimators.

In order to reduce the bias of the GSE [5] suggested to incorporate explicitly a $\beta\lambda_j^{2d}$ term in the estimation to take into account the effect of the added noise on the spectral density of z_t and proposed a modified Gaussian semiparametric estimator (MGSE) defined as

$$(\tilde{d}_M, \tilde{\beta}_M) = \arg\min_{\Delta\times\Theta}\left[\log\left(\frac{1}{m}\sum_{j=1}^{m}\frac{\lambda_j^{2d} I_{yj}}{1+\beta\lambda_j^{2d}}\right) + \frac{1}{m}\sum_{j=1}^{m}\log\{\lambda_j^{-2d}(1+\beta\lambda_j^{2d})\}\right]$$

where $\Theta = (0, \Theta_1)$, $\Theta_1 < \infty$, $\Delta = [\Delta_1, \Delta_2]$, $0 < \Delta_1 < \Delta_2 < 1/2$. The upper bound in the bandwidth is relaxed now to comply $m^{1+2\alpha}(\log m)^2/n^{2\alpha} \to 0$ as $n \to \infty$ which allows a gain in asymptotic efficiency. In the fractional ARIMA processes the MGSE achieves a rate of convergence arbitrarily close to $n^{2/5}$ which is the upper bound of the rate of convergence of the Gaussian semiparametric estimator in the absence of additive noise. However with an additive noise the best possible rate of convergence achieved by the GSE is $n^{2d/(4d+1)}$. Regarding the bias, the MGSE has a bias of order $O(\lambda_m^{\alpha})$ instead of $O(\lambda_m^{2d})$ which is the bias of the GSE in the presence of an additive noise.

Sun and Phillips [8] extended the log periodogram regression in a similar manner. From (4) with $f'_u(0) = 0$

$$\begin{aligned} \log I_{zj} &= \log C - c_0 + d(-2\log\lambda_j) + \log\left(1 + \frac{f_u(0)}{C}\lambda_j^{2d}\right) + O(\lambda_j^{\alpha}) + U_{zj} \qquad (5) \\ &= \log C - c_0 + d(-2\log\lambda_j) + \frac{f_u(0)}{C}\lambda_j^{2d} + O(\lambda_j^{\alpha^*}) + U_{zj} \end{aligned}$$

where $\alpha^* = \min(4d, \alpha)$. Sun and Phillips [8] proposed a non linear log periodogram regression $\log I_{zj} = a + d(-2\log\lambda_j) + \beta\lambda_j^{2d} + U_{zj}$ for $\beta = f_u(0)/C$, such that the non linear log periodogram regression estimator (NLPE) are

$$(\hat{a}, \hat{d}, \hat{\beta}) = \arg\min \sum_{j=1}^{m} (\log I_{zj} - a + d(2\log\lambda_j) - \beta\lambda_j^{2d})^2 \qquad (6)$$

The bias of $\hat{d}$ is of order $O(\lambda_m^{\alpha^*})$ which is produced by the $O(\lambda_j^{\alpha^*})$ omitted in the regression in (6). Correspondingly the upper bound of m for the asymptotic normality is $O(n^{2\alpha^*/(2\alpha^*+1)})$. Sun and Phillips [8] only consider the case $\alpha = 2$ so that $\alpha^* = 4d$ and the behaviour of m is restricted to be $O(n^{8d/(8d+1)})$ with a bias of order $O(\lambda_m^{4d})$, but the extension to $\alpha < 2$ is straightforward. The asymptotic efficiency of the NLPE is higher than in the standard LPE but lower than the asymptotic efficiency of the MGSE when $\alpha > 4d$. The reason of this behaviour is the approximation of the log expression in (5). After this modification the regression model of [8] is still non linear and does not imply any computational advantage. Instead, noting (5) we propose the following non linear regression model

$$\log I_{zj} = a + d(-2\log\lambda_j) + \log(1 + \beta\lambda_j^{2d}) + U_{zj} \qquad (7)$$

which only leaves an $O(\lambda_j^{\alpha})$ term out of explicit consideration.

2 Asymptotic bias of the periodogram

Consider the following assumptions:

A.1: z_t in (1) is a long memory signal plus noise process with y_t an LM process with spectral density function in (2) with $d < 0.5$ and u_t is stationary with positive and bounded continuous spectral density function $f_u(\lambda)$.

A.2: y_t and u_t are independent.

Theorem 2.1. *Let z_t satisfy assumptions A.1 and A.2 and define $L_j(d) = E\left[\frac{I_{zj}}{C\lambda_j^{-2d}}\right]$. Then, considering j fixed $L_j(d) = A_{1j} + A_{2j} + o(n^{-2d})$ where*

$$\lim_{n\to\infty} A_{1j} = \int_{-\infty}^{\infty} \psi_j(\lambda) \left|\frac{\lambda}{2\pi j}\right|^{-2d} d\lambda\,, \quad \lim_{n\to\infty} n^{2d} A_{2j} = \int_{-\infty}^{\infty} \psi_j(\lambda) \frac{f_u(0)}{C(2\pi j)^{-2d}} d\lambda$$

with $\psi_j(\lambda) = \frac{2}{\pi}\frac{\sin^2\frac{\lambda}{2}}{(2\pi j - \lambda)^2}$.

Remark 1: In the LMSV case $f_u(0) = \sigma_\xi^2/2\pi$. The influence of the noise is clear here, the larger the variance of the noise the higher the relative bias of the periodogram. This explains the high bias of semiparametric estimates in LMSV models under a low signal to noise ratio in [2] and [1].

Remark 2: When $d < 0$ the bias increases without limit as n increases. This justifies the difficulties encountered when estimating a negative d in perturbed long memory series [3] and [1].

Theorem 2.2. *Let z_t satisfy assumptions A.1 and A.2, and consider a sequence of positive integers $j = j(n)$ such that $j/n \to 0$ as $n \to \infty$. Then*

$$L_j(d) = 1 + O\left(\frac{\log j}{j} + \lambda_j^{\min(\alpha,2d)}\right)$$

3 The ALP estimator

The augmented log periodogram estimator (ALPE) is defined as

$$(\tilde{a}, \tilde{d}, \tilde{\beta}) = \arg\min \sum_{j=1}^{m} (\log I_{zj} - a + d(2\log\lambda_j) - \log(1 + \beta\lambda_j^{2d}))^2 \qquad (8)$$

Concentrating the constant a out

$$(\tilde{d}, \tilde{\beta}) = \arg\min_{\Delta\times\Theta} \sum_{j=1}^{m} (\log I_{zj}^* + d(2\log\lambda_j)^* - \log^*(1 + \beta\lambda_j^{2d}))^2 \qquad (9)$$

where for a general ξ_t we use the notation $\xi_t^* = \xi_t - \bar{\xi}$ where $\bar{\xi} = \sum \xi_t/n$.

The first order conditions[1] of this minimization problem are

$$S(\tilde{d}, \tilde{\beta}) = 0 \qquad \text{where} \qquad S(d,\beta) = \sum_{j=1}^{m} \begin{pmatrix} x_{1j}^*(d,\beta) \\ x_{2j}^*(d,\beta) \end{pmatrix} W_j(d\beta)$$

with

$$\begin{aligned} x_{1j}(d,\beta) &= 2\left(1 - \frac{\beta\lambda_j^{2d}}{1+\beta\lambda_j^{2d}}\right)\log\lambda_j \,, \quad x_{2j}(d,\beta) = -\frac{\lambda_j^{2d}}{1+\beta\lambda_j^{2d}} \,, \\ W_j(d,\beta) &= \log I_{zj}^* + d(2\log\lambda_j)^* - \log^*(1+\beta\lambda_j^{2d}) \end{aligned}$$

Let d_0 be the true unknown memory parameter and d any admissible value and consider the same notation for the rest of parameters to estimate. Define the diagonal matrix $D_n = diag(\sqrt{m}, \lambda_m^{2d_0}\sqrt{m})$ and the matrix

$$\Omega = \begin{pmatrix} 4 & -\frac{4d_0}{(2d_0+1)^2} \\ -\frac{4d_0}{(2d_0+1)^2} & \frac{4d_0^2}{(4d_0+1)(2d_0+1)^2} \end{pmatrix}$$

[1] If we allow $\beta = 0$ a similar result (available upon request) to that in [8] is achieved.

Consider the following assumptions:

B.1: y_t and u_t are independent Gaussian processes.

B.2: $f_u(\lambda)$ is continuous on $[-\pi, \pi]$, bounded above and away from zero with bounded second derivative in a neighbourhood of zero.

B.3: The spectral density of y_t satisfy

$$f_y(\lambda) = C\lambda^{-2d}(1 + E\lambda^{\alpha} + o(\lambda^{\alpha}))$$

for some finite E and $\alpha \in (4d_0, 2]$.

B.4: For some positive constant K, as $n \to \infty$,

$$\frac{m^{2\alpha+1}}{n^{2\alpha}} \to K.$$

Assumption B.1 is quite severe and excludes LMSV models where u_t is not Gaussian but a log chi-square. Considering recent results, Gaussianity of signal and noise could be relaxed. However this would significantly complicate the technical details of the proofs and we prefer to keep the technical requirements to a minimum. Assumption B.2 restricts the behaviour of u_t and B.3 imposes a particular spectral behaviour of y_t around zero. This local specification permits to obtain the asymptotic bias of $\tilde{d}$ in terms of E. We restrict our analysis to the case $\alpha > 4d_0$ where the ALPE achieves a lower bias and higher asymptotic efficiency than the NLPE. In the standard fractional ARIMA process as considered in [8] $\alpha = 2$. We consider also $\alpha < 2$ which may be relevant in some situations, and permit a direct extension to the seasonal or cyclical long memory case. Assumption B.4 restricts the behaviour of the bandwidth m in a similar manner as in [8] but allowing a larger m.

Theorem 3.1. *Let z_t in (1) satisfy assumption B.1-B.3 and m satisfy B.4. Then as $n \to \infty$*

$$D_n \begin{pmatrix} \tilde{d} - d_0 \\ \tilde{\beta} - \beta_0 \end{pmatrix} \xrightarrow{d} N\left(\Omega^{-1}b, \frac{\pi^2}{6}\Omega^{-1}\right)$$

where

$$b = (2\pi)^{\alpha} K 2 \begin{pmatrix} -\frac{\alpha}{(1+\alpha)^2} \\ \frac{\alpha d_0}{(2d_0+\alpha+1)(2d_0+1)(1+\alpha)} \end{pmatrix} E.$$

The asymptotic bias of $\tilde{d}$ is then

$$ABias(\tilde{d}) = \left(\frac{m}{n}\right)^{\alpha} K_0 \quad \text{where} \quad K_0 = \frac{(2\pi)^{\alpha}\alpha(2d_0+1)(\alpha - 2d_0)E}{4d_0(1+\alpha)^2(2d_0+\alpha+1)}$$

In contrast to the LPE and NLPE, the ALPE $\tilde{d}$ has an asymptotic positive bias which decreases with d_0. The asymptotic variance and mean square error are

$$
\begin{aligned}
AVar(\tilde{d}) &= \frac{\pi^2}{24m}C_d \quad \text{where} \quad C_d = 1 + \frac{1+4d_0}{4d_0^2} \\
AMSE(\tilde{d}) &= \frac{\pi^2}{24m}C_d + \left(\frac{m}{n}\right)^{2\alpha} K_0^2.
\end{aligned}
$$

The optimal bandwidth, in an asymptotic MSE sense, is

$$
m_{opt} = \left(\frac{\pi^2 C_d}{48\alpha K_0^2}\right)^{\frac{1}{2\alpha+1}} n^{\frac{2\alpha}{2\alpha+1}}.
$$

The optimal bandwidth of the ALPE increases with n faster than the corresponding m_{opt} of the NLPE. Correspondingly the AMSE($\tilde{d}$) converges to zero at a rate $n^{-2\alpha/(2\alpha+1)}$ which is faster that the $n^{-4d_0/(4d_0+1)}$ obtained with the optimal m in the LPE and if $\alpha > 4d_0$ (as in the $\alpha = 2$ case) it is faster than the $n^{-8d_0/(8d_0+1)}$ rate achieved by the NLPE with an optimal m.

4 Finite sample performance

We compare the finite sample performance of the LPE and NLPE with the ALPE in a LMSV

$$
z_t = y_t + u_t
$$

for $(1-L)^{0.45}y_t = w_t$ and $u_t = \log \varepsilon_t^2$, for ε_t and w_t independent, ε_t is standard normal and $w_t \sim N(0, \sigma_w^2)$ for $\sigma_w^2 = 0.5, 0.1$. These values correspond to long run noise to signal ratios $f_u(0)/f_w(0) = \pi^2$, $5\pi^2$. The first value is close to the values considered in [3] and [8]. The second one corresponds more closely to the values found in financial time series. Since ε_t is standard normal, u_t is a $\log \chi_1^2$ and consequently assumption B.1 does not hold. However we consider relevant to show that the ALPE can be applied in LMSV models which are an essential tool in the modelling of financial time series, and justify in that way our conjecture of no necessity of Gaussianity of the added noise.

The Monte Carlo is carried out in SPlus 2000, generating y_t with the option arima.fracdiff.sim and for the non linear optimization we use nlminb for $0.0001 < d < 0.7$ providing the gradient and the hessian. We just consider a sample size of $n = 1024$ which is comparable with the size of many financial series and permits the exact use of the Fast Fourier Transform. The grid of bandwidths analysed is $m = 10(2)\ldots, 500$. The number of replications is 1000. The advantages of the ALPE over both the LPE and NLPE are clear in Figure 1.

5 Long memory in Ibex35 volatility

In this section we analyze the persistence of the volatility of the Spanish stock index Ibex35 composed of the 35 more actively traded stocks for the period 1-10-93 to 22-3-96 half-hourly. The returns are constructed by first

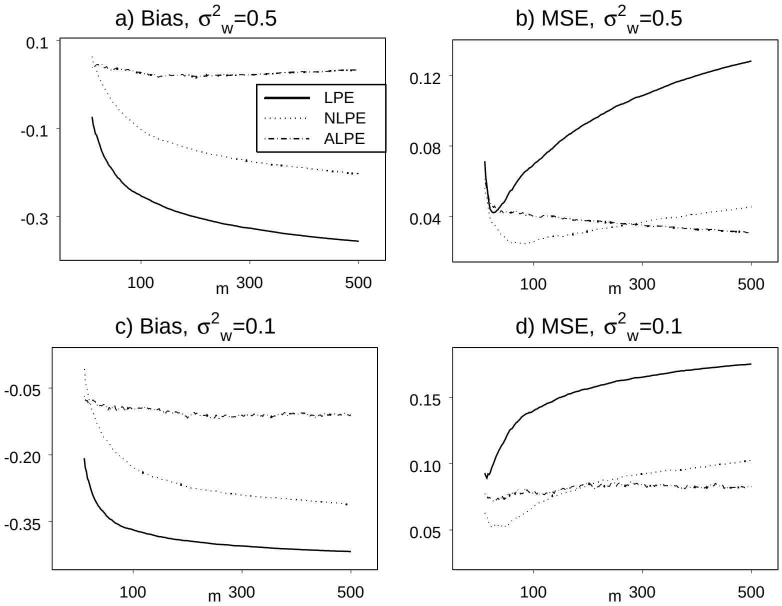

Figure 1: Bias of LPE, NLPE and ALPE, $d = 0.45$.

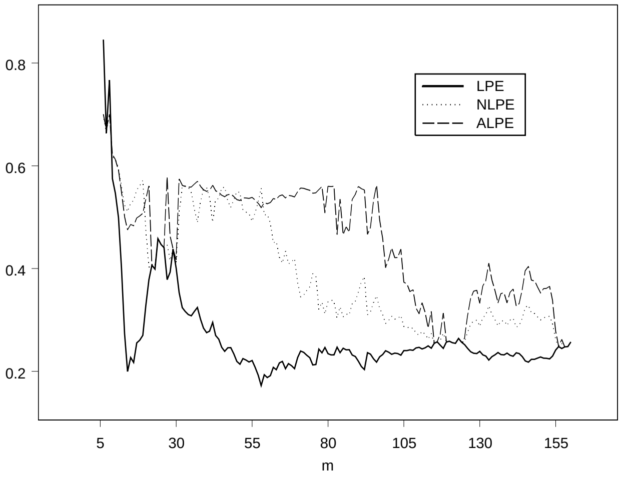

Figure 2: Log periodogram estimates (IBEX35).

differencing the logarithm of the transaction prices of the last transaction every 30 minutes, omitting incomplete days. After this modification we get the series of intra-day returns x_t, $t = 1, \ldots, 7260$. Figure 2 show the LPE, NLPE and ALPE for a grid of bandwidths $m = 6, \ldots, 160$. The decreasing behaviour of the LPE is similar to that of the Gaussian semiparametric estimation in Figure 3. However the NLPE and ALPE are higher and more stable with m sustaining the Monte Carlo results in the previous section. Comparing Figures 2 and 3 the resemblance of the LPE and GSE on one hand and the MGSE and the ALPE on the other, are evident.

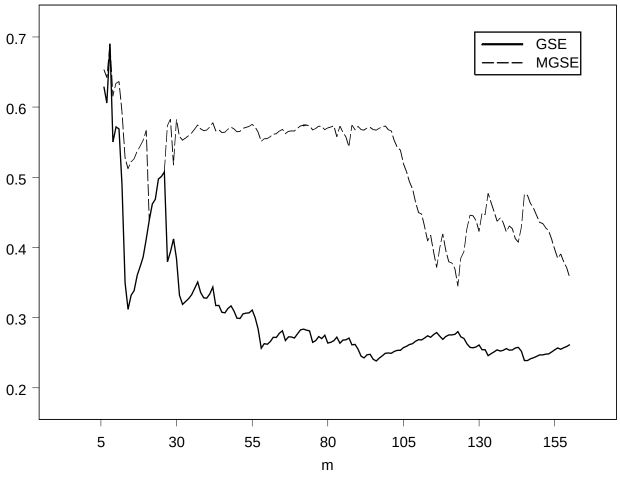

Figure 3: Standard and modified Gaussian semiparametric estimates (IBEX35).

DISTAL POINTS VIEWED IN KOHONEN'S SELF-ORGANIZING MAPS

Anna Bartkowiak

Key words: Multivariate data visualization, self-organizing maps, outliers, distal points.

COMPSTAT 2004 section: Data visualization.

Abstract: Kohonen's self-organizing maps are a recognized tool for finding representative data vectors and clustering the data. To what extent is it possible to preserve the topology of the data in the constructed planar map? We address the question looking at distal data points located at the peripherals of the data cloud and their position in the provided map. Several data sets have been investigated; we present the results for two of them: the Glass data (dimension $d = 7$) and the Ionosphere data (dimension $d = 32$). It was found that the distal points are reproduced either at the edges (borders) of the map, or at the peripherals of dark regions visualized in the maps.

1 Problem

Kohonen's self-organizing maps [5], [12] are a recognized tool for finding representative data vectors and clustering the data. The method provides also a 'map' of the data. It is expected that the map will preserve a large part of the topology from the data space. To what extent is it possible to preserve the topology of the data in the constructed planar map? After all, the data are multidimensional, and the map has only two dimensions! Various neighborhood relations have been investigated, see [11], [4] and the references therein. However, little attention has been paid to the outliers and distal points of the data and how are they reproduced in the map. Maruzabál and Muñoz [6] have discussed extensively that problem and concluded that self-organizing maps are not a good tool for identifying outliers. An assessment of Kohonen's method was given by Morlini [7].

Since then, we got a graphical tool, the UMAT technique, which permits to represent distances in a planar map by smoothed color hues. The UMAT technique was already implemented in Kohonen's SOM_PAK package (1995); the technique is also available in the Matlab `SomTB2` package [13]. This gives us a powerful tool to analyze the representation of the data in the map.

The aim of the paper is to investigate, how the data points located at the peripherals of the data cloud are represented in the map. Such points are also called 'distal points', see Wouters et al., Biometrics 2003, p. 1136. The distal points might be outliers, or alternatively, they might be just extreme or peripheral points of the data cloud. Several data sets have been investigated. We present here the results for two of them: the Glass data, which contain possibly four outliers (this was not further pursued), and the Ionosphere data, which seem to be a mixture with no apparent outliers.

For each of the investigated data sets we have found the top 20 distal points; this was done using robust Mahalanobis distances [9]. Next the found 20 points were projected to the map and their position in the map was observed. It was stated that the distal points are reproduced either at the edges (borders) of the map, or at the peripherals of dark regions visualized in the map.

The paper is scheduled as follows: In section 2 we present briefly the methods. Sections 3 and 4 contain the detailed analyzes for the Glass and the Ionosphere data. Section 5 contains some concluding remarks.

2 Methods

We consider data vectors $\mathbf{x}_i,\ i = 1, \ldots, N$, with $\mathbf{x}_i = (x_{i1}, \ldots, x_{id})$. Thus d denotes the number of variables (dimensionality), and N is the number of data vectors. The size of the data set is: $N \times d$.

Determining the distal points

The distal points were determined using robust Mahalanobis distances evaluated using the `fastmcd` algorithm developed by Rousseeuw and van Driessen [9]. For calculations we have used the Matlab function `fastmcd` offered by the cited authors. The function yields (a.o.) an index-plot of the robust Mahalanobis distances. Let $\mathbf{x}_i \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma}),\ i = 1, \ldots, N$. It may be shown that squared Mahalanobis distances, evaluated for the data vectors $\mathbf{x}_i$, are distributed as χ^2_d.

Let $\chi^2_{.975}$ denote the (upper) 0.975 quantile of the χ^2_d distribution. Data points with Mahalanobis distances greater then $\sqrt{chi^2_{.975}}$ are suspected to be outliers.

Constructing the map

The methodology of Kohonen's self-organized maps id described in many sources, see, e.g., [5], [12], [6]. For the calculations we have used the Matlab `SomTB2` package [13]. Before starting the analysis, the data were standardized to mean equal zero and variance equal 1.

The basis for a self-organizing map is a lattice of given size. We have chosen a rectangular lattice composed of square units. The nodes of the grid contain neurons that are able to learn the distribution of the data. Let M denote the number of neurons. We have: $M = m_1 \times m_2$, with m_1 and m_2 denoting the side-lengths of the lattice. Each neuron designates a regular (in our case: square) map unit. The neurons are in one–to–one correspondence with prototypes of the data (called by Kohonen 'code-book vectors') located in the data space R^d.

During the process of learning, the code-book vectors adapt themselves to the distribution of the data. At the end of the learning, the entire data space is subdivided into adjacent regions; each region contains one representative code-book vector. Each data point has assigned its nearest code-book vector.

We may display in the map various information about the data. For instance, we may show, by appropriate shadowing of the map, how distant are the prototypes in the data space. The hues depend on the chosen colormap. Dark hues may, e.g., indicate that the respective prototypes are distant, bright hues may mean that the prototypes are close.

It might be also interesting to know how many data vectors are represented by each prototype. This information may be obtained using the technique 'som_hits', shortly: 'hits'. We pass through the data and find for each data vector $\mathbf{x}_i$, $(i = 1, \ldots, N)$ its closest prototype. Say, for $\mathbf{x}_i$ this is the prototype no. h. It is in correspondence with the neuron no. h, which in turn is contained in map unit no. h. Shortly it is said that the map unit no. h was hit by the vector $\mathbf{x}_i$. After passing through the entire set of data we obtain the *counts*, an array of size [1:M], memorizing how many times a map unit was 'hit' by subsequent data vectors. The same may be done for a subset of the data (in our case: the subset of distal points), or for a different set of data with the same dimension d. The counts (number of hits) may be also displayed in the map: either in the form of properly enlarged markers, or in the form of labels expressing digitally the number of hits. We will display them in a template of the map.

3 Visualization of the Glass data

The Glass data (source: [10]) contains $N = 214$ data vectors, each characterized by $d = 7$ variables (from the original data we have taken for our analysis the variables 2–8). The data exhibit a high multivariate kurtosis (the excess kurtosis $G_2 = 142.67$).

Index-plot for robust Mahalanobis distances calculated by the `fastmcd` procedure [9] is shown in Figure 1. One may notice that there are four outstanding points, which might be eventually considered as outliers. However, there are other data points which have quite large Mahalanobis distances. We have identified the top 20 points with the largest Mahalanobis distances – in the following these 20 points will be referred to as 'distal' points.

The map constructed for the entire glass data is shown in Figure 2. Nodes of the map represent neurons, which are in one-to-one correspondence with data prototypes located in the data space. Color shades indicate for distances of corresponding prototypes in R^d, looking in east-south directions of the map. The 20 distal points are marked by big squares squares. The topological error [13] amounts $t_e = 0.084$ (in scale [0, 1]), which is quite good.

The *counts*, containing the number of hits received by subsequent units (see explanation in previous page) are shown in the templates below.

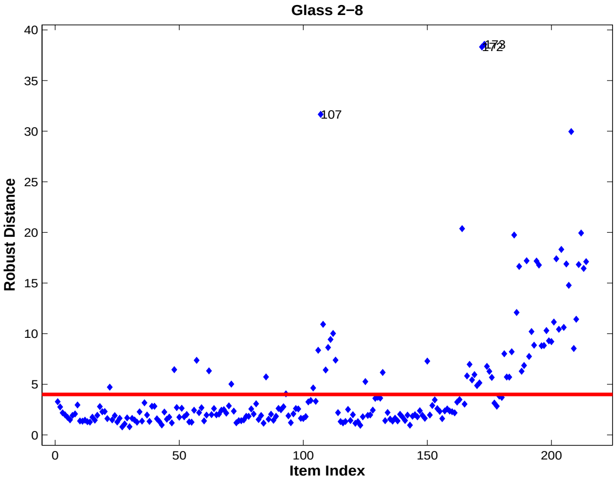

Figure 1: Robust Mahalanobis distances for the Glass data. The top four outlying points are: no.s 173, 172, 107, 208.

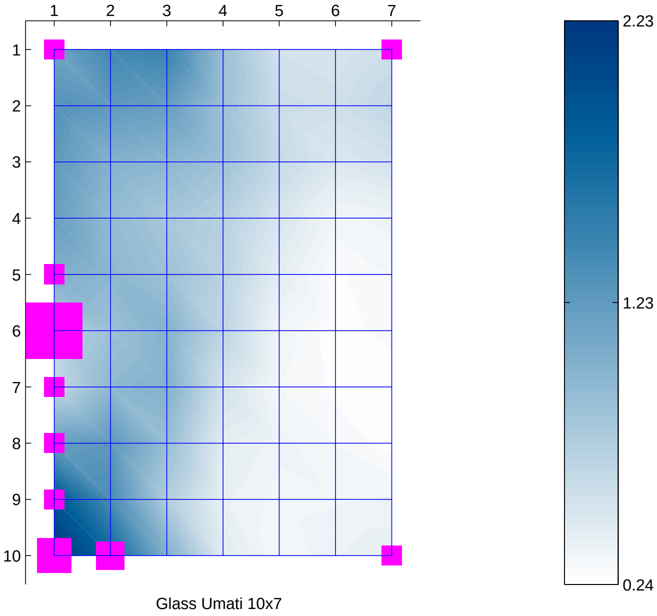

Figure 2: Map designed by a lattice 10 × 7 obtained for the standardized Glass data. The 20 distal points are shown as big squares put over the map nodes. Notice, that all distal points appear at borders of the map.

4 Visualization of the Ionosphere data

The Ionosphere data (source: [10]) contains $N = 351$ data vectors, each characterized by 35 variables; from these the first variable is the no. of the data vector, and the last a string characterizing class membership (binary). From the original data we have taken for our analysis the variables 3–34, thus we have $d = 32$. The data exhibit a high multivariate kurtosis (the excess kurtosis amounts $G_2 = 1684.65$).

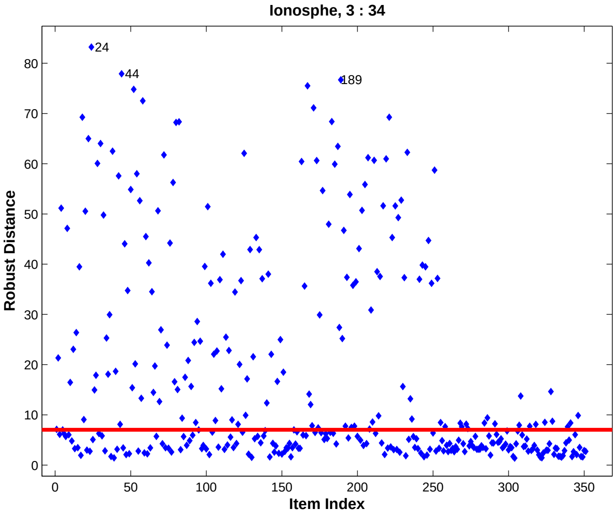

Figure 3: Robust Mahalanobis distances for the Ionosphere data. There are no outliers, only distal points. The distribution seems to be a mixture.

Plot of robust Mahalanobis distances for these data is shown in Figure 3. One may notice, that truly there are no outliers, only a lot of distal (peripheral) points. The composition of the data is quite interesting. It seems that we have here to deal with a mixture.

The top 20 distal points are the following ones (listed in increasing value of their Mahalanobis distances): [207 72 125 233 38 187 30 22 80 82 183 18 7221 171 58 52 167 189 44 24].

The map constructed for the entire (standardized) Ionosphere data is shown in Figure 4. The topological error [13] amounts here $t_e = 0.064$ (in scale [0, 1]), which is very satisfactory and indicates for a good preservation of the topology of the original data. The map units hit by the chosen 20 distal points are shown as big squares put over the nodes of the map. Distances between prototypes in R^d (when looking at east-south directions of the map) are indicated by hues of the colors, as shown in the color-bar at the right of the figure. One may notice that some of the distal points have placed themselves at the borders of the map; other distal points appear at the borders of dark regions appearing in the map.

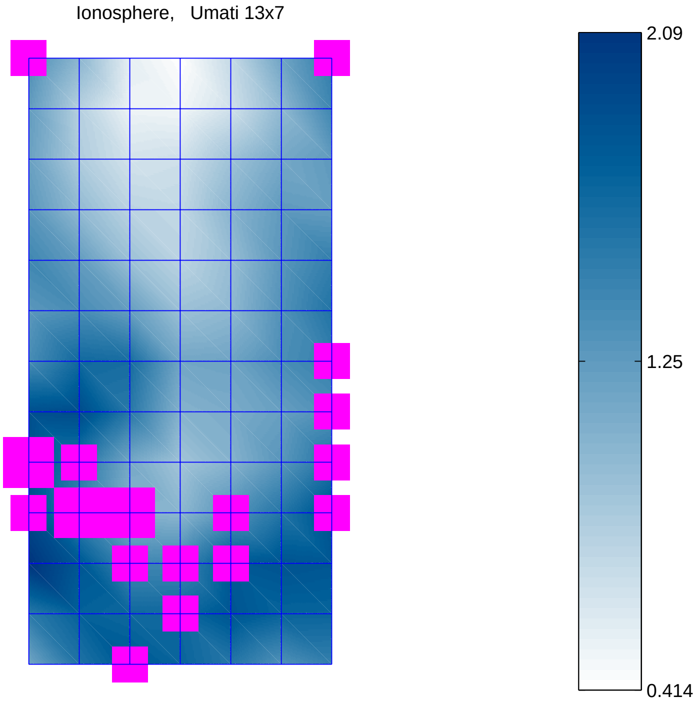

Figure 4: SOM obtained for the standardized Ionosphere data ($d = 32$) with 20 distal points marked by big squares put over the nodes of the map. Increasing darkness indicates for increasing distance between the prototypes. Notice that distal points appear either on the borders of the map, or at the borders of dark areas.

The *counts*, i.e. the number of hits into subsequent map units (a unit is identified by a map node) are shown in the templates below.

The entire data set was subdivided into 3 categories: 1) Top 20 distal points exhibiting the largest Mahalanobis distances in Figure 3; 2) Mild distal points with Mahalanobis distances greater then 15.0; remind that for normal data the respective 0.975 quantile equals to $\sqrt{\chi^2_{.975;32}} = 7.03$; 3) Remainder, containing 260 data points with moderate and small Mahalanobis distances (≤ 15.0).
One may notice the difference in location of hits caused by data points belonging to the 1st and 2nd categories opposed to the 3rd category.

5 Discussion and final remarks

The presented results agree with conclusions of Morlini [7]. Indeed, Kohonen's maps, when properly used, offer many highly interesting possibilities of data exploration.

Competitive methods might be: The *Neuroscale* mapping and the *Generative Topographic mapping.* The *neuroscale* mapping (see [3], also [8] and the references therein) seems to be very promising. An example of application in analysis of erosion data is shown in [2]. Preliminary comparisons of self-organizing maps (SOMs) and the GTM method are reported in [1].

PLS-COX MODEL: APPLICATION TO GENE EXPRESSION

Philippe Bastien

Key words: Cox model, PLS regression, gene profiling.

COMPSTAT 2004 section: Partial least squares.

Abstract: With advances in high-density DNA microarray technology, gene expression profiling is extensively used to discover new markers and new therapeutic targets. This technique supposes to take into account the expression of thousands of genes with respect to a limited number of patients. To predict survival probability on the basis of gene expression signatures can become a very useful diagnostic tool. In the context of highly multidimensional data the classical Cox model does not work. The PLS-Cox model by operating a dimension reduction of the gene expression space directed towards the explanation of the risk function appears particularly useful. It allows the determination of signatures of genomic expressions associated with survival, to predict the survival probability from these profiles, and reduce inter individual variability by changing the level of adjustment from a phenotypical level to a genotypical level.

1 Introduction

The proportional hazard regression model suggested by [5] to study the relationship between the time to event and a set of covariates in the presence of censoring, is the model most commonly used for the analysis of survival data. However, like multivariate regression models, it supposes that there are more observations than variables, complete data, and variables not strongly correlated between them. These constraints are often crippling in practice. In particular the analysis of transcriptomic data supposes to take into account the expression of thousands of genes compared to only a limited number of patients. The solution suggested is to initially operate a dimension reduction of the space of genes directed towards the explanation of the risk function. One then builds a Cox model on the PLS components.

Alizadeh et al. [2] identified from the expression of genes of 40 subjects suffering from diffuse large B-cell lymphomas (DLBCL) two subgroups, each characterized by a distinct gene expression signature. These were associated with very different clinical prognoses. Using information on patients survival allows the determination of genotypic signatures linked to the risk function. Survival probabilities have then been carried out from these expression profiles. We show that these genotypic signatures bring additional informations to an index of existing clinical risk.

2 Methods

The suggested method associate PLS regression [9] with the Cox model. It has already been used on epidemiological data [3]. Its specificity is that it takes into account the censoring information in the construction of PLS components.

PLS-Cox algorithm

Let $X_0 = x_1, \ldots, x_p$ a matrix whose columns are gene expression (log ratio). One seeks successively m orthogonal PLS components T_h which are linear combinations of the x_j. In particular the research of the h-th.PLS component Th is carried out according to the following steps:

Step 1: For $j = 1$ to p, calculate the coefficients of regression a_{hj} of x_j in the Cox model with covariates $T_1, T_2, \ldots, T_{h-1}$ and x_j.
Step 2: Normalize the column vector ah formed by $a_{hj} : w_h = a_h / \|a_h\|$.
Step 3: Calculate the residual X_{h-1} of the linear regression of X_0 on $T_1, \ldots, T_{h-1}$.
Step 4: Calculate the component $T_h = X_{h-1} w_h / w'_h w_h$.
Step 5: Express the component T_h according to $X_0 : T_h = X_0 w^*_h$.

The prediction of the risk function h(t) is then carried out in a natural way with the Cox model adjusted on PLS components. The regression equation can also be written according to the original data with the coefficients confidence intervals estimated by bootstrap resampling.

Cross-validation

The number k of PLS components T_h was chosen by cross-validation. Each patient's score was estimated using a training data set of $N - 1$ samples (leave-one-out CV). Let i be the subscript for sample i and $-i$ the subscript when sample i is leaved out. The score for patient i on h-th PLS component is defined as:

$$t_{h,j} = x_{h-1,i}\, w_{h,-i} = \left(x_{0,i} - \sum_{j=1}^{h-1} t_{j,i}\, p'_{j,-i} \right) w_{h,i}$$

with: $x_{h-1,i}$ the i-th row of the residual matrix X_{h-1}; $w_{h,-i}$ the weights based on $X_{h-1,-i}$; $p'_{j,-i}$ the loadings, defined as the coefficients of $T_{j,-i}$ in the regression of $X_{0,-i}$ on $T_{1,-i}, \ldots, T_{j,-i}$, the j first PLS components carried out on $X_{0,-i}$.

PLS-Cox and PLS-GR

The Cox-PLS algorithm uses the principles of the NIPALS algorithm [10] and can also function in the presence of missing data. The PLS-Cox model is a particular case of PLS generalized linear regression [4].

Estimation of the survivor function

During the prediction phase, a proportional hazard model is fitted with the k PLS scores $T_1, \ldots, T_k$ as covariates. Let $S_0(t) = \exp\left[-\int_0^i h_o(u)du\right]$ the baseline unspecified survivor function, $T_i' = (t_{i1}, \ldots, t_{ik})$, and $\beta' = (\beta_1, \ldots, \beta_k)$. The survivor function given the scores T_i is: $S(t, T_i) = S_0(t, T_i)^{\exp(T_i', \beta)}$. The calculation of the non-parametric maximum likelihood of $S_0(t)$ [6] is based on the product limit estimate with similar argument to that used in obtaining kaplan-Meier estimate.

Let $t_{(1)}, \ldots, t_{(l)}$ be the distinct failures times, the likelihood function is maximized by taking $S_0(t) = S_0(t_{(i)} + 0)$ for $t_{(i)} < t \leq t_{(i+1)}$ and allowing probability mass to fall only at the observed failure time $t_{(i)}$. This leads to the consideration of a discrete model with hazard contribution $1 - \alpha_i$ at $t_{(i)}$. Let

$$\hat{S}_0(t) = \prod_{j/t(j)<t} \hat{\alpha}_j$$

the survival probability at time t

$$\hat{S}_i(t) = \prod_{j/t(j)<t} \hat{\alpha}_j^{\exp T_i \beta}$$

the survival probability at time t for a patient with covariates T_i.

The maximum likelihood estimate $\hat{\alpha}_i$ of α_i is obtained numerically from:

$$\sum_{k \in F_i} \frac{\hat{u}_k}{1 - \hat{\alpha}_i^{\hat{u}_k}} = \sum_{l \in R(t_i)} \hat{u}_l$$

with $\hat{u}_k = \exp(T_k' \hat{\beta})$, F_i the set of individuals failing at time $t_{(i)}$ and $R_{(ti)}$ the risk set at time $t_{(i)}$. In case where there are no ties then the set F_i contains only one individual and the solution to the above equation can be solved analytically and is given by

$$\hat{\alpha}_i = \left[1 - \left(\hat{u} / \sum_{l \in R(t_i)} \hat{u}_l\right)\right]^{\hat{u}_i^{-l}} .$$

One finds the Kaplan-Meier estimator when $T_i = 0$ for all the individuals:

$$\hat{S}(t) = \prod_{j/t(j)<t} \frac{(n_j - d_j)}{n_j} .$$

3 Application

The data set from [2] consists of gene expression level from cDNA experiments involving three prevalent adult lymphoid malignancies: Diffuse large B-cell lymphoma (DLBCL), B-Cell chronic Lymphocytic Leukemia (BCLL), and Follicular Lymphoma (FL). Data are available on the study supplement web site (`http://llmpp.nih.gov/lymphoma/data.shtml`).

CDNA targets were prepared from experimental mRNA samples and were labelled with Cy5-dye during reverse transcription. A reference cDNA sample was prepared from a combination of nine different lymphoma cell lines and was labelled with Cy3-dye. Cy-labelled experimental and reference cDNAs were mixed and hybridised onto the microarray The standardized intensity ratio of fluorescence was then quantified for each gene. It reflects the relative abundance of the gene in each experimental sample of mRNA compared to the reference sample.

By using clustering analysis, Alizadeh and al. [2] identified two DLBCL sub-groups with different transcriptomic profiles. They correspond to distinct levels of lymphocytes B differentiation: Germinal Center B-like (19 patients) and Activated B-like (21 patients). In complement to the transcriptomic data, the duration of patients survival was also collected. Among the 40 patients 22 events (death) were observed and the 18 remaining survival durations being censured. Patients with a DLBCL of the Germinal center B-like have, on average, a significantly better survival than those with Activated B-like type as shown on figure 1. The molecular classification of the tumours on the basis of their genetic expression profile thus allows to highlight sub-types of cancer non identified.

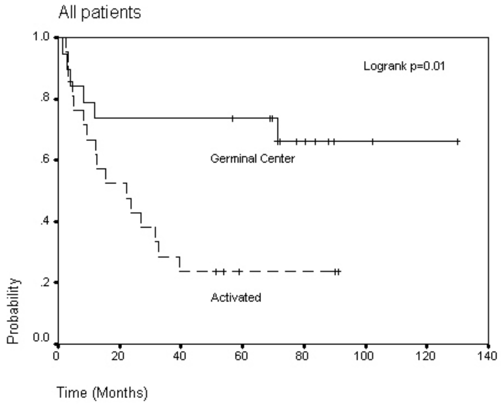

Figure 1: Kaplan-Meier survival curves estimates by molecular sub-groups.

4 Results

One Thousand and height hundred genes were selected from over more than 13000 to having different expressions to the two molecular types (ttest, $p < 0.05$). We retained two PLS components by cross-validation. Once PLS-

Cox model has been estimated, the significance of genes coefficients could be ascertain in a non parametric framework by means of a bootstrap procedure. Bootstrap confidence intervals were computed based on the 2.5 and 97.5 percentiles of the bootstrap empirical distribution (balanced bootstrap, B=500).

Figure 2 presents coefficients confidence intervals of the PLS-Cox model on two components expressed according to their original data (log ratio). The coefficients were sorted by ascending values. In order to simplify PLS components, only genes having a significant contribution at the 5 % threshold were taken into account. It explains the clear separation on both sides of the ordinate axis.

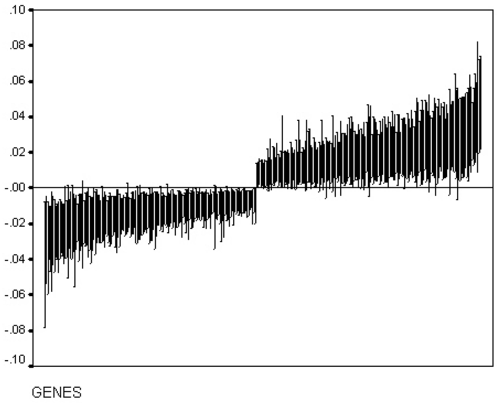

Figure 2: 95% bootstrap confidence intervals for genes coefficients.

The following graph (figure 3) presents the individual distributions for the patients of the Activated B-like type (dotted line) and for those of Germinal center B-like type (continuous line). The letters represent the average distributions by molecular type. The distributions were estimated by cross-validation with two PLS components.

Based on the log-ratio of gene expressions for the mean levels of PLS components, the survival curves demonstrated more marked prognoses between the two molecular types in comparison to the survival estimation using Kaplan-Meier. The genotypic signatures of the two molecular types appear well associated with the different prognoses, with very minor overlaps.

International prognostic indicator (IPI)

A clinical index scored from 0 to 5 is used to define sub-groups of patients suffering from DLBCL. The subjects of the group with the lowest scores IPI (0-2) have a better prognostic than those having highest scores (3-5). Alizadeh et al [2] showed that in the group with the lowest risk factors, the

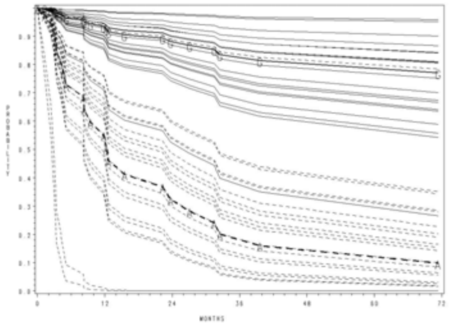

Figure 3: Cross-validated survival curves.

patients presenting a profile of genetic expression of Germinal center B-like type had a significantly better survival (Logrank, $p < 0.05$) that those of Activated B-like type. They did not observe a similar effect in the higher risk factors group ($p = 0.55$) as illustrated in figure 4.

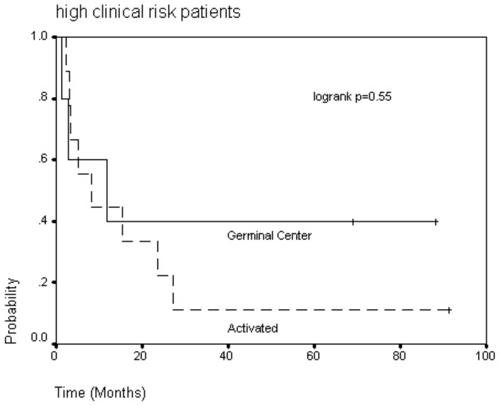

Figure 4: Kaplan-Meier survival curves for the high clinical risk patients.

The Cox-PLS model on the higher risk factors group, taking into account the transcriptomic information is more selective and allows the differentiation of the two molecular types. Figure 5 shows the individual distributions of survival estimated by cross-validation.

The gene expression signatures makes it possible to differentiate the two molecular types.

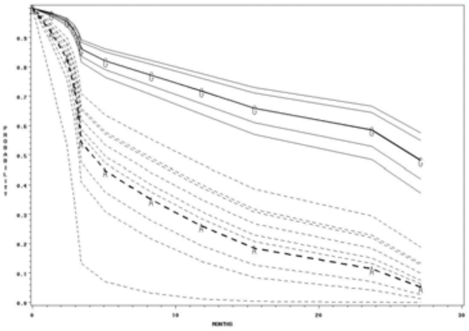

Figure 5: Cross-validated survival curves for the high clinical risk patients.

5 Discussion

With advances in high-density cDNA microarray technology, gene expression profiling is extensively use to discover new markers and new therapeutic targets. This technique supposes to take into account the expression of thousands of genes with respect to only a limited number of patients. To predict survival probability on the basis of gene expression signatures can become a very useful diagnostic tool. In the context of highly multidimensional data the classical Cox model does not work.

Recently Nguyen and Rocke [7] illustrated using the example of [2] the use of PLS components as covariates to predict the probabilities of survival in a Cox model. However their model was not completely satisfactory, since it did not take into account the censoring information in the estimation of PLS component, thus inducing a potential bias in their estimates.

The PLS-Cox model described above shows major improvement with respect to the method proposed by [7]. It takes into account the censoring information in the estimation of PLS components. In case of missing data, PLS components are computed in accordance with the NIPALS algorithm. Moreover statistical significance of gene coefficients is ascertain using bootstrap validation procedure.

The PLS-Cox model by operating a dimension reduction of the genes expression space directed towards the explanation of the risk function appears particularly useful. It allows the determination of signatures of genomic expressions associated with survival, to predict the survival probability from these profiles, and reduce inter individual variability by changing the level of adjustment from a phenotypical level to a genotypical level. In order to assess the efficacy of new drugs, study design will benefit from a better characterisation of patient groups made possible by genomic expression profiling.

TESTING SOLUTION QUALITY IN STOCHASTIC PROGRAMMING: A SINGLE REPLICATION PROCEDURE

Guzin Bayraksan and David P. Morton

Key words: Stochastic programming, Monte Carlo simulation.

COMPSTAT 2004 section: Optimization.

Abstract: We develop a procedure for testing the quality of a candidate solution for a class of stochastic programs. Quality is defined via the optimality gap and the procedure's output is a confidence interval on this gap. We review a multiple-replications procedure and then, we present a result that justifies a computationally simplified single-replication procedure. We compare empirical coverage results of the two procedures for a newsvendor problem.

1 Introduction

We consider a stochastic optimization problem of the form

$$z^* = \min_{x \in X} Ef(x, \tilde{\xi}), \tag{1}$$

where f is a real-valued function that determines the cost of operating with decision x under a realization of the random vector $\tilde{\xi}$, whose distribution is assumed known. $X \subseteq \mathbb{R}^n$ denotes the set of constraints that the decision vector x must obey and E is the expectation operator. As simple as it is to state, (SP) represents a large class of problems that can be found in the statistics and operations research literature. Our motivation comes from a special class of (SP) known as two-stage stochastic programs with recourse. The well-known two-stage stochastic linear program with recourse was introduced independently by [2], [4], in which

$$\begin{aligned} f(x, \tilde{\xi}) = cx \ + \ & \min_{y \geq 0} \quad \tilde{q}y \\ & \text{s.t} \quad \tilde{W}y \geq \tilde{r} - \tilde{T}x, \end{aligned}$$

$X = \{x : Ax = b, x \geq 0\}$ and $\tilde{\xi} = (\tilde{q}, \tilde{W}, \tilde{r}, \tilde{T})$ is a random vector on $(\Xi, \mathcal{B}, P)$. This formulation can be extended to multiple stages, integer restrictions can be imposed in any of the stages and nonlinear constraints and objective function terms can be added. Stochastic programs with recourse have been successfully applied to problems from finance, energy, telecommunications, transportation, logistics and supply chain management (e.g., [10]).

We do not restrict ourselves to the linear recourse model. Instead we make the following assumptions with respect to (SP).

(A1) $f(\cdot, \tilde{\xi})$ is continuous on X, w.p.1,
(A2) $E \sup_{x \in X} f^2(x, \tilde{\xi}) < \infty$,
(A3) $X \neq \emptyset$ and is compact.

As the dimension of the random vector $\tilde{\xi}$ grows, (SP) gets harder and often impossible to solve exactly, unless the cost function f has simple structure, or the number of realizations is small. In such cases, an intuitive approach is to resort to sampling and approximate the problem with

$$z_n^* = \min_{x \in X} \frac{1}{n} \sum_{i=1}^{n} f(x, \tilde{\xi}^i). \tag{2}$$

$\tilde{\xi}^1, \tilde{\xi}^2, \ldots, \tilde{\xi}^n$ may be independent and identically distributed (i.i.d.) as $\tilde{\xi}$ or may be generated according to another sampling scheme. Let x^* denote an optimal solution to (SP) with optimal cost z^*. Similarly, let x_n^* and z_n^* denote an optimal solution and the optimal cost of (SP$_n$). Consistency and other asymptotic properties of estimators x_n^* and z_n^* have been studied extensively in the literature, see e.g., [1], [5], [6], [9].

In this paper, we discuss Monte Carlo sampling-based procedures for testing solution quality in stochastic programs. Determining whether a solution is of high quality (optimal or near optimal) is a fundamental question in optimization. Given a candidate solution $\hat{x}$, we define its quality by its optimality gap, $\mu_{\hat{x}} = Ef(\hat{x}, \tilde{\xi}) - z^*$. In the next section, we review how to construct confidence intervals (CIs) on the optimality gap using a multiple replications procedure [7]. Then, we show how to obtain a valid CI using only a single replication. Finally, we examine a newsvendor problem with uniform demand and compare empirical coverage results for the two procedures.

2 Review of multiple replications procedure

Let $\tilde{\xi}^1, \tilde{\xi}^2, \ldots, \tilde{\xi}^n$ be i.i.d. from the distribution of $\tilde{\xi}$. Then, by interchanging minimization and expectation we obtain a statistical lower bound on z^*,

$$Ez_n^* = E\left[\min_{x \in X} \frac{1}{n} \sum_{i=1}^{n} f(x, \tilde{\xi}^i)\right] \leq \min_{x \in X} E\left[\frac{1}{n} \sum_{i=1}^{n} f(x, \tilde{\xi}^i)\right] = \min_{x \in X} Ef(x, \tilde{\xi}) = z^*.$$

This result establishes that z_n^* has a negative bias, $Ez_n^* - z^* \leq 0$. It can also be shown that $Ez_n^* \leq Ez_{n+1}^*$ for all n. This monotonicity result tells us that on average we get better estimates of the optimal value as the sample size increases.

Given a feasible decision $\hat{x} \in X$ and a sample size n for (SP$_n$), we bound the optimal value of (SP) using the above lower

bound result, $Ez_n^* \leq z^* \leq Ef(\hat{x}, \tilde{\xi})$. The right inequality comes from suboptimality of $\hat{x}$. An upper bound on the optimality gap for $\hat{x}$ is then

$Ef(\hat{x},\tilde{\xi}) - Ez_n^*$. We estimate this quantity by

$$G_n(\hat{x}) = \frac{1}{n}\sum_{i=1}^{n} f(\hat{x},\tilde{\xi}^i) - \min_{x\in X}\frac{1}{n}\sum_{i=1}^{n} f(x,\tilde{\xi}^i). \tag{3}$$

The first term on the right-hand side of (3) is an upper bound estimate and converges to $Ef(\hat{x},\tilde{\xi})$, w.p.1, by the strong law of large numbers. The second quantity, z_n^*, is a lower bound estimate on z^*. In expectation, it provides a lower bound and under (A1)-(A3) converges to z^*, w.p.1 (see subsequent Lemma 3.1). When a common stream of random numbers, $\tilde{\xi}^1, \tilde{\xi}^2, \ldots, \tilde{\xi}^n$, is used in calculating both terms in (3), $G_n(\hat{x}) \geq 0$, w.p.1. This approach also facilitates variance reduction.

Because of the minimization in (3), $G_n(\hat{x})$ (or, its scaled version $\sqrt{n}(G_n(\hat{x}) - \mu_{\hat{x}})$) is, in general, not normally distributed even as n grows large. Therefore, in [7] confidence intervals are constructed by employing replications, an approach frequently used in simulation for estimating the mean of a random variable with an unknown or non-normal distribution. We summarize below the multiple replications procedure (MRP) to construct a CI on the optimality gap. Let $t_{n,\alpha}$ be the $1-\alpha$ quantile of the Student's t distribution with n degrees of freedom.

MRP:

Input: Desired CI level $0 < \alpha < 1$, sample size n, replication size n_g and a candidate solution $\hat{x} \in X$.

Output: $(1-\alpha)$-level confidence interval on $\mu_{\hat{x}}$.

2. Calculate gap estimate and sample variance by
```

$$\bar{G}(n_g) = \frac{1}{n_g}\sum_{i=1}^{n_g} G_n^i(\hat{x}) \quad \text{and} \quad s_G^2(n_g) = \frac{1}{n_g - 1}\sum_{i=1}^{n_g}\left(G_n^i(\hat{x}) - \bar{G}(n_g)\right)^2.$$

```
3. Output one-sided CI on $\mu_{\hat{x}}$, $\left[0, \bar{G}(n_g) + t_{n_g-1,\alpha}s_G(n_g)/\sqrt{n_g}\right]$.
```

Since $\bar{G}(n_g)$ is a sample mean of i.i.d. random variables, it is possible to use the standard central limit theorem (CLT) to construct a $(1-\alpha)$-level CI for the optimality gap given in step 3. Due to the negative bias of z_n^*, $E\bar{G}(n_g) \geq Ef(\hat{x},\tilde{\xi}) - z^*$. Thus, for sufficiently large n_g, we can infer that

$$P\left(Ef(\hat{x},\tilde{\xi}) - z^* \leq \bar{G}(n_g) + \frac{t_{n_g-1,\alpha}s_G(n_g)}{\sqrt{n_g}}\right) \approx 1-\alpha \tag{4}$$

and hence that the CI formed by MRP will cover the optimality gap of $\hat{x}$ with the desired probability.

3 Single replication procedure

When applying the multiple replication procedure reviewed above, the replication size is typically taken to be $n_g \geq 30$ to have a valid statistical inference. This constitutes a major drawback as one needs to solve at least 30 optimization problems (in step 1.2) in order to determine whether a candidate solution is of high quality. In this section, we show how a single replication, $n_g = 1$, can be used to make a valid statistical inference on the quality of a candidate solution.

As before, we assume that the candidate solution $\hat{x} \in X$ is given, and we use the following additional notation. For a feasible solution, $x \in X$, let $\bar{f}_n(x) = \frac{1}{n}\sum_{i=1}^{n} f(x,\tilde{\xi}^i)$, $\sigma^2(x) = \text{var}[f(\hat{x},\tilde{\xi}) - f(x,\tilde{\xi})]$ and $s_n^2(x) = \frac{1}{n-1}\sum_{i=1}^{n}[(f(\hat{x},\tilde{\xi}^i) - f(x,\tilde{\xi}^i)) - (\bar{f}_n(\hat{x}) - \bar{f}_n(x))]^2$. Note that $G_n(\hat{x})$ given in equation (3) can be written as $\bar{f}_n(\hat{x}) - z_n^*$, with the understanding that the same n observations $\tilde{\xi}^1, \tilde{\xi}^2, \ldots, \tilde{\xi}^n$ are used in $\bar{f}_n(\hat{x})$ and z_n^*. Below we state the single replication procedure (SRP).

SRP:

Input: Desired CI level $0 < \alpha < 1/2$, sample size n and a candidate solution $\hat{x} \in X$.

Output: $(1-\alpha)$-level confidence interval on $\mu_{\hat{x}}$.

1. Sample i.i.d. observations $\tilde{\xi}^1, \tilde{\xi}^2, \ldots, \tilde{\xi}^n$ from the distribution of $\tilde{\xi}$.
2. Solve (SP$_n$) to obtain x_n^*.
3. Calculate $G_n(\hat{x})$ as given in (3) and

$$s_n^2(x_n^*) = \frac{1}{n-1}\sum_{i=1}^{n}\Big[(f(\hat{x},\tilde{\xi}^i) - f(x_n^*,\tilde{\xi}^i)) - (\bar{f}_n(\hat{x}) - \bar{f}_n(x_n^*))\Big]^2 .$$

4. Output one-sided CI on $\mu_{\hat{x}}$, $[0,\ G_n(\hat{x}) + t_{n-1,\alpha} s_n(x_n^*)/\sqrt{n}\ ]$.

In the MRP, n_g i.i.d. observations of $G_n(\hat{x})$ are calculated and the sample variance of these gap estimates is used to form the CI. In contrast, only one value of $G_n(\hat{x})$ is calculated in SRP and the individual observations, $f(\hat{x},\tilde{\xi}^i) - f(x_n^*,\tilde{\xi}^i)$ for $i = 1, \ldots, n$, are used to calculate the sample variance. Below, we show how solving a single replication yields enough information to make a valid statistical inference concerning the quality of a candidate solution. Before stating the theorem, we require the following lemma that establishes consistency of the estimators. Let X^* denote the set of optimal solutions to (SP) and let $x_{\min}^* \in \arg\min_{x\in X^*} \text{var}[f(\hat{x},\tilde{\xi}) - f(x,\tilde{\xi})]$. So, $x_{\min}^*$ is a solution with minimum variance of $f(\hat{x},\tilde{\xi}) - f(x,\tilde{\xi})$, $\sigma^2(x_{\min}^*)$, among all the optimal solutions.

Lemma 3.1. *Assume (A1)-(A3) and that $\tilde{\xi}^1, \tilde{\xi}^2, \ldots, \tilde{\xi}^n$ are i.i.d. as $\tilde{\xi}$. Then,*

(i) $z_n^* \to z^*$, *w.p.1,*

(ii) all limit points of $\{x_n^*\}$ *lie in* X^*, *w.p.1,*

(iii) $\liminf_{n\to\infty} s_n^2(x_n^*) \geq \sigma^2(x_{\min}^*)$, *w.p.1.*

Proof: (A2) implies that $E \sup_{x \in X} f(x, \tilde{\xi}) < \infty$. Therefore, (i) follows immediately from Theorem A1 of [8, p.69]. (A1)-(A3) implies $\bar{f}_n(x)$ converges uniformly to $Ef(x, \tilde{\xi})$, w.p.1 on X. This coupled with (i) implies (ii). To prove (iii), we first show that the sequence of continuous functions $s_n^2(x)$ converges to $\sigma^2(x)$ uniformly, w.p.1 on X. Let $g(x, \tilde{\xi}) = f(\hat{x}, \tilde{\xi}) - f(x, \tilde{\xi})$. Then, with $\bar{g}_n(x) = \frac{1}{n} \sum_{i=1}^n g(x, \tilde{\xi}^i)$ we have

$$s_n^2(x) = \frac{n}{n-1} \left\{ \frac{1}{n} \sum_{i=1}^n \Big(g(x, \tilde{\xi}^i) - Eg(x, \tilde{\xi}) \Big)^2 - \Big(\bar{g}_n(x) - Eg(x, \tilde{\xi}) \Big)^2 \right\}.$$

The first term in the curly brackets is a sample mean of i.i.d. random variables and by Lemma A1 of [8, p.67] converges uniformly, w.p.1, to $\sigma^2(x) = \operatorname{var} g(x, \tilde{\xi})$. Also, by the same lemma, $\bar{g}_n(x)$ converges uniformly to $Eg(x, \tilde{\xi})$, w.p.1, i.e., $\sup_{x \in X} \Big| \bar{g}_n(x) - Eg(x, \tilde{\xi}) \Big| \to 0$, w.p.1. This implies

$$\sup_{x \in X} \Big(\bar{g}_n(x) - Eg(x, \tilde{\xi}) \Big)^2 = \left(\sup_{x \in X} \Big| \bar{g}_n(x) - Eg(x, \tilde{\xi}) \Big| \right)^2 \to 0, \text{ w.p.1.}$$

The sum of these two terms, $a_n(x) = \frac{1}{n} \sum_{i=1}^n (g(x, \tilde{\xi}^i) - Eg(x, \tilde{\xi}))^2 - (\bar{g}_n(x) - Eg(x, \tilde{\xi}))^2$, then converges uniformly to $\sigma^2(x)$, w.p.1. To show uniform convergence of $\frac{n}{n-1} a_n(x)$, consider the following inequality

$$\sup_{x \in X} \left| a_n(x) + \frac{a_n(x)}{n-1} - \sigma^2(x) \right| \le \sup_{x \in X} \left| a_n(x) - \sigma^2(x) \right| \quad + \\ \sup_{x \in X} \left| \frac{a_n(x) - \sigma^2(x)}{n-1} \right| \quad + \quad \sup_{x \in X} \left| \frac{\sigma^2(x)}{n-1} \right|.$$

By the above argument the first two terms on the right-hand side converge to 0, w.p.1. By (A2), $\sup_{x \in X} \sigma^2(x) < \infty$. Thus, the last term also converges to 0, establishing uniform convergence.

Since X is compact, there exists a subsequence N along which $\{x_n^*\}_{n \in N}$ converges to a point in X and by (ii) this point is in X^*. So, using the uniform convergence shown above,

$$\lim_{\substack{n \to \infty \\ n \in N}} s_n^2(x_n^*) \ge \inf_{x \in X^*} \sigma^2(x), \text{ w.p.1.}$$

The subsequence N is arbitrary and hence we obtain (iii).

Theorem 3.1. *Assume (A1)-(A3) and that $\tilde{\xi}^1, \tilde{\xi}^2, \ldots, \tilde{\xi}^n$ are i.i.d. as $\tilde{\xi}$. Given $0 < \alpha < 1/2$, for the SRP,*

$$\liminf_{n \to \infty} P \left(\mu_{\hat{x}} \le G_n(\hat{x}) + \frac{t_{n-1,\alpha} s_n(x_n^*)}{\sqrt{n}} \right) \ge 1 - \alpha. \tag{5}$$

Proof: When $\hat{x} \in X^*$, inequality (5) is trivial. Suppose $\hat{x} \notin X^*$. Recall that $z_n^* = \min_{x \in X} \bar{f}_n(x)$. Thus,

$$G_n(\hat{x}) = \bar{f}_n(\hat{x}) - z_n^* \geq \bar{f}_n(\hat{x}) - \bar{f}_n(x), \quad \forall x \in X.$$

Replacing x by $x^*_{\min} \in \arg\min_{x \in X^*} \sigma^2(x)$ we obtain,

$$\begin{aligned} & P\left(G_n(\hat{x}) + \frac{t_{n-1,\alpha} s_n(x_n^*)}{\sqrt{n}} \geq \mu_{\hat{x}} \right) \\ \geq \quad & P\left(\bar{f}_n(\hat{x}) - \bar{f}_n(x^*_{\min}) + \frac{t_{n-1,\alpha} s_n(x_n^*)}{\sqrt{n}} \geq \mu_{\hat{x}} \right) \qquad (6) \\ = \quad & P\left(\frac{(\bar{f}_n(\hat{x}) - \bar{f}_n(x^*_{\min})) - \mu_{\hat{x}}}{\sigma(x^*_{\min})/\sqrt{n}} \geq -t_{n-1,\alpha} \frac{s_n(x_n^*)}{\sigma(x^*_{\min})} \right), \qquad (7) \end{aligned}$$

where in (7) we assume $\sigma^2(x^*_{\min}) > 0$. Note that if $\sigma^2(x^*_{\min}) = 0$ then $\text{var}\,[\bar{f}_n(\hat{x}) - \bar{f}_n(x^*_{\min})] = \frac{1}{n}\sigma^2(x^*_{\min}) = 0$ and it follows from (6) that (5) is again trivial. Since $\bar{f}_n(\hat{x}) - \bar{f}_n(x^*_{\min})$ is a sample mean of i.i.d. random variables, by the CLT we have

$$\lim_{n \to \infty} P\left(\frac{(\bar{f}_n(\hat{x}) - \bar{f}_n(x^*_{\min})) - \mu_{\hat{x}}}{\sigma(x^*_{\min})/\sqrt{n}} \geq -t_{n-1,\alpha} \right) = 1 - \alpha. \qquad (8)$$

By Lemma 3.1,

$$\liminf_{n \to \infty} \frac{s_n(x_n^*)}{\sigma(x^*_{\min})} \geq 1, \quad \text{w.p.1.} \qquad (9)$$

Combining (8) and (9) via a converging-together argument we obtain (5).

Theorem 3.1 justifies construction of the approximate $(1-\alpha)$-level one-sided confidence interval for $\mu_{\hat{x}} = Ef(\hat{x}, \tilde{\xi}) - z^*$, given in step 4 of SRP without requiring $G_n(\hat{x}) = \bar{f}_n(\hat{x}) - z_n^*$ to be asymptotically normal. The intuitive reason for this is that minimization of the sample mean in z_n^*, while making asymptotic analysis of this random variable more difficult, projects the normal distribution so that the resulting confidence interval is conservative.

We reviewed a procedure in which we use $n_g \geq 30$ replications and introduced a procedure with just one replication, $n_g = 1$. However, the theory presented above is asymptotic, giving us the desired coverage only as the sample size grows to infinity. To test the small-sample performance of the described procedures, we apply them in the next section to the newsvendor problem and compare empirical coverage results.

4 An example: newsvendor problem

The newsvendor problem is a classical example of a stochastic program with simple recourse and its properties are well known, e.g., [3, p.15]. We briefly review its formulation. Let r be the selling price of a newspaper, $0 < c < r$

be its cost to the vendor, and $\tilde{\xi}$ denote the nonnegative random demand. The vendor's problem is to find the number of papers to buy, x, so that the expected profit is maximized. So, the problem is formulated as $\max\{-cx + rE\min\{x,\ \tilde{\xi}\} : x \geq 0\}$ and its solution is given by x^* that solves $\inf_{x \geq 0} P(\tilde{\xi} \leq x) \geq (r-c)/r$, which is simply $\int_0^{x^*} dF(\xi) = (r-c)/r$, when the demand distribution is continuous with cumulative distribution function F. Note that the newsvendor problem is of the form (SP) with $f(x, \tilde{\xi}) = cx - r\min\{x,\ \tilde{\xi}\}$ and $X = \{x : x \geq 0\}$.

We assume $\tilde{\xi} \sim U(0,b)$, $b > 0$ and hence modify X to $\{x : 0 \leq x \leq b\}$. Note that (A1)-(A3) hold. To perform the tests, we set $\alpha = 0.10$. For the problem parameters, we use $c = 5$, $r = 15$ and $b = 10$. This problem has optimal solution $x^* = 6\frac{2}{3}$ with expected profit $z^* = 33\frac{1}{3}$. For the candidate solution $\hat{x}$, we pick a solution that has expected profit 10% from the optimum. We use $\hat{x} = 8.775$ with $Ef(\hat{x}, \tilde{\xi}) = 30$ and with an optimality gap of $\mu_{\hat{x}} = 3\frac{1}{3}$. For the SRP, we construct 100,000 confidence intervals and for the MRP, we take $n_g = 30$ and construct 10,000 intervals for each value of the sample size. We take sample sizes, n, between 50 and 1,000. The table below summarizes the results. We report "coverage", i.e., the proportion, $\hat{p}$, of CIs containing the optimality gap and the half width, $1.645(\hat{p}(1-\hat{p})/k)^{1/2}$, of a two-sided 90% CI for the true coverage probability, where k =10,000 for MRP and 100,000 for SRP. For example, when n =1,000 for the MRP the table indicates $\hat{p} = 0.9267$ so that we are confident at level 0.90 that the coverage probability, i.e., the left-hand side of (4), is in $[0.9224, 0.9310]$.

n	MRP	SRP
50	0.9873 ± 0.0018	0.8756 ± 0.0017
100	0.9741 ± 0.0026	0.8895 ± 0.0016
200	0.9594 ± 0.0032	0.8898 ± 0.0016
300	0.9483 ± 0.0036	0.8946 ± 0.0016
400	0.9390 ± 0.0039	0.8944 ± 0.0016
500	0.9359 ± 0.0040	0.8937 ± 0.0016
600	0.9350 ± 0.0041	0.8962 ± 0.0016
700	0.9299 ± 0.0042	0.8960 ± 0.0016
800	0.9287 ± 0.0042	0.8959 ± 0.0016
900	0.9317 ± 0.0041	0.8970 ± 0.0016
1000	0.9267 ± 0.0043	0.8970 ± 0.0016

Empirical coverage results: $\hat{p} \pm 1.645(\hat{p}(1-\hat{p})/k)^{1/2}$ for various values of n, where k =10,000 for MRP and 100,000 for SRP.

The coverage for the MRP exceeds the desired coverage of 90% but shrinks toward 90% as the sample size increases. The bias, $Ez_n^* - z^*$, constitutes a major part of the CI formed by MRP and thus this CI tends to overestimate the optimality gap. As indicated in Section 2, the bias shrinks as n increases and the coverage of MRP falls as n grows. The SRP, on the other hand, has slightly less than the desired coverage of 90%. Even though the bias is larger when the sample size is small, the number of times a single replication CI contains the optimality gap approaches 90% from below. We explain this as follows. $G_n(\hat{x})$ is more variable for small sample sizes, and we have observed from the individual replications that when it is small, $s_n(x_n^*)$ also tends to be small, resulting in a narrow CI width. In particular, this happens when x_n^* is close to $\hat{x}$, even though $\hat{x}$ is not close to x^*. In ongoing research we further examine this effect and other alternatives to the single replication procedure that improve empirical performance.

LOW RISK FITS TO DISCRETE INCOMPLETE MULTI-WAY LAYOUTS

Rudolf Beran

Key words: Submodel selection, multiparametric asymptotics.

COMPSTAT 2004 section: Model selection, functional data analysis.

Abstract: The discrete multi-way layout is a widespread data-type associated with regression, experimental designs, gene or protein chips, digital images or videos, and more. A discrete multi-way layout has a finite number of factor level combinations. The layout may be unbalanced or incomplete or both. We consider candidate fits to an incomplete layout that are least squares fits to certain submodels induced by tensor product space ANOVA models for a complete layout. The candidate estimator with smallest estimated risk is selected. Multiparametric asymptotics under a general (saturated) Gaussian model show that the selected estimator achieves smallest asymptotic risk over the candidate class through bias-variance trade-off.

1 Introduction

Each factor that influences the responses in a *discrete* multi-way layout has a finite number of levels, as in classical experimental design, digital images or videos, gene or protein chips, and regression. The factors can be either ordinal or nominal or some of each. Pioneering results on low-risk fits to multi-way layouts include Stein's [8] shrinkage estimators for complete balanced discrete two-way layouts with both factors nominal and Mallow's [7] study of C_p as a criterion for selecting a submodel fit. Tukey's [10] computational experiments in discrete one- or two- or three-way layouts with ordinal factors indicated that smoothing can bring out pattern. Beran [1], [2] studied low risk adaptive penalized least squares fits to a discrete one-way layout whose factor is either ordinal or nominal.

Related in spirit are spline estimators of a mean function on a one-way layout with a *continuous* ordinal factor that is observed at discrete points [11], [5] and smoothing spline tensor product space ANOVA techniques for functional data analysis [12], [6]. The methods in this paper are designed for large, incomplete, *discrete* multi-way layouts with little or no replication. Regression models are a leading case.

As candidate estimators, we consider least squares fits to submodels for the observed incomplete layout that are induced by tensor product space ANOVA submodels for an associated complete multi-way layout of means. We estimate the risk of each candidate estimator under a general model that does *not* assume correctness of any submodel. Finally, we select the candidate fit that minimizes estimated risk. We show that the selected submodel fit has relatively low asymptotic risk under the general model as the number of observed factor-level combinations tends to infinity. This low asymptotic risk is achieved through variance-bias trade-off.

2 Candidate fits to the saturated model

Consider k_0 factors, either nominal or ordinal, in which factor k has p_k distinct levels. Let $\mathcal{I}$ denote the set of all k_0-tuples $i = (i_1, i_2, \ldots, i_{k_0})$ such that $1 \leq i_k \leq p_k$ for $1 \leq k \leq k_0$. The component i_k indexes the levels of factor k. A *complete* k_0-way layout of means consists of real values $\{m_i : i \in \mathcal{I}\}$. We order the $p = \prod_{k=1}^{k_0} p_k$ elements of the index set $\mathcal{I}$ in mirrored dictionary order: i_{k_0} serves as the first "letter" of the word, i_{k_0-1} as the second "letter", and so forth. Hereafter we assume that $\mathcal{I}$ is so ordered. Taken in this order, the indexed means for the complete multi-way layout form the $p \times 1$ vector

$$m = \{\ldots\{\{m_{i_1,i_2,\ldots,i_{k_0}} : 1 \leq i_1 \leq p_1\}, 1 \leq i_2 \leq p_2\}, \ldots, 1 \leq i_{k_0} \leq p_{k_0}\}. \quad (1)$$

Observations are available on the means $\{m_i : i \in \mathcal{I}_0\}$, where $\mathcal{I}_0$ is a subset of $\mathcal{I}$. In general, these observations $y = \{\{y_{ij} : 1 \leq j \leq n_i\}, i \in \mathcal{I}_0\}$ form an *incomplete unbalanced* k_0-way layout. The vector y is $n \times 1$ with $n = \sum_{i \in \mathcal{I}_0} n_i$. Let $q \leq p$ denote the cardinality of $\mathcal{I}_0$. Define the means-incidence matrix D to be the $q \times p$ matrix of zeroes and ones such that $m_D = Dm$ lists, in vector form, the means $\{m_i : i \in \mathcal{I}_0\}$ for the observed incomplete k_0-way layout. Let C be the $n \times q$ data-incidence matrix that suitably replicates components of the vector $m_D = Dm$ into the vector $\eta = \mathrm{E}(y) = Cm_D$. For a complete layout of data, q equals p and D is just the identity matrix. The general Gaussian *saturated model* for the incomplete layout of observations y puts no restrictions on the mean vector m:

$$y \sim N(\eta, \sigma^2 I_n), \text{ where } \eta = Cm_D = CDm, \quad m \in R^p. \quad (2)$$

2.1 Generic candidate submodel fits

Consider a submodel of the saturated model in which m is restricted to a given subspace of R^p. This condition has several mathematical expressions.

Theorem 2.1. *Let V be a $p \times r$ matrix whose columns form an orthonormal basis for the r-dimensional subspace $\mathcal{V}$. Let $Q = VV'$. Then the following assertions are equivalent: (a) $m \in \mathcal{V}$; (b) $m = V\gamma$ for some $\gamma \in R^r$; (c) $m = Q\beta$ for some $\beta \in R^p$; (d) $m = Qm$.*

The symmetric idempotent matrix Q is the unique orthogonal projection of R^p into $\mathcal{V}$. Its eigenvalues are either zero or one. The expression $Q = VV'$ is a spectral decomposition of Q. Because Q has eigenvalue one r times and eigenvalue zero $p - r$ times, there exist many eigenvector matrices V such that $Q = VV'$.

For Q a projection as in the Theorem, define *submodel*(Q) by imposing the constraint $m = Qm$ on the saturated model (2). Taking Q to be the identity matrix I_p recovers the saturated model itself. Let $\eta(Q) = \mathrm{E}(y)$, evaluated under submodel(Q). By the foregoing Theorem, $\eta(Q) = CDQ\beta = CDV\gamma$. Consequently, the least squares estimator of $\eta(Q)$ under submodel(Q) has several equivalent expressions in which the superscript $^+$ denotes the Moore-Penrose inverse.

Theorem 2.2. *Let $M(Q) = CDQ(CDQ)^+ = CD(CDQ)^+ = CDV(CDV)^+$ and let $M = M(I_p) = CD(CD)^+ = CC^+$. The least squares estimator of $\eta(Q)$ under submodel(Q) is $\hat{\eta}(Q) = M(Q)y$. In particular, the least squares estimator of η under the saturated model is $\hat{\eta} = My$.*

This result can be derived thorough properties of the Moore-Penrose inverse. The matrices $M(Q)$ and M are both symmetric idempotent and satisfy $MM(Q) = M(Q) = M(Q)M$.

For each Q in a class of projection matrices that express tentative prior conjectures about m, we will consider $\hat{\eta}(Q)$ as a (usually biased) candidate estimator for η in the saturated model for the unbalanced incomplete k_0-way layout. The associated candidate estimator for the cell means $m_D = Dm$ is then $\hat{m}_D(Q) = C^+\hat{\eta}(Q)$. Although submodel fits generate the candidate estimators, it is not assumed in this paper that any submodel of the saturated model (2) holds.

2.2 Tensor product candidate submodel fits

To generate useful candidate projections Q, we first express the ANOVA decomposition for a complete k_0-way layout of means in projection form. Let $\mathcal{S}$ denote the set of all subsets of $\{1, 2, \ldots, k_0\}$, including the empty set $\emptyset$. The cardinality of $\mathcal{S}$ is 2^{k_0}.

For every k, define the $p_k \times 1$ vector u_k and the $p_k \times p_k$ matrices J_k, H_k by $u_k = p_k^{-1/2}(1, 1, \ldots, 1)'$, $J_k = u_k u_k'$, and $H_k = I_{p_k} - J_k$. For each k, the symmetric idempotent matrices J_k and H_k have rank (or trace) 1 and $p_k - 1$ respectively. Let U_k be any $p_k \times (p_k - 1)$ matrix such that $(u_k|U_k)$ is an orthogonal matrix. Then the foregoing entails that $H_k = U_k U_k'$.

For every set $S \in \mathcal{S}$, define $P_{S,k} = J_k$ if $k \notin S$ and $P_{S,k} = H_k$ if $k \in S$. Define the $p \times p$ Kronecker product matrix $P_S = \bigotimes_{k=1}^{k_0} P_{S,k_0-k+1}$. Evidently P_S is symmetric idempotent for every $S \in \mathcal{S}$; if $S \neq \emptyset$, the rank (or trace) of P_S is $\prod_{k \in S}(p_k - 1)$; the rank (or trace) of $P_\emptyset$ is 1; if S_1 and S_2 are two different sets in $\mathcal{S}$, then $P_{S_1}P_{S_2} = 0 = P_{S_2}P_{S_1}$; and $\sum_{S \in \mathcal{S}} P_S = I_p$.

Consequently, the $\{P_S \colon S \in \mathcal{S}\}$ are orthogonal projections that decompose R^p into 2^{k_0} mutually orthogonal subspaces. The ANOVA decomposition of a complete k_0-way layout of means is the identity, for every $m \in R^p$,

$$m = \sum_{S \in \mathcal{S}} P_S m. \tag{3}$$

Here $P_\emptyset m$ is the overall mean term in the decomposition. If $S \neq \emptyset$, $P_S m$ is the main effect or interaction term defined by the factors $k \in S$. This

ANOVA decomposition suggests a rich variety of choices for the projection matrix Q that determines submodel(Q) of the saturated model (2) for the incomplete k_0-way layout. The central ideas are as follows:

All factors nominal. Let $\{\mathcal{A}_j \colon 1 \leq j \leq j_0\}$ denote a collection of subsets of $\mathcal{S}$ that is partially ordered under the inclusion operation. Let

$$Q_{\mathcal{A}_j} = \sum_{S \in \mathcal{A}_j} P_S \tag{4}$$

and let $\mathcal{Q} = \{Q_{\mathcal{A}_j} \colon 1 \leq j \leq j_0\}$. The candidate estimators $\{\hat{\eta}(Q) \colon Q \in \mathcal{Q}\}$ for η are least squares fits to the designated ANOVA submodels.

All factors ordinal. Without loss of generality, assume that the indexing of the levels of an ordinal factor follows their numerical order. Prior conjecture may then be that adjacent means in the k_0-way layout vary smoothly as a function of the ordinal factor levels. Tensor product space submodels that express this are described through the following general scheme.

Let $W_k(c_k)$ be any $p_k \times c_k$ matrix of rank $c_k \leq p_k$ whose first column is proportional to u_k and whose successive columns are increasingly wiggly. For instance, the columns of $W_k(c_k)$ could be successive powers, from zero to $c_k - 1$, of the vector of levels of factor k. Define the orthogonal projections $G_k(c_k) = W_k(c_k)W_k(c_k)^+$ and $K_k(c_k) = G_k(c_k) - J_k$. Define $P_{S,k} = J_k$ if $k \notin S$ and $P_{S,k} = K_k(c_k)$ if $k \in S$. For $c = (c_1, c_2, \ldots, c_{k_0})$, define $P_S(c) = \bigotimes_{k=1}^{k_0} P_{S,k_0-k+1}$.

In analogy to the preceding paragraph, let

$$Q_{\mathcal{A}_j}(c) = \sum_{S \in \mathcal{A}_j} P_S(c) \tag{5}$$

and let $\mathcal{Q} = \{Q_{\mathcal{A}_j}(c) \colon 1 \leq j \leq j_0, 1 \leq c_1 \leq d_1, 1 \leq c_2 \leq d_2, \ldots 1 \leq c_{k_0} \leq d_{k_0}\}$. The estimators $\{\hat{\eta}(Q) \colon Q \in \mathcal{Q}\}$ are a class of candidate submodel estimators for η.

Some factors nominal, some factors ordinal. We proceed in similar fashion, choosing the multiplicands $P_{S,k}$ in the cross-factor Kronecker product according to the nominal or ordinal nature of each factor, as above.

3 Adaptive low risk submodel fits

We will assess the performance of the candidate estimator $\hat{\eta}(Q)$ of $\eta = CDm$ through its risk under normalized quadratic loss, $L(\hat{\eta}(Q), \eta) = q^{-1}|\hat{\eta}(Q) - \eta|^2$. Let $r(Q) = \text{rank}(M(Q)) = \text{rank}(CDQ)$. The risk of candidate estimator $\hat{\eta}(Q) = M(Q)y$ under the saturated model is then

$$R(\hat{\eta}(Q), \eta, \sigma^2) = \mathrm{E}L(\hat{\eta}(Q), \eta) = q^{-1}[\sigma^2 r(Q) + |M(Q)\eta - \eta|^2]. \tag{6}$$

Recall that $\hat{\eta} = My$ is the least squares estimator of η under the saturated model. Let denote $\hat{\sigma}^2$ denote a consistent estimator of σ^2. Apart from possible bias in $\hat{\sigma}^2$, Mallow's [7] C_p criterion and Stein's [9] unbiased risk estimator both yield the estimator

$$\hat{R}(\hat{\eta}(Q)) = q^{-1}[|\hat{\eta} - \hat{\eta}(Q)|^2 + (2r(Q) - q)\hat{\sigma}^2] \tag{7}$$

for the risk (6) of $\hat{\eta}(Q)$ under the saturated model.

The *pooling* variance estimator $\hat{\sigma}^2_P$, potentially useful when n equals or is not much larger than q, is $\hat{\sigma}^2_P = [n - r(Q_L)]^{-1}|y - \hat{\eta}(Q_L)|^2$, where Q_L is a projection in $\mathcal{Q}$ with rank $r(Q_L)$. This biased estimator is consistent for σ^2 when $n - r(Q_L)$ tends to infinity and $[n - r(Q_L)]^{-1}|\eta - \eta(Q_L)|^2$ tends to zero.

The *first-difference* variance estimator $\hat{\sigma}^2_{FD}$ is potentially useful when $n = q$, in which case the data forms an incomplete multi-way layout with one observation per cell. Form all possible first differences of adjacent $\{y_{i1}\}$ along each coordinate direction. Then $\hat{\sigma}^2_{FD}$ is defined to be one-half of the average of the squared first differences. This biased estimator is consistent for σ^2 when q tends to infinity and the quantity obtained by replacing each y_{i1} in $\hat{\sigma}^2_{FD}$with m_i tends to zero.

Let $\mathcal{Q}$ denote a finite class of candidate projections Q, constructed as in the previous section, whose cardinality may depend on q. The *adaptive estimator* of η is defined to be the candidate estimator with smallest estimated risk:

$$\hat{\eta}_{\mathcal{Q}} = \hat{\eta}(\hat{Q}), \text{ where } \hat{Q} = \underset{Q \in \mathcal{Q}}{\operatorname{argmin}} \hat{R}(\hat{\eta}(Q)). \tag{8}$$

Asymptotic analysis supports the claim that the risk of $\hat{\eta}_{\mathcal{Q}}$ approximately minimizes risk among all candidate estimators $\{\hat{\eta}(Q) \colon Q \in \mathcal{Q}\}$.

Theorem 3.1. *Let $\#\mathcal{Q}$ be the number of projections in the class $\mathcal{Q}$. Suppose that $\lim_{q\to\infty} q^{-1/2}\#\mathcal{Q} = 0$ and $\lim_{q\to\infty} \#\mathcal{Q} \sup_{|\eta|^2 \le qa\sigma^2} \mathrm{E}|\hat{\sigma}^2 - \sigma^2| = 0$ for every $a > 0$ and $\sigma^2 > 0$. Then, for W equal to either $R(\hat{\eta}_{\mathcal{Q}}, \eta, \sigma^2)$ or $L(\hat{\eta}_{\mathcal{Q}}, \eta)$,*

$$\lim_{q\to\infty} \sup_{|\eta|^2 \le q\sigma^2 a} \mathrm{E}|W - \min_{Q\in\mathcal{Q}} R(\hat{\eta}(Q), \eta, \sigma^2)| = 0 \tag{9}$$

and

$$\lim_{q\to\infty} \sup_{|\eta|^2 \le q\sigma^2 a} \mathrm{E}|W - \hat{R}(\hat{\eta}_{\mathcal{Q}})| = 0. \tag{10}$$

Under the multiparametric asymptotics of this theorem, in which the number q of unknown means tends to infinity, the loss and corresponding risk of a candidate estimator converge to a common value. According to (9), the risk and loss of the adaptive estimator $\hat{\eta}_{\mathcal{Q}}$ converge to the minimum risk achievable over the class of candidate estimators $\{\hat{\eta}(Q) \colon Q \in \mathcal{Q}\}$. Equation (10) asserts that the estimated risk of the adaptive estimator $\hat{\eta}_{\mathcal{Q}}$ is a trustworthy asymptotic approximation to both its actual risk and loss.

Proof idea. Matrices $M(Q)$ and M are each symmetric and idempotent and satisfy $MM(Q) = M(Q) = M(Q)M$. Evidently $\operatorname{rank}(M) = \operatorname{tr}[C(C'C)^{-1}C'] = q$. The matrix $M - M(Q)$ is therefore symmetric and idempotent; has rank $q - r(Q)$; and satisfies $M(Q)[M - M(Q)] = 0$. We have the spectral decompositions $M(Q) = U_Q U_Q'$ and $M - M(Q) = \bar{U}_Q \bar{U}_Q'$, where U_Q is $n \times r(Q)$, $\bar{U}_Q$ is $n \times (q - r(Q))$, $U_Q' U_Q = I_{r(Q)}$, $\bar{U}_Q' \bar{U}_Q = I_{q-r(Q)}$, and $U_Q' \bar{U}_Q = 0$. It follows that the $n \times q$ matrix $U = (U_Q | \bar{U}_Q)$ is orthogonal and that $M = U_Q U_Q' + \bar{U}_Q \bar{U}_Q' = UU'$.

Let $z = U'y$ and $\xi = U'\eta$. Under the saturated model, z has a $N(\xi, \sigma^2)$ distribution and $\eta = M\eta = U\xi$. Let f_Q denote the q-dimensional vector whose first $r(Q)$ components equal 1 and whose other components equal 0. Let $F_Q = \operatorname{diag}\{f_Q\}$. By Theorem 1 and the preceding paragraph, $\hat{\eta}(Q) = U_Q U_Q' y = U F_Q z$ and $\hat{\eta} = UU'y = Uz$. For any vector h, let $\operatorname{ave}(h)$ denote the average of the components of h. For any two vectors g and h of the same dimension, let gh denote the vector formed by componentwise multiplication. Equations (6), (7), and the preceding notations yield the canonical forms $L(\hat{\eta}(Q), \eta) = q^{-1} |f_Q z - \xi|^2$, $R(\hat{\eta}(Q), \eta, \sigma^2) = \operatorname{ave}[f_Q^2 \sigma^2 + (1 - f_Q)^2 \xi^2]$, and $\hat{R}(\hat{\eta}(Q)) = \operatorname{ave}[f_Q^2 \hat{\sigma}^2 + (1 - f_Q)^2 (z^2 - \hat{\sigma}^2)]$ for loss, risk, and estimated risk.

Let V denote either loss $L(\hat{\eta}(Q))$ or the estimated risk $\hat{R}(\hat{\eta}(Q))$. Applying Theorem 2.1 in [3] to the preceding canonical forms establishes existence of a finite constant C such that

$$\mathrm{E}|V - R(\hat{\eta}(Q), \eta, \sigma^2)| \le C[q^{-1/2}(\sigma^2 + \sigma\{\operatorname{ave}(\xi)^2\}^{1/2}) + \mathrm{E}|\hat{\sigma}^2 - \sigma^2|]. \quad (11)$$

for every projection $Q \in \mathcal{Q}$. An argument based on this inequality yields the Theorem conclusions.

4 Example: coal ash data

The coal ash data from [4, p. 34], records percentage of coal ash in 208 assay samples. The data forms an incomplete two-way layout with one observation for each coordinate pair at which an assay sample is obtained. The factors row coordinate and column coordinate are both ordinal and range over $p_1 = 23$ and $p_2 = 16$ equally spaced levels respectively. It seems likely, a priori, that the coal ash means vary smoothly with geographical location. We construct candidate projections by the tensor product space method previously described, using the discrete cosine basis: For $1 \le k \le 2$, the first column of $W_k(c_k)$ is the vector u_k already defined and the succeeding columns are

$$w_{kc} = \{(2/p_k)^{1/2} \cos[(2r-1)(c-1)\pi/(2p_k)] \colon 1 \le r \le p_k\}, \quad 2 \le c \le c_k. \quad (12)$$

Let $\mathcal{A}_1 = \{\emptyset, \{1\}, \{2\}\}$ and let $\mathcal{A}_2 = \{\emptyset, \{1\}, \{2\}, \{1,2\}\}$. Let $\mathcal{C} = \bigcup_{j=2}^{8} \{(j,j)\}$. For every $c \in \mathcal{C}$, define $Q_{\mathcal{A}_j}(c)$ by equation (5) and its preceding paragraph and let $\mathcal{Q} = \{Q_{\mathcal{A}_j}(c) \colon 1 \le j \le 2, c \in \mathcal{C}\}$. For the coal-ash data, the first difference variance estimate is $\hat{\sigma}_{FD}^2 = 1.038$.

The following table lists estimated risks for the candidate estimators $\{\hat{\eta}(Q) \colon Q \in \mathcal{Q}\}$:

c	(2,2)	(3,3)	(4,4)	(5,5)	(6,6)	(7,7)	(8,8)
$Q_{\mathcal{A}_1}(c)$	.213	.232	.150	.148	.134	.151	.155
$Q_{\mathcal{A}_2}(c)$	.222	.243	.192	.238	.261	.333	.385

The additive submodel fit $\hat{\eta}(Q_{\mathcal{A}_1}(6,6))$ has smallest estimated risk among these competitors. Moreover, its estimated risk .134 is about one-eighth of the estimated risk 1.038 of the least squares fit to the saturated model. The latter fit coincides with the raw data in this example and is clearly not useful. Through variance-bias trade-off, our data-driven algorithm selects a submodel fit that is visually appealing, has the structural simplicity of additivity, and has much lower risk under the saturated model (see the preceding theorem). This adaptive submodel fit compresses the data so as to discard more noise than signal.

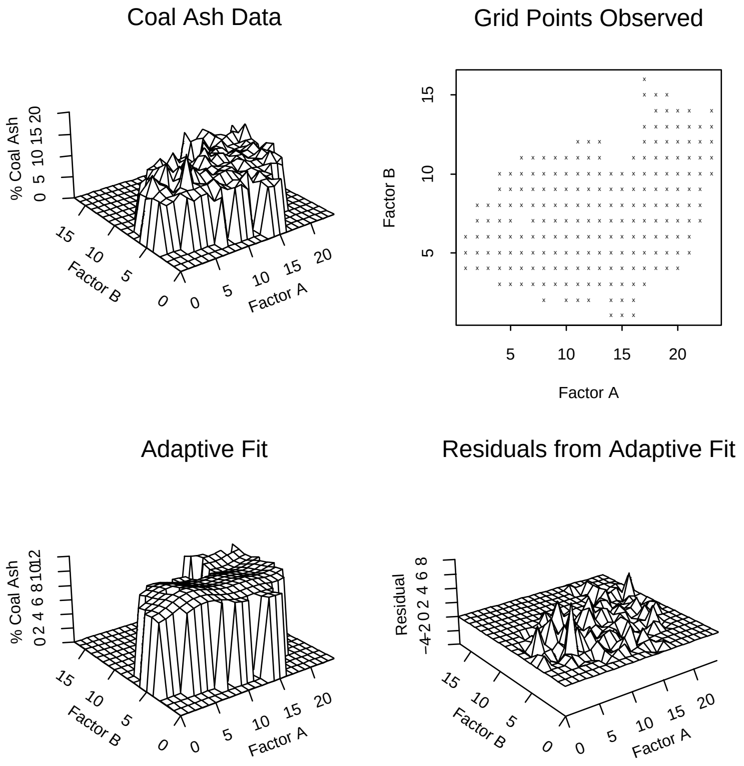

Figure 1: The Coal Ash data, its factor level grid, the low risk adaptive submodel fit $\hat{\eta}(Q_{\mathcal{A}_1}(6,6))$ using the discrete cosine basis, and residuals.

APPROXIMATE REGENERATIVE BLOCK-BOOTSTRAP FOR MARKOV CHAINS

Patrice Bertail and Stéphan Clémençon

Key words: Bootstrap, Markov chains, Edgeworth expansions, Nummelin splitting, algorithms.

COMPSTAT 2004 section: Resampling method.

Abstract: In this paper we propose a modification of the original ARBB algorithm based on the "2-split" method considered by Schick [10]. We also show how the asymptotic results obtained for the RBB in the regenerative case may be extended to this modified ARBB procedure at the cost of some small loss in the Edgeworth expansions, which is closely linked to the uniform rate for estimating the transition kernel of the chain over a well chosen small set.

1 Introduction

Prolongating ideas introduced in Datta & McCormick [4], Bertail & Clémençon [1], [2] proposed a general resampling method, namely the *Regenerative Block Bootstrap* (RBB in abbreviated form), for bootstrapping statistics based on data $X_1, \ldots, X_n$ drawn from (eventually nonstationary) regenerative Markov chains. When the chain (positive Harris recurrent) possesses a known atom, they proved that this resampling method is second order correct up to $O_P(n^{-1})$ in the case of the studentized sample mean statistic under specific Cramer and "block moment" conditions (less restrictive than the exponential strong mixing rate condition generally assumed when the matter is to deal with dependent data). This is the optimal rate that may be attained by the naive Bootstrap method in the i.i.d. case (see Hall [6]). These results should be put in contrast with the usual rates that may be attained by the *Moving Block Bootstrap* (MBB), which are at best $O_P(n^{-3/4})$ (see Götze & Künsch [5]). We emphasize that the RBB straightforwardly applies to numerous specific regenerative models, widely used in the modeling of queuing and storage systems, and to all countable Markov chains. Resting on the theoretical construction introduced by Nummelin [9], namely the *Nummelin splitting technique*, which is based on the crucial notion of *small set* (cf. [8]), any general Harris Markov chain could be considered as regenerative in the sense of the existence of a regenerative extension. Bertail & Clémençon [2] proposed a resampling procedure, the *Approximate Regenerative Block Bootstrap* (ARBB), that generalizes the RBB method and applies to all Harris Markov chains. The method is based on the prior knowledge of a small set for the chain and a practical approximation of the *Nummelin splitting extension*. It thus consists in using an empirical method to build approximatively a realization drawn from a regenerative extension of the chain and in applying the RBB methodology to the latter.

The outline of the paper is as follows. In section 2 the principles of the ARBB are briefly recalled and a modification of the original method using a variant of the "2-split" trick is presented. In section 3 an asymptotic result claiming the second order asymptotic validity of this ARBB method for studentized sample mean statistics is stated. Finally, in section 4, practical selection rules for the tuning parameters of the algorithm are proposed and some simulation results are presented.

2 Nummelin splitting approximation and ARBB

2.1 Notation and basic notions

Here and throughout we shall use the same notations as in section 2 of Bertail & Clémençon [2]. Consider $X = (X_n)_{n\in\mathbb{N}}$ a positive recurrent Markov chain on a countably generated state space $(E, \mathcal{E})$ with transition probability $\Pi(.,.)$, stationary probability measure μ and initial distribution ν. We denote by P_ν (respectively P_x for x in E, resp. P_A for $A \in \mathcal{E}$) the probability measure on the underlying space such that $X_0 \sim \nu$ (resp. conditionally to $X_0 = x$, resp. conditionally to $X_0 \in A$), by $E_\nu(.)$ the P_ν-expectation (resp. by $E_x(.)$ the P_x-expectation, resp. by $E_A(.)$ the P_A-expectation) and by $I\{\mathcal{A}\}$ the indicator function of the event $\mathcal{A}$.

We recall that a set $S \in \mathcal{E}$ is said to be *small* (see Meyn & Tweedie [8]) if there exist $k \in \mathbb{N}$, a probability measure Φ supported by S, and $\delta > 0$ such that $\forall x \in S, \forall A \in \mathcal{E}, \quad \Pi^k(x, A) \geq \delta\Phi(A)$, denoting by Π^k the k-th iterate of Π (recall that small sets always exist for irreducible chains). When this holds, we shall say that X satisfies the minorization condition $\mathcal{M}(k, S, \delta, \Phi)$. Even if it entails to replace the chain $(X_n)_{n\in\mathbb{N}}$ by $\big((X_{nk}, \dots, X_{n(k+1)-1})\big)_{n\in\mathbb{N}}$, we suppose $k = 1$ in what follows. We assume further that the family of the conditional distributions $\{\Pi(x, dy)\}_{x\in E}$ and the initial distribution ν are dominated by a σ-finite measure λ of reference, so that $\nu(dy) = f(y)\lambda(dy)$ and $\Pi(x, dy) = p(x, y)\lambda(dy)$ for all $x \in E$. In this case, the condition $\mathcal{M}(k, S, \delta, \Phi)$ entails that Φ is also absolutely continuous with respect to λ and $p(x, y) \geq \delta\phi(y)$, $\lambda(dy)$ a.s, for any $x \in S$, with $\Phi(dy) = \phi(y)d\lambda(y)$. We assume

$\mathcal{H}_0$: The chain X satisfies condition $\mathcal{M}(1, S, \delta, \Phi)$ for some known parameters $S \in \mathcal{E}$ such that $\mu(S) > 0$, $\delta > 0$ and probability $\Phi(dy) = \phi(y)d\lambda(y)$ supported by S such that $\inf_{y\in S}\phi(y) > 0$.

The Nummelin splitting technique consists in constructing a bivariate Markov chain $X^{\mathcal{M}} = ((X_n, Y_n))_{n\in\mathbb{N}}$, called the *split chain*, taking its values in the state space $E \times \{0, 1\}$. This construction entails that, conditionally to $X^{(n+1)} = (X_1, \dots, X_{n+1})$, the Y_i's, $1 \leqslant i \leqslant n$, are independent Bernoulli r.v.'s. The Bernoulli parameter is δ, unless X has hit the small set S at time i. And in the case when $X_i \in S$, Y_i is drawn from the Bernoulli distribution with parameter $\delta\phi(X_{i+1})/p(X_i, X_{i+1})$. We denote by $\mathcal{L}^{(n)}(p, S, \delta, \phi, X^{(n+1)})$

the probability distribution of $Y^{(n)} = (Y_1, \ldots, Y_n)$ conditionally to $X^{(n+1)}$, which is simply the tensor product of these Bernoulli distributions. The whole point of the construction consists in the fact that $A_{\mathcal{M}} = S \times \{1\}$ is an atom for the split chain $X^{\mathcal{M}}$, which inherits all the communication and stochastic stability properties from X. In particular, the sample path of $X^{\mathcal{M}}$ can be classically divided into *regeneration blocks* corresponding to the blocks of observations between successive visits of the split chain to $A_{\mathcal{M}}$, which are i.i.d. r.v.'s valued in the torus $T = \cup_{n=1}^{\infty} E^n$, by virtue of the strong Markov property. For a given time $m^* \in \mathbb{N}$ that will be fixed later, we shall here consider the regeneration times

($i.e.$ the times i at which $X_i \in S$ and $Y_i = 1$) posterior to m^*, which are denoted by $\tau_{m^*} \doteq \tau_{m^*}(1) = \inf\{k \geqslant m^* + 1/\ X_k \in S, Y_k = 1\}$, $\tau_{m^*}(j) = \inf\{k > \tau_{m^*}(j-1)/\ X_k \in S, Y_k = 1\}$ for $j \geqslant 2$. We denote by $l_{m^*,n} = \sum_{i=m^*+1}^{n} I\{X_i \in S, Y_i = 1)$ the number of visits to the set $A_{\mathcal{M}} = S \times \{1\}$ between time $m^* + 1$ and time n. The corresponding regeneration blocks are denoted by $\mathcal{B}_{0,m^*} = (X_{m+1}, \ldots, X_{\tau_{m^*}(1)})$, $\mathcal{B}_{1,m*} = (X_{\tau_{m^*}(1)+1}, \ldots, X_{\tau_{m^*}(2)}), \ldots, \mathcal{B}_{l_{m^*,n}-1,m^*} = (X_{\tau_{m^*}(l_{m^*,n}-1)+1}, \ldots, X_{\tau_{m^*}(l_{m^*,n})})$, $\mathcal{B}^{(n)}_{l_{m^*,n},m^*}= (X_{\tau_{m^*}(l_{m^*,n})+1}, \ldots, X_n)$.

2.2 Approximate Nummelin splitting construction

Of course these blocks are practically unknown since their construction explicitly depends on the unknown transition density $p(x, y)$ (see § 2.1). The proposal of Bertail & Clémençon [2] for approximating this construction consists in using an estimate $p_n(x, y)$ of the transition density computed from data $X_1, \ldots, X_n$ to generate a random vector $(\widehat{Y}_1, \ldots, \widehat{Y}_n)$, conditionally to $X^{(n+1)}$, drawn from the distribution $\mathcal{L}^{(n)}(p_n, S, \delta, \phi, X^{(n+1)})$. However this estimation step induces strong dependency problems that make the second order properties of the ARBB procedure very difficult to study, when applied to the data $(X_1, \widehat{Y}_1), \ldots, (X_n, \widehat{Y}_n)$. Here we propose a modification of the method based on the well known semiparametric "splitting trick".

Given the data $X^{(n+1)}$, keep the first m observations $X^{(m)} = (X_1, \ldots, X_m)$ only to compute an estimate $p_m(x, y)$ of $p(x, y)$ such that $p_m(x, y) \geq \delta\phi(y)$, $\lambda(dy)$ a.s. and $p_m(X_i, X_{i+1}) > 0$, $1 \leqslant i \leqslant n$. To ensure that the observations $X^{(m^*,n+1)} = (X_{m^*+1}, \ldots, X_{n+1})$, which shall be used for forming the pseudo-regeneration blocks to resample, are independent from the first m observations ($i.e.$ that a regeneration, or equivalently a visit of $X^{\mathcal{M}}$ to $A_{\mathcal{M}}$, occurs between time $m + 1$ and time m^*) with overwhelming probability, we separate them by a small gap of length p. We will typically choose $m^* = m+p$ with m, p and m^* depending on n such that $p = O(m)$ as $n \to \infty$. This procedure is very similar to the *2-split method* proposed in Schick [10], except that the user is here free to pick the exact number p of deleted observations, within the limits of the previous asymptotic constraint. In the following, we take $m \to \infty$ as $n \to \infty$, so as to get a consistent estimator $p_m(x, y)$, at a rate sufficiently slow (typically such that $\frac{m}{n} \to 0$ as $n \to \infty$) to ensure that the number of pseudo-blocks to resample also tends to infinity as $n \to \infty$.

Conditionally to $X^{(n+1)}$, draw then a vector $(\widehat{Y}_{m^*+1}, \ldots, \widehat{Y}_n)$ from the distribution estimate $\mathcal{L}^{(n-m^*)}(p_m, S, \delta, \phi, X^{(m^*, n+1)})$. From a practical viewpoint, it actually suffices to draw the $\widehat{Y}_i$'s at times i when the chain visits the set S (*i.e.* when $X_i \in S$), which are the only time points at which the split chain may regenerate: at such a time i, draw $\widehat{Y}_i$ according to the Bernoulli law with parameter $\delta\phi(X_{i+1})/p_m(X_i, X_{i+1}))$. Count then the number of visits $\widehat{l}_{m^*,n} = \sum_{i=m^*+1}^{n} I\{X_i \in S, \widehat{Y}_i = 1)$ to $A_{\mathcal{M}} = S \times \{1\}$ between time $m^* + 1$ and time n and divide the truncated sample path $X^{(m^*,n)}$ into $\widehat{l}_n + 1$ blocks, corresponding to the pieces of the data segment between consecutive visits to $A_{\mathcal{M}}$, $\widehat{\mathcal{B}}_{0,m^*} = (X_{m^*+1}, \ldots,\ X_{\widehat{\tau}_{m^*}(1)})$, $\widehat{\mathcal{B}}_{1,m^*} = (X_{\widehat{\tau}_{m^*}(1)+1}, \ldots,\ X_{\widehat{\tau}_{m^*}(2)}), \ldots,$ $\widehat{\mathcal{B}}^{(n)}_{l_{m^*,n},m^*} = (X_{\widehat{\tau}_{m^*}(\widehat{l}_{m^*,n})+1}, \ldots,\ X_n)$ with $\widehat{\tau}_{m^*}(0) = m^*$ and for any $j \geqslant 1$, $\widehat{\tau}_{m^*}(j) = \inf\left\{k > \widehat{\tau}_{m^*}(j-1),\ X_k \in S, \widehat{Y}_k = 1\right\}$. For convenience, denote by $l(\widehat{\mathcal{B}}_{j,m^*}) = \widehat{\tau}_{m^*}(j+1) - \widehat{\tau}_{m^*}(j)$ the length of the block $\widehat{\mathcal{B}}_{j,m^*}$, $j \geqslant 1$.

2.3 Approximate Regenerative Block Bootstrap

Let $T_{n+1} = T_{n+1}(X^{(n+1)})$ be a statistic of interest and $S_{n+1} = S_{n+1}(X^{(n+1)})$ be an adequate standardization of the latter. The modified ARBB algorithm (which we still call ARBB algorithm for the sake of the simplicity) consists then in applying the RBB procedure in the following manner.

1. Draw sequentially bootstrap data blocks $\mathcal{B}_1^*, \ldots,\ \mathcal{B}_k^*$ independently from the empirical distribution $F_{m^*,n} = (\widehat{l}\ _{m^*,n} - 1)^{-1} \sum_{j=1}^{\widehat{l}_{m^*,n}-1} \delta_{\widehat{\mathcal{B}}_{j,m^*}}$ of the blocks $\widehat{\mathcal{B}}_{1,m^*}, \ldots,\ \widehat{\mathcal{B}}_{\widehat{l}_{m^*,n}-1,m^*}$ conditioned on $X^{(n+1)}$, until the length of the bootstrap data series $L^*(k) = \sum_{j=1}^{k} l(\mathcal{B}_j^*)$ is larger than n. Let $l_n^* = \inf\{k \geqslant 1,\ L^*(k) > n\}$.

2. From these bootstrap data blocks, reconstruct a pseudo-trajectory by binding the blocks together, getting the reconstructed *ARBB sample path* $X^{*(n)} = (\mathcal{B}_1^*, \ldots, \mathcal{B}_{l_n^*-1}^*)$. Then compute the *ARBB statistic* $T_n^* = T_{L^*(l_n^*)}(X^{*(n)})$ and the *ARBB standardization* $S_n^* = S_{L^*(l_n^*)}(X^{*(n)})$.

3. The *ARBB distribution* is then given by $H_{ARBB}(x) = P^*(S_n^{*-1}(T_n^* - T_{n+1}) \leqslant x \mid X^{(n+1)})$, which may be approximated by a classical Monte-Carlo resampling scheme.

As shown in Bertail & Clémençon [2], the sequential resampling in step 1 allows to approximatively mimic the renewal property of the split chain and to efficiently reproduce the second order structure.

3 Second order properties for linear functionals

3.1 Basic estimators

Let $f : E \to \Re$ be a μ-integrable function. Our parameter of interest is now the unknown mean $\mu(f) = E_\mu(f(X_1))$. Although the sample mean $\mu_{n+1}(f) = (n+1)^{-1}\sum_{i=1}^{n+1} f(X_i)$ is an asymptotically normal estimator of $\mu(f)$ under simple moment conditions, we shall consider the truncated sample mean based on the data segment $(X_{\widehat{\tau}_{m^*}(1)+1}, \ldots,, X_{\widehat{\tau}_{m^*}(1_{m^*,n})})$ only (or equivalently on the blocks $\widehat{\mathcal{B}}_{1,m^*}, \ldots, \widehat{\mathcal{B}}_{\widehat{l}_{m^*,n}-1,m^*}$), since the matter is here to deal with estimators of which the distribution may be accurately approximated (refer to the discussions in Bertail & Clémençon [1], [2]). Denote by $\widehat{n} = \widehat{\tau}_{_{m^*}}(\widehat{l}_{_{m^*},n}) - \widehat{\tau}_{_{m^*}}(1) = \sum_{j=1}^{\widehat{l}_{m^*,n}-1} l(\widehat{\mathcal{B}}_{j,m^*})$ the length of this segment. Set $f(\widehat{\mathcal{B}}_{j,m^*}) = \sum_{i=1+\widehat{\tau}_{m^*}(j)}^{\widehat{\tau}_{m^*}(j+1)} f(X_i)$, $j \geqslant 1$, $\widehat{\mu}_{m^*,n}(f) = \widehat{n}^{-1}\sum_{j=1}^{\widehat{l}_{m^*,n}-1} f(\widehat{\mathcal{B}}_{j,m^*})$, $\widehat{\sigma}^2_{m^*,n}(f) = \widehat{n}^{-1}\sum_{j=1}^{\widehat{l}_{m^*,n}-1}\{f(\widehat{\mathcal{B}}_{j,m^*}) - \widehat{\mu}_{m^*,n}(f)l(\widehat{\mathcal{B}}_{j,m^*})\}^2$. It can easily be shown by using the argument of Theorems 17.2.2 and 17.3.6 in Meyn & Tweedie [8] that, under suitable block moment conditions, $\widehat{\mu}_{m^*,n}(f)$ is asymptotically normal and $\widehat{\sigma}^2_{m^*,n}(f)$ is a consistent estimator of the asymptotic variance of $\widehat{\mu}_{m^*,n}(f)$ (resp., of $\mu_{n+1}(f)$), namely $\sigma^2(f) = E_{A_\mathcal{M}}(\tau_{A_\mathcal{M}})^{-1}E_{A_\mathcal{M}}((\sum_{i=1}^{\tau_{A_\mathcal{M}}}\{f(X_i) - \mu(f)\})^2)$, where $\tau_{A_\mathcal{M}} = \inf\{k \geqslant 1/\ X_k \in S,\ Y_k = 1\}$ and $E_{A_\mathcal{M}}(.)$ denotes the conditional expectation given $(X_0, Y_0) \in S \times \{1\}$. We then define the *unstudentized mean* $\widehat{\varsigma}_n = \widehat{n}^{1/2}\frac{\widehat{\mu}_{m^*,n}(f)-\mu(f)}{\sigma(f)}$ *and the studentized mean* $\widehat{t}_n = \widehat{n}^{1/2}\frac{\widehat{\mu}_n(f)-\mu(f)}{\widehat{\sigma}_{m^*,n}(f)}$. Bertail & Clémençon [1] have shown how to obtain Edgeworth expansions up to $O(n^{-1})$ for such quantities using the same technique as in Bolthausen [3] and in Malinovskii [7].

3.2 Asymptotic validity of the ARBB

Let $P^*(.)$ denote the conditional probability under the resampling scheme described in step 1 (see § 2.3) for given $X^{(n+1)}$. Consider now the ARBB counterparts of the statistics introduced above: $\mu_n^*(f) = n^{*-1}\sum_{j=1}^{l_n^*-1} f(\mathcal{B}_j^*)$ and $\sigma_n^{*2}(f) = n^{*-1}\sum_{j=1}^{l_n^*-1}\{f(\mathcal{B}_j^*) - \mu_n^*(f)l(\mathcal{B}_j^*)\}^2$ with $n^* = \sum_{j=1}^{l_n^*-1} l(\mathcal{B}_j^*)$. Define also the ARBB version of the pseudo-regenerative unstudentized sample mean by $\widehat{\varsigma}_n^* = n^{*1/2}\sigma_n^*(f)^{-1}(\mu_n^*(f) - \widehat{\mu}_n(f))$ and the one of the pseudo-regenerative studentized mean by $\widehat{t}_n^* = n^{*1/2}\sigma_n^*(f)^{-1}(\mu_n^*(f) - \widehat{\mu}_n(f))$. We shall use the following assumptions. Let $k \geqslant 2$ and set $\tau_S = \inf\{i \geqslant 1/\ X_i \in S\}$.

$\mathcal{H}_1(f, k)$: The small set S is such that $\sup_{x\in S} E_x((\sum_{i=1}^{\tau_S}|f(X_i)|)^k) < \infty$.

$\mathcal{H}_2(k)$: The small set S is such that $\sup_{x\in S} E_x(\tau_S^k) < \infty$.

These conditions may be classically replaced by some Liapounov's drift conditions (see Meyn & Tweedie [8]). For a sequence of nonnegative real numbers $\alpha = (\alpha_n)_{n\in\mathbf{N}}$ converging to 0 as $n \to \infty$, consider

$\mathcal{H}_3 : p(x,y)$ is uniformly estimated by $p_m(x,y)$ based on $X^{(m)}$ at the rate α_m at least for the MSE when error is measured by the L^∞ loss over $S \times S$:

$$\lim_{m\to\infty} \alpha_m^{-1} \left(E \left(\sup_{(x,y)\in S\times S} |p_m(x,y) - p(x,y)|^2 \right) \right)^{1/2} = 0.$$

$\mathcal{H}_4(k)$: The sequences $m = m(n)$ and $p = p(n)$ are chosen such that $n^{1/k} \leq p \leq m$ and $m/n \to 0$ as $n \to \infty$.

$\mathcal{H}_5$: $\overline{lim}_{t\to\infty}$ $\sup_{x\in S}$ $|E_x(\exp(it\sum_{i=1}^{\tau_S}\{f(X_i) - \mu(f)\}))| < 1$ (Cramer type condition).

$\mathcal{H}_6$: There exists $N > 0$ such that the N-fold convolution of the density of $(\sum_{i=1}^{\tau_S}\{f(X_i) - \mu(f)\})^2$ is uniformly bounded over any starting value $X_0 = x$ in S.

We then have the following results :

Theorem 3.1. *Under assumptions $\mathcal{H}_0$, $\mathcal{H}_1(f,k)$, $\mathcal{H}_2(k)$ $\mathcal{H}_3$, $\mathcal{H}_4(k)$ and $\mathcal{H}_5(k)$ with $k > 6$, we have the second order validity of the ARBB distribution both in the standardized and unstandardized case:*

$$\sup_{x\in\mathbb{R}} |P^*(\widehat{\varsigma}_n^* \leq x) - P_\nu(\widehat{\varsigma}_n \leq x)| = O_{P_\nu}(n^{-1/2}\alpha_m \vee n^{-1/2}n^{-1}m\}) \ ,$$

as $n \to \infty$. And if these conditions holds for some $k > 8$ and $\mathcal{H}_6$ hold, we have as $n \to \infty$:

$$\sup_{x\in\mathbb{R}} |P^*(\widehat{t}_n^* \leq x) - P_\nu(\widehat{t}_n \leq x)| = O_{P_\nu}(n^{-1/2}\alpha_m \vee n^{-1/2}n^{-1}m).$$

In particular if $\alpha_m = m^{-1/2}\log(m)$, by choosing $m = n^{2/3}$, the ARBB is second order correct up to $O(n^{-5/6}\log(n))$.

Proof: The proof is based on the same technical ideas as in Bertail & Clémençon [1], [2] (refer to these papers for further details). It relies on establishing the closeness between the conditional distribution of the blocks $\mathcal{B}_{1,m^*}, \ldots, \mathcal{B}_{l_{m^*,n},m^*}$ dividing the segment $X^{(m^*,n)} = (X_{m^*+1}, \ldots, X_{n+1})$ according to the $l_{m^*,n}$ visits of $(X_i, Y_i)_{m^*<i\leqslant n}$ to the atom $A_\mathcal{M}$ between time m^*+1 and time n and the conditional distribution of the blocks $\widehat{\mathcal{B}}_{1,m^*}, \ldots, \widehat{\mathcal{B}}_{\widehat{l}_{m^*,n},m^*}$ dividing $X^{(m^*,n)}$ according to the $\widehat{l}_{m^*,n}$ successive visits of $(X_i, \widehat{Y}_i)_{m^*<i\leqslant n}$ to $A_\mathcal{M}$, for given $X^{(n+1)}$. By coupling arguments one may show that, under $\mathcal{H}_2(2\gamma)$, $\gamma \geqslant 2$ and $\mathcal{H}_3$, there exists a constant C such that for $i \in \{1,2\}$,

$$E_\nu(|\widehat{\tau}_i - \tau_i|^\gamma) \leqslant C\alpha_m, \tag{1}$$

with the further notations $\tau_1 = \tau_{m^*}(1)$, $\widehat{\tau}_1 = \widehat{\tau}_{m^*}(1)$, $\tau_2 = \tau_{m^*}(l_{m^*,n})$ and $\widehat{\tau}_2 = \widehat{\tau}_{m^*}(\widehat{l}_{m^*,n})$. Now set $T_n^{(k)}(f) = n^{-1}\sum_{j=1}^{l_{m^*,n}-1} f(\mathcal{B}_{j,m^*})^k$ and $\widetilde{T}_n^{(k)}(f) =$

$n^{-1}\sum_{j=1}^{\widehat{l}_{m^*,n}-1} f(\widehat{\mathcal{B}}_{j,m^*})^k$ for $1 \leqslant k \leqslant 3$, with by convention $T_n^{(k)}(f) = 0$ (respectively, $\widetilde{T}_n^{(k)}(f) = 0$) when $l_{m^*,n} \leqslant 1$ (resp., when $\widehat{l}_{m^*,n} \leqslant 1$) and set

$$D_n^{(k)}(f) = E_\nu \left| T_n^{(k)}(f) - \widetilde{T}_n^{(k)}(f) \right| .$$

Then, following line by line the argument in Bertail & Clémençon [2], we have as $n \to \infty$

$$D_n^{(1)}(f) = O((n-m-p)^{-1}\alpha_m), \tag{2}$$

$$D_n^{(k)}(f) = O(\alpha_m),\ \text{for } k = 2,\ 3. \tag{3}$$

Observing that, conditioned on $X^{(n+1)}$, the reconstructed ARBB sample path does not keep the markovian structure but still forms a regenerative sequence, the results in Malinovskii [7] (resp. in Bertail & Clémençon [1] allow to derive an explicit Edgeworth expansion (E.E.) up to the second order for the unstudentized ARBB version (resp., for the studentized ARBB version). Given (2) and (3) it is straightforward to check that the conditions of validity of these E.E. hold and that the empirical moments appearing in the empirical E.E. of the ARBB distribution converges to their theoretical counterparts at the rate α_m at least. Moreover the bias induced by the first and last pseudo-regeneration blocks does not perturb the E.E. up to $O_P(n^{-1}\alpha_m)$. The main difficulty actually consists in establishing an E.E. for the original statistic. In the unstudentized case, since the functional is then linear, it simply amounts to control the error induced by a split at the "wrong place" for the first (resp. the last) block (*i.e.* the distance between τ_i and $\widehat{\tau}_i$, $i = 1, 2$): this is typically of the same order as the deviation (2). The unstandardized mean thus admits an E.E. on powers of $(n-m-p)^{-1/2}$, which in turn coincides with the E.E. of the empirical mean up to $O(n^{-1/2}(m/n))$. In the studentized case one must first check that the variance estimate computed from the pseudo-blocks is close to the variance estimate based on the regeneration blocks up to $O_P(n^{-1}\alpha_m)$, conditionally to the first m observations. Combining $\mathcal{H}_4(k)$ with $\mathcal{H}_2(k)$, for $k > 4$, it is straightforward that the probability that the split chain does not visit the regeneration set $S \times \{1\}$ between m and $m+p$ is typically of order $O(n^{-1})$. Subsequently to a regeneration occurring between $m+1$ and $m+p$, the remaining observations may be then decomposed into true regeneration blocks (independent from the first m observations) using the same partitioning arguments as in Malinovskii [7] or Bertail & Clémençon [1], [2]. This yields the validity of the E.E. on powers of $(n-m-p)^{-1/2} = n^{-1/2} + O(n^{-1/2}(m/n))$. A straightforward optimization argument leads to the last statement. ■

4 Tuning parameters and simulation results

The main tuning parameter relies in the choice of the small set. If the transition density $p(x, y)$ is continuous on some neighborhood $V_{x_0}(\varepsilon)^2 =$

$[x_0-\varepsilon, x_0+\varepsilon]^2$ of some fixed point $(x_0,\, x_0)$ such that $p(x_0, x_0) > 0$, then there exists $\delta = \delta(\varepsilon, p) \in]0,\, 1[$ such that $\inf_{(x,y)\in V_{x_0}^2} p(x,y) \geqslant \delta(2\varepsilon)^{-1}$. Such a compact interval $V_{x_0}(\varepsilon)$ is thus a small set for X. It satisfies condition $\mathcal{M}(1, V_{x_0}(\varepsilon), \delta, \mathcal{U}_{V_{x_0}(\varepsilon)})$, where $\mathcal{U}_{V_{x_0}(\varepsilon)}$ denotes the uniform distribution on $V_{x_0}(\varepsilon)$. Hence, in the case when one knows x_0, ε and δ such that (2) holds (this simply amounts to know a uniform lower bound estimate for the probability of returning to $V_{x_0}(\varepsilon)$ in one step), one may effectively apply the ARBB methodology to X. A possible selection rule for ε relies on fixing x_0 and searching for $\varepsilon > 0$ so as to maximize the expected number of regeneration-blocks conditionally to the observed trajectory $X^{(n+1)}$, that is

$$\begin{aligned} N_n(\varepsilon,p) &= E(\textstyle\sum_{i=m^*+1}^{n} I\{X_i \in V_{x_0}(\varepsilon),\, Y_i = 1\}\,|X^{(n+1)}) \\ &= \tfrac{\delta(\varepsilon,p)}{2\varepsilon}\textstyle\sum_{i=m^*+1}^{n} I\{(X_i, X_{i+1}) \in V_{x_0}(\varepsilon)^2\}\tfrac{1}{p(X_i,X_{i+1})}. \end{aligned}$$

Since the transition density p and its minimum over $V_{x_0}(\varepsilon)^2$ are unknown, a practical criterion $\widehat{N}_n(\varepsilon)$ to optimize is obtained by replacing p by p_m and $\delta(\varepsilon,p)/2\varepsilon$ by a sharp lower bound $\widehat{\delta}_m(\varepsilon, p_m)/2\varepsilon$ for p_m over $V_{x_0}(\varepsilon)^2$. The final procedure may be then implemented in 4 steps as follows. Let x_0 be fixed.

1. Compute an estimator $\widehat{p}_m$ of the transition density, for instance of Nadaraya-Watson's type, with $m = Cn^{2/3}, C > 0$.
2. Select the small set $V_{x_0}(\varepsilon)$ by maximizing the empirical criterion $\widehat{N}_n(\varepsilon)$ described above over $\varepsilon > 0$. This yields $\widehat{\varepsilon}_{m,opt}$ and a corresponding minimum value $\widehat{\delta}_{m,opt}$.
3. At each time $i > m^*$ when $(X_i, X_{i+1}) \in [-\widehat{\varepsilon}_{m,opt}, \widehat{\varepsilon}_{m,opt}]^2$, draw independent Bernoulli r.v.'s $\widehat{Y}_i$ with parameter $1-\widehat{\delta}_{m,opt}(2\varepsilon_{m,opt})^{-1}/\widehat{p}_m(X_i, X_{i+1})$. At each time i such that $\widehat{Y}_i = 1$, divide the trajectory, getting data blocks of random size.
4. Apply the ARBB procedure to the sample mean as previously described.

Because the tuning parameters p_m, $\widehat{\varepsilon}_{m,opt}$, $\widehat{\delta}_{m,opt}$ explicitly depends on the first m observations only, the "2-split" technique ensures that the ARBB resampling will not be asymptotically perturbed by the latter.

In the following tables, we compare the quantile of order γ of the true distribution (TD) of the mean respectively. We take $X_0 = 0$, ε_i *i.i.d.* $\sim N(0,1)$ and consider

-an AR(1) model : $X_i = \rho X_{i-1} + \varepsilon_i$, with $\rho = 0.95$ and $n = 200$, $m = 68 = [2 * n^{2/3})]$.

-an AR model with a ARCH(1) structure $X_i = \rho X_{i-1} + (1+\alpha X_{i-1}^2)^{1/2}\varepsilon_{i,}$ $\rho = 0.6$, $\alpha = 0.1$. See Bertail and Clémençon [2] for comparison with the ARBB without the double splitting trick. The performance are quite similar and suggest that the ARBB without the splitting trick enjoy the same second order properties.

	AR		AR-ARCH		
γ	TD	ARBB	TD	ARBB	ASY
1	-3.63	-3.72	-2.53	-2.65	-2.32

TWO MEASURES OF CREDIBILITY OF EVOLUTIONARY TREES

Martin Betinec

Key words: Evolutionary tree, clustering, classification, bootstrap, DNA, Trichomonas.

COMPSTAT 2004 section: Biostatistics, Clustering.

Abstract: Evolutionary tree is a dendrogram that is used to asses genetical similarity of biological objects. The contribution concerns two methods that use bootstrap to verify the credibility of the built tree. The measures are compared on gene sequences of Trichomonadinæ family.

1 Introduction

Evolutionary trees, also known as *Phylogenetic trees*, constitute in biology a way of describing evolution of the observed organisms. From the mathematical point of view, these trees are a special type of classification trees (dendrograms). Not only this method enables a demonstration of relationships among objects, i.e. to answer the question 'which assay is close to this one in evolution', but it can also quantify the distance between clusters of objects. The distance is proportional to the length of the branch connecting the corresponding clusters.

This paper concerns two methods (sections 4 and 5) that use bootstrap for estimation of the confidence mentioned above. We will try to demonstrate why it is possible to claim something reliable about connection between our data set and the real world from the information bootstrap populations can produce. We compare these two methods in section 6 using a real data set that is introduced in section 2.

2 Data

For the demonstration of the results we will use the data that were assembled by a group of biologists of the Faculty of Science of Charles University in Prague lead by prof. Flégr, see `http://prfdec.natur.cuni.cz/~flegr/`. They investigated a part of the genome of a unicellular organisms of the *Trichomonadinæ* family. The data are to be published, but they have not been up to now, so the names of the isolates are replaced with ordinals. For our illustration we will use 22 of them. For $i = 1, \ldots, 22$ we denote the isolates:

$$\boldsymbol{x}_i = \underbrace{(\text{A,T,G, } \ldots, \text{ C,T,A,T})}_{1870 \text{ nucleotides}},$$

where the capital letters are the first letters of the nucleotides' names:
A – adenine, T – thymine, C – cytosine, G – guanine.

3 Tree growing

We compose a data matrix $\boldsymbol{X}$ from the row vectors $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{22}$. So, its dimensions are 22×1870.

There are three important questions for determination of distances between the vectors of $\boldsymbol{X}$. Choice of a *method* of agglomeration, a *distance* and *encoding* the nucleotides which can influence shaping the estimated tree.

3.1 Encoding of nucleotides

For the latter, we need to consider their chemical affinity, probability of their point mutation etc. For more detailed discussion on this topic see [1]. After testing various reasonable encodings (see [2]) a relative independence of the shape of the tree on this factor was realized. Finally, we will use the following in accordance with ([5]):

$$\big(\text{A,G,C,T}\big) = \big(1, 2, 5, 6\big)\,. \tag{1}$$

3.2 Distance

All the metrics that were used (with logical exception of the *supremal*) caused very similar trees. Finally, we will work with the *Euclidean* metric, which produces exactly the same tree as the *Manhattan*, and very similar to *Canberra* metric, see [2].

Obviously, it is possible to leave out the constant column vectors of the matrix $\boldsymbol{X}$. They don't bring any additional information about distance of rows because the corresponding terms are zeros. By that we reduce the dimension of the matrix $\boldsymbol{X}$ from (22×1870) to (22×566).

Various methods of cluster analysis were examined, i.e. *single* and *complete linkage*, *group average*, *Ward's*, *centroid* and *median*. It was realized that the resulting trees were very similar (except *Ward's* method). Finally, we will use *the nearest neighbour principle* to construct dendrograms in this article (see Figure 1). Not only because of the fact that the group of the similar methods was bigger; we also made sure of the proper method by principal component analysis, for details see [2].

4 The method of relative frequencies

The simplest estimate of confidence level of a single branch v of the tree $\widehat{\Psi}$ can be obtained as a relative frequency of occurrence of v at the bootstrapped trees. According to its author, the method is called Felsenstein's.

In each iteration $b = 1, \cdots, B$, we randomly select some of the columns of the matrix $\boldsymbol{X}$ with replacement and from these chosen vectors we create

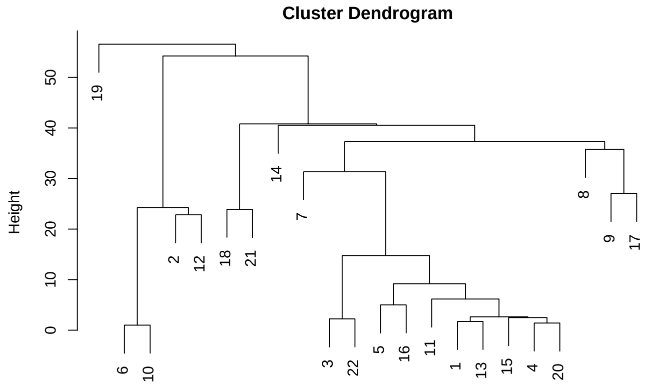

Figure 1: The single linkage tree.

a bootstrap matrix $\boldsymbol{X}_b^*$ of the same size as $\boldsymbol{X}$, i.e. every column vector of the matrix $\boldsymbol{X}$ can be drawn with the same probability. Then we grow a tree $\widehat{\Psi}_b^*$ from the matrix $\boldsymbol{X}_b^*$.

We define the **confidence level** of the branch v as:

$$\alpha_F(v) \overset{df}{=} \frac{1}{B}\#\big\{b : \widehat{\Psi}_b^* \ni v\ \big\}, \tag{2}$$

where # means "a number of elements of" and B is a number of bootstrap iterations. It is not far to seek adaptation of the algorithm for more branches.

The following section will focus in some detail on the relation of the calculated estimate of the confidence level and reality, i.e. in explaining how it is possible to estimate $\alpha = \mathbf{P}\widehat{\Psi} \equiv \Psi$.

4.1 Theoretical background

We suppose that the columns $\boldsymbol{x}^1, \dots, \boldsymbol{x}^{566}$ of the matrix $\boldsymbol{X} = \big(\boldsymbol{x}^1, \dots, \boldsymbol{x}^{566}\big)$, where $x_l^k \in \big\{\text{A,G,T,C}\big\}$, $k = 1, \dots, 566$, $l = 1, \dots, 22$ are randomly selected (with range $n = 566$) from some probability distribution on the space of **all possible non-constant** vectors $\boldsymbol{\xi}$ of dimension 22 over the alphabet $\big\{\text{A,G,T,C}\big\}$. We denote this space as $\mathcal{X}$, i.e. $\mathcal{X} = \big\{\boldsymbol{\xi}_1, \dots, \boldsymbol{\xi}_K\big\}$, where $K = 4^{22} - 4 = 1.7592 \cdot 10^{13}$.

By the diagram

$$\boldsymbol{X} \Longrightarrow \text{cluster an.} \Longrightarrow \widehat{\Psi} \qquad \boldsymbol{X}^* \Longrightarrow \text{cluster an.} \Longrightarrow \widehat{\Psi}^* \quad \text{resp.}, \tag{3}$$

we can describe both areas of reality - the *practical* and the *virtual*, but it cannot be used for the description of the *theoretical* area we are interested in. That is why we move into space $\mathcal{P}$, which is space of **probability vectors**. Their components π_i are probabilities of including the vectors $\boldsymbol{\xi}_i \in \mathcal{X}$ into the sample $(i = 1, \dots, K)$.

$$\mathcal{P} \overset{df}{=} \Big\{\boldsymbol{\pi} = \big(\pi_1, \dots, \pi_K\big)' \quad \pi_i = \mathbf{P}\boldsymbol{\xi}_i \text{ involved into the sample}\Big\} \tag{4}$$

Theoretical probabilities $\boldsymbol{\pi}$ correspond to the **observed frequencies** of appearance of the vectors $\boldsymbol{\xi}_i$ in the columns of the data matrix $\boldsymbol{X}$, i.e.

$$\boldsymbol{\Upsilon} = \left(\Upsilon_1, \ldots, \Upsilon_K\right)', \qquad \text{where} \quad \Upsilon_i \overset{df}{=} \#\left\{j :\ \boldsymbol{x}^j = \boldsymbol{\xi}_i\right\} \quad i = 1, \ldots, K\,,$$

or the **relative frequencies**

$$\widehat{\boldsymbol{\pi}} = \left(\widehat{\pi}_1, \ldots, \widehat{\pi}_K\right)', \qquad \text{where} \quad \widehat{\pi}_i \overset{df}{=} \frac{1}{n} \#\left\{j :\ \boldsymbol{x}^j = \boldsymbol{\xi}_i\right\} = \frac{\Upsilon_i}{n}\,. \tag{5}$$

From the bootstrapped matrices $\boldsymbol{X}_b^* = \left(\boldsymbol{x}^n * 1b, \ldots, \boldsymbol{x}^n * 566b\right)$, $b = 1, \ldots, B$, we could obtain for $i = 1, \ldots, K$ by analogy $\boldsymbol{\Upsilon}_b^* = \left(\Upsilon_{b,1}^*, \ldots, \Upsilon_{b,K}^*\right)'$ and $\widehat{\boldsymbol{\pi}}_b^* = \left(\widehat{\pi}_{b,1}^*, \ldots, \widehat{\pi}_{b,K}^*\right)'$.

Obviously (for $K = 4^{22} - 4$ and $n = 566$):

$$\boldsymbol{\Upsilon} \sim \text{Multi}_K(n, \boldsymbol{\pi}) \qquad\qquad \text{a} \qquad\qquad \boldsymbol{\Upsilon}^* \sim \text{Multi}_K(n, \widehat{\boldsymbol{\pi}})\,. \tag{6}$$

Now, we can express the tree growing, described by diagram (3) as:

$$\widehat{\boldsymbol{\pi}} \Longrightarrow \widehat{\Psi}\,, \qquad \text{resp.} \qquad \widehat{\boldsymbol{\pi}}_b^* \Longrightarrow \widehat{\Psi}_b^*.$$

Similarly, we can imagine that also the theoretical probabilities $\boldsymbol{\pi}$ correspond to some theoretical tree Ψ that describes the true relations among the observed organisms.

It is also worth noticing that one and the same tree can be grown from two different probabilistic vectors $\widehat{\boldsymbol{\pi}}^{(1)}$ and $\widehat{\boldsymbol{\pi}}^{(2)}$. Therefore, the space $\mathcal{P}$ is split into the disjoint classes of equivalency $\mathcal{P} = \dot{\bigcup}_i \mathcal{P}_i$. For these classes holds:

$$\left\{\mathcal{P}_i \ni \widehat{\boldsymbol{\pi}}^{(1)} \quad \& \quad \mathcal{P}_j \ni \widehat{\boldsymbol{\pi}}^{(2)}\right\} \qquad \Longrightarrow \qquad \left\{\,\widehat{\Psi}^{(1)} \equiv \widehat{\Psi}^{(2)} \quad \Leftrightarrow \quad i = j\,\right\}, \tag{7}$$

where $\widehat{\Psi}^{(j)}$ corresponds to the tree grown from $\widehat{\boldsymbol{\pi}}^{(j)}$, $j = 1, 2$.

Let us return to the original problem of estimating confidence of our tree Ψ. What we want to know is the probability of the accordance of $\widehat{\Psi}$ with its theoretical pattern Ψ. So, we are interested in:

$$\alpha = \mathbf{P}\widehat{\Psi} \equiv \Psi = \mathbf{P}\boldsymbol{\pi} \in \mathcal{P}_i\,|\widehat{\boldsymbol{\pi}} \in \mathcal{P}_i \tag{8}$$

We estimated this probability by (2) as an empirical probability (relative frequency) of the fact that the branch in question of the bootstrapped tree $\widehat{\Psi}^*$ grown from $\boldsymbol{X}^*$ corresponds to the given branch of the original tree $\widehat{\Psi}$:

$$\alpha_F = \widehat{\mathbf{P}}_{\widehat{\boldsymbol{\pi}}^*|\widehat{\boldsymbol{\pi}}}(\widehat{\boldsymbol{\pi}}^* \in \mathcal{P}_i\,|\widehat{\boldsymbol{\pi}} \in \mathcal{P}_i)\,. \tag{9}$$

To have an idea of the error we caused by this estimation, it is necessary to know the conditional distribution $\widehat{\boldsymbol{\pi}}^*$ (the aposteriori distribution of $\boldsymbol{\pi}$ respectively) with $\widehat{\boldsymbol{\pi}}$ fixed, so $\mathcal{L}\left(\widehat{\boldsymbol{\pi}}^*\,|\widehat{\boldsymbol{\pi}}\right)$ (resp. $\mathcal{L}\left(\boldsymbol{\pi}\,|\widehat{\boldsymbol{\pi}}\right)$).

We know the first one, because it follows from the formula (6):

$$\mathcal{L}\big(n\widehat{\boldsymbol{\pi}}^* \,|\widehat{\boldsymbol{\pi}}\big) = \mathrm{Multi}_K(n, \widehat{\boldsymbol{\pi}})\,. \tag{10}$$

The aposteriori distribution $\mathcal{L}\big(\boldsymbol{\pi}\,|\widehat{\boldsymbol{\pi}}\big)$ can be expressed by the sample distribution $\widehat{\boldsymbol{\pi}}$ conditional by $\boldsymbol{\pi}$. Considering the model, it holds:

$$\mathcal{L}\big(n\widehat{\boldsymbol{\pi}}\,|\boldsymbol{\pi}\big) = \mathrm{Multi}_K(n, \boldsymbol{\pi})\,. \tag{11}$$

Multinomial distribution is conjugated with Dirichlet's, therefore:

Lemma 4.1. *$\mathcal{L}\big(\widehat{\boldsymbol{\pi}}^*\,|\widehat{\boldsymbol{\pi}}\big)$ and $\mathcal{L}\big(\boldsymbol{\pi}\,|\widehat{\boldsymbol{\pi}}\big)$ have the following properties:*

1. *Let the apriori distribution of $\boldsymbol{\pi}$ be uninformative, then*

$$\mathcal{L}\big(\boldsymbol{\pi}\,|\widehat{\boldsymbol{\pi}}\big) = Dir_K(n\widehat{\boldsymbol{\pi}})\,. \tag{12}$$

2. *They both are concentrated only on those $\boldsymbol{\xi}_i$ for which $\pi_i > 0$, i.e. on columns of the matrix $\boldsymbol{X}$.*
3. *They have identical mean.*
4. *Their covariance matrices equal asymptotically, (i.e. $\Sigma^* = \frac{n+1}{n}\Sigma$)*

The main advantage of this estimate of the confidence level of the evolutionary tree (defined by (2)) is its simplicity. Moreover, it is easy to implement its algorithm. Last but not least benefit lies in rapidity of its calculation. However, the resulting estimate could be sometimes quite misguiding.
A problem appears if we cannot guarantee fulfilling of the assumptions of the lemma 4.1 – its consequences cannot be guaranteed either.

The estimated confidence level α_F could be very distant from the real α. Considering the complexity of the space $\mathcal{P}$, it is not easy to recognize whether that situation comes on. Let us try a more delicate approach.

5 Improved estimator

5.1 Theory

We suppose the model (4) like in section 4. Further, we shall remind ourselves that the space $\mathcal{P}$ is split by the rule (7), so $\mathcal{P} = \dot{\bigcup}_i \mathcal{P}_i$.

Let us reserve a subscript $i = 1$ for that part of the space $\mathcal{P}$ which contains the vector $\widehat{\boldsymbol{\pi}}$, hence $\mathcal{P}_1 \ni \widehat{\boldsymbol{\pi}}$. Let $\overline{\mathcal{P}}_1 = \dot{\bigcup}_{i\neq 1} \mathcal{P}_i$ be a complement of $\mathcal{P}_1$. Not only will we consider the fact that $\widehat{\boldsymbol{\pi}} \in \mathcal{P}_1$ like in previous section, but we will also take into account the distance of $\widehat{\boldsymbol{\pi}}$ from the boundary of the area $\mathcal{P}_1$. Motivation for this effort is following: the vector $\boldsymbol{\pi}$ should lie "near around" the vector $\widehat{\boldsymbol{\pi}}$, because $\widehat{\boldsymbol{\pi}}$ (a vector of the observed relative frequencies) is generated from $\boldsymbol{\pi}$ by assumed model (5). Hence, the confidence level

$$\alpha = \mathbf{P}\boldsymbol{\pi} \in \mathcal{P}_1\,|\widehat{\boldsymbol{\pi}} \in \mathcal{P}_1\,, \tag{13}$$

should be higher, if $\widehat{\boldsymbol{\pi}}$ lied “somewhere in the middle” of $\mathcal{P}_1$ than in the case of $\widehat{\boldsymbol{\pi}}$ situated near the boundary of $\mathcal{P}_1$.

Let $\partial\mathcal{P}_1$ assign a border of $\mathcal{P}_1$. Let $\boldsymbol{\pi}_0$ be the closest point of $\partial\mathcal{P}_1$ to $\widehat{\boldsymbol{\pi}}$, hence

$$\boldsymbol{\pi}_0 \overset{df}{=} \arg \min_{\breve{\boldsymbol{\pi}} \in \partial\mathcal{P}_1} d(\widehat{\boldsymbol{\pi}}, \breve{\boldsymbol{\pi}}) \,, \tag{14}$$

where $d(.\,,.)$ is an arbitrary *metric* on $\mathcal{P}$.

In the previous section we got a bootstrap population by means of frequencies of the occurrence that had been generated from $\widehat{\boldsymbol{\pi}}$, see (6). Now, we will generate new frequencies from $\boldsymbol{\pi}_0$, so for $b = 1, \dots, B_2$

$$\boldsymbol{\Upsilon}_b^{**} = \left(\Upsilon_{1b}^{**}, \dots, \Upsilon_{Kb}^{**}\right)' , \qquad \text{where} \qquad \Upsilon_{ib}^{**} \overset{df}{=} \#\left\{j : \boldsymbol{x}^n * * jb = \boldsymbol{\xi}_i\right\} , \tag{15}$$

$$\boldsymbol{\Upsilon}_b^{**} \sim \text{Multi}_K(n, \boldsymbol{\pi}_0) \qquad \text{and} \qquad \widehat{\boldsymbol{\pi}}_b^{**} = \frac{1}{n} \boldsymbol{\Upsilon}^{**} \,. \tag{16}$$

Our intention is to estimate the confidence value (13). We can proceed in our reflection as follows. The elements of the bootstrap population $\widehat{\boldsymbol{\pi}}_b^{**}$ are generated from the boundary point $\boldsymbol{\pi}_0$. The closer these elements $\widehat{\boldsymbol{\pi}}_b^{**}$ are to $\overline{\mathcal{P}}_1$ (compared to the position of $\widehat{\boldsymbol{\pi}}$, i.e. the smaller the estimated variance of $\widehat{\boldsymbol{\pi}}_b^{**}$ is), the smaller is the probability of the placement of the vector of the true probabilities $\boldsymbol{\pi}$ in $\overline{\mathcal{P}}_1$. The reason is that we suppose that the vector of the observed relative frequencies $\widehat{\boldsymbol{\pi}}$ was obtained by $\boldsymbol{\pi}$ by the same type of generation as in the case of generation of $\widehat{\boldsymbol{\pi}}_b^{**}$ from $\boldsymbol{\pi}_0$, cf. (6), (16). Summary: The closer $\widehat{\boldsymbol{\pi}}_b^{**}$ are to $\overline{\mathcal{P}}_1$ compared to the position of $\widehat{\boldsymbol{\pi}}$, the higher α is.

We define a new *confidence level:*

$$\alpha_{_E} \overset{df}{=} \widehat{\mathbf{P}}_{\widehat{\boldsymbol{\pi}}***|\boldsymbol{\pi}_0}(d(\widehat{\boldsymbol{\pi}}^{**}\!, \overline{\mathcal{P}}_1) \le d(\widehat{\boldsymbol{\pi}}, \overline{\mathcal{P}}_1) \,|\, \widehat{\boldsymbol{\pi}} \in \mathcal{P}_1) \,. \tag{17}$$

There is a consequence of this definition: $1 - \alpha_{_E}$ is an analogy of p value in the classical testing of hypotheses which can be illustrated by the following example.

Let $Z_1, \dots, Z_n \overset{iid}{\sim} N(\mu, 1)$. The investigated hypotheses are:
H: $\mu \le \mu_0$ vs. K: $\mu > \mu_0$.

Vector $\boldsymbol{\pi}_0 \in \partial\mathcal{P}_1$ corresponds to $\mu = \mu_0$ that is the point at the border between H and K. We estimate μ by $\widehat{\mu} = \widehat{\mu}(Z_1, \dots, Z_n)$ after finishing the experiment ($\widehat{\mu}$ is the analogy of $\widehat{\pi}$). Knowing the value of $\widehat{\mu}$, we know $\mathcal{P}_1 \ni \widehat{\mu}$, too. We want to confirm that $\mu \in \mathcal{P}_1$, i.e. we want to reject the negation, hence $H \equiv \overline{\mathcal{P}}_1$.

We denote $Z_1^{**}, \dots, Z_n^{**} \overset{iid}{\sim} N(\mu_0, 1)$ a sample bootstrapped from the null hypothesis H and an appropriate estimate $\widehat{\mu}^{**} = \widehat{\mu}^{**}(Z_1^{**}, \dots, Z_n^{**})$ (which is an analogy of $\widehat{\boldsymbol{\pi}}^{**}$), then

$$p = \mathbf{P}_{\mu_0}(\widehat{\mu}^{**} > \widehat{\mu}) = \mathbf{P}_{\mu_0}(\widehat{\mu}^{**} - \mu_0 > \widehat{\mu} - \mu_0) = \mathbf{P}_{\mu_0}(\mathrm{d}\left(\widehat{\boldsymbol{\mu}}^{**}, \overline{\mathcal{P}}_1\right) > \widehat{\mu} - \mu_0) \,,$$

where $\mathrm{d}\left(\widehat{\boldsymbol{\mu}}^{**}, \overline{\mathcal{P}}_1\right) = \widehat{\mu}^{**} - \mu_0$ for $\widehat{\mu}^{**} > \mu_0$ or 0 otherwise.

The $\alpha_{_E}$ level defined by (17) takes into account the shape of the $\mathcal{P}_1$ area more than the $\alpha_{_F}$ level does, e.g. while $\alpha_{_E} = \alpha_{_F}$ in the case of straight boundary, in the case of strictly convex $\overline{\mathcal{P}}_1$ area it holds $\alpha_{_E} \leq \alpha_{_F}$, as is shown in [5] and also in [1].

There still remains a question: how to compute $\alpha_{_E}$.

5.2 Calculation

The authors of [5] proposed a solution based on bias-corrected percentile confidence intervals, see [3], [4]. Detailed proof can be found in [1].

The technique of calculation is quite complicated, for detailed description see [5] or [1]. It contains two bootstrap resamplings. First one (of size B_1) is the same procedure as estimation of α_F. It serves for the identification of the bootstrap trees $\widehat{\Psi}_b^*$ that do not correspond to $\widehat{\Psi}$. Using those $\widehat{\Psi}_b^*$ the π_0 is estimated by $\widehat{\pi}_0^b$ with precision 2^{-L}. In this case we use $L = 10$ and 14, see tab. 1. The next step is bootstrapping (of size B_2) from $\widehat{\pi}_0^b$ described at (16). Then α_E is estimated:

$$\alpha_E \doteq \Phi\left(\frac{z^{(\alpha_F)} - z_0}{1 + a(z^{(\alpha_F)} - z_0)} - z_0\right), \tag{18}$$

where Φ is the distribution function of N(0,1), $z^{(\alpha_F)} = \Phi^{-1}(\alpha_{_F})$, $z_0 = \Phi^{-1}\Big(\mathbf{P}_{\boldsymbol{\pi}_0}(\widehat{\pi}^{**} \in \mathcal{P}_1)\Big)$ and 'acceleration constant' a is computed during second bootstrap.

6 Results

The branches are numbered increasingly according to the order they are joined by in the Table 1. It can be seen there that α_F is much more stable in changing parametres then α_E. The unstability of α_E could be caused by the small values of B_2 as claims [5]. In [1], there were estimated α_E for dendrogram of 13 objects (of only 73 different components each) using B_1 up to 10000, B_2 up to 200 and the results were stable. With 22 objects (of 566 components each), the computation is very time consuming[1], see Table 1[2].

Besides the description of evolution, there could be another task – to find reasonable clusters of related objects. Figure 1 proposes three clusters: {`19`}, {`6,..., 12`} and {`18, ..., 17`}. If there are more clusters, we continue to divide the largest one. There is a sequence of joining levels which are very close to each other, so the division finally stops on 7 or 8 clusters (the same results come from other hierarchical clustering methods from PCA, too – see [2]). The levels α_F and α_E can help to determine the proper number

[1] calculated on `AMD Duron, 750 MHz, 64 kB Cache, 512 Mb RAM`

[2] the format of time is `h: mm: ss`; the NA value is in fact 6:28:01, but this calculation was not the only process running at that time.

A STATISTICAL DATABASE FOR THE TRADE SECTOR: A PROTOTYPE OF A NEW DATA COLLECTION TOOL

Silvia Biffignandi and Stefano Pisani

Key words: Satellite account for trade, fiscal data, interactive database.

COMPSTAT 2004 section: Official statistics.

Abstract: This paper focuses on the problems arising in the construction of an integrated database which uses administrative financial registers, on the advantages of the database obtained and on its characteristics. To be precise, in this study information coming from two different types of taxes is compared. The first tax is VAT (value added tax), which is applied in a standardized way at European level. The second tax is the Regional Tax on Production (in Italian IRAP), which is a tax applied in Italy. Each source of data is set up with reference to the reasons why tax is applied, therefore each gives a partial description of the internal trade. In order to use the above-mentioned sources for economic analysis, statistical work is required.

1 Introduction

New strategies for the data formation process enable us to obtain large amounts of information, regarding both the kind of phenomena being studied and the sectorial and territorial level of detail.

In addition, the use of administrative data conveniently combined with survey data permits us to obtain a wider coverage of the universe. Innovations in progress and the harmonization of the definitions belonging to the statistical system tend to create the basis for the increasing transparency of the data production process and improved comparability of data originating from different sources.

The data base, presented in this paper (called ECOFISCOM[1]) is aimed at the economic analysis of internal trade, carried out by satellite accounting tool [1], [2], therefore, the administrative archives which retain the information relative to the taxable base and not the tax itself. This taxable base, correctly evaluated, allows us to calculate approximately the typical size of macroeconomies which, given the enormity of the data base used, can be employed for the micro analysis of internal trade.

This paper is organized as follows. Paragraph 2 presents the objectives of the proposed data base and the conceptual framework contained within the information as the need arises, paragraph 3 describes the characteristics of the data base regarding both content in terms of data, indicators, data

[1] This acronym show that the data base aims at the economic analysis of the internal trade using fiscal data (ECOnomic, FISCal, COMmerce database).

processing facilities and information technology aspects. Some concluding remarks (par. 4) summarize the innovative results of the paper and future developments.

2 The conceptual framework

Archive integration needs the creation of a series of information which is coherent and harmonized from various points of view. First of all it is necessary to create a connection between the definitions and the classification of aggregates from different sources of integration.

Regarding the IVA and IRAP archives, this has been done by referring to the definitions in national accounting. These definitions are standardized at an internazional level [6]. and, therefore, the Italian administrative data can be compared with that of other nations. Table 1 outlines the first table comparing the fiscal dimensions and between these and the national accounting aggregates.

The table shows that the two revenues being examined supply a representative picture which is almost complete for the main macro-economical quantities which make up the total of the sources and end uses.

IRAP	**IVA**	**National accounting**
Total Positive Components	Turnover	Production
Total Negative Components	Total purchases and import	Interm. Consumption Import
Value of net production (VPN)	Value Added	Value Added
Labour costs	Labour costs	Labour costs
Redemptions	Redemptions	Redemptions
	Export	Export
	Redeemable goods (purchases and transfer)	Investments

Table 1: Table of connections between financial account definitions and national accounting.

While analysing fiscal data, it is important to bear in mind the limits, it is therefore essential to underline that measurements based on such data are affected by the phenomenon of turnover under-declaration (or costs over-declaration), due to fraud or tax evasion. However, it is possible to achieve useful information that relies on relative assumptions rather than absolute considerations. Observing the fiscal reality constitutes a valid starting point for the formulation of hypotheses on compulsory integrations in order to introduce the so-called “underground economy” issue.

3 The ECOFISCOM database

3.1 Content

One of the characteristic and qualifying aspects of the archive has been the effort made to build up metadata, which allows data stored in the databases to be produced in a conceptual framework which is coherent not only between administrative databases but also with national accountability. This archive of metadata, is mainly made up of an essential reference for the transparency of data and the correct use of data for statistical analysis.

For each of the IVA and IRAP aggregates shown in table 1, in actual fact, both the definitions in fiscal terms as well as the existing relationship with the national accounting system are reported in the metadata database.

When the archive is consulted the results are presented in a standard table which is compared alongside each aggregate IRAP with the corresponding IVA.

For the aggregates which do not correspond to either of the two sides of the table are empty. The analysis deriving from the information which is obtained from two diverse sources, provided the metadata available, enables each user to carry out quality analysis of the data, aimed at understanding if the numerical differences reflect a differing economic meaning from the aggregate or that there is an error in the way that information is collected.

Going over to the analysis of the structure of data files, the illustration of the initial template (figure 1) from the ECOFISCOM data base shows the key questions proffered by the user. These are: economic activity, territory, value chain production. The interrogative key for a sector of economic activities, is articulated in two sectors: in the first a standard European classification is proposed (NACE rev.1), the second supplies a more aggregated version aimed at economic analysis, which is typical of the satellite accountability of internal trade.

This level of aggregation, defined in a Eurostat [4], offers a synthetic representation which allows a complete analysis for both the distribution channels as well as by market sector. Regarding interrogation in the NACE sector, it is interesting to underline the dynamic character of ECOFISCOM, since it is possible to ask the database with a digit ranging from 5 to 1. The data base, in actual fact, is not based on pre-coded tables, but is interfaced with a program which, each time, makes up the result of the information required. Regarding the key to territorial questions, apart from being generated for the whole of Italy, these can be layered by geographical breakdowns (5) and regions (20).

Examining the territorial differences, the potential of the information clearly emerges, deriving from the use of two different tax source data bases: IVA and IRAP. From the first, the location of the company can be recognized while the second, shows the position of local units in the country. The combined analyses of the two archives, gives us a view of the location of where

decisions are made for production units and how these decision making centres deploy local workforces.

An important innovative aspect of ECOFISCOM is the reconstruction of the productive value chain [5]. which is provided as pre-packed output from the database. The value chain approach means, among other things, that the process of price formation can be clarified during the various exchanges which take place from the moment something is produced to its final end use. Particularly, a quantitative comparison can be obtained of the gap which is created between the price of goods leaving the production unit (at production) and the consumer price, which means that the inflationary rate, as it is perceived by the end users, can be evaluated[2]. Within this gap the most influential part is represented by profit margins, in as much that the volume is represented by a buffer which allows the inflationistic tensions to be tightened or loosened as the case may be Biffignandi et al. [2].

3.2 The implementation of information technology and the output characteristics

This database has been developed within an SAS framework applying AF modules for the value chains production for the representation and interrogation of data. The data selected from the statistical basis according to the above mentioned criteria can be extrapolated according to the most common formats (Excel, Dbase, etc).

[2] The two price systems differ for transports, trade margins and VAT, since the three items are all excluded from the production prices; they are included in the consumer prices.

Several standard analyses of the data, with their relative graphic representations, have already been drawn up. In Fig. 2, for example, the value chains production, measured by the aggregates IRAP and IVA are shown, according to the conceptual scheme illustrated in table 1, in other words represented by the positive components of income (IRAP) and the turnover (IVA). The example allows us to further illustrate the informative interest of the fiscal data base. The information relative to each variable can be further broken down according to the following characteristics of the company: location in the country, judicial status, size (expressed in terms of extent of turnover).

As mentioned previously, ECOFISCOM offers the possibilty of analysing the territorial disaggregation of the trade sector. Given the relevance of the information, however, even referring to national data, it is considered useful to include a distinction between companies acting on a regional scale to those present on a larger national scale (pluri-regional).

The judicial status of a company, above all, provides us with further information which is useful for economical analysis, as it brings to light how internal trade is articulated on traditional family values (taxable individuals) or on more complex setups like joint stock companies.

The size aspect is highlighted by distinguishing between economic subjects according to the turnover. In this case, Fig. 2, clearly shows that the Italian distribution system is extremely fractionalized and characterized by an extremely high presence of small companies. For this reason, the lower turnover companies stand out, grouped together into a single open class those companies which present turnovers of over 10 billion lira.

Figure 3 shows the template relative to the value chain production of the product group “Texture and finishing of textiles”. Here, only the IVA database is used since the kind of tax applied lends itself better to the template used. Since IVA is applied at the moment when the sale is carried out, the corresponding base highlights the path goods take from production to when they are sold.

In the template, on the top right hand side, the turnover of the production sector is shown, as distinguished from that part destined for overseas markets and that sold on the Italian market.

The relative data for the economic categories of wholesale exchanges are shown below (code 51561), which are specialized in the sale of the same goods. In this group, purchase data is highlighted for purchase and resale, which represent the goods acquired or the production sector (the upper part of the template) or imported.

These goods can in turn be destined for the domestic market or export markets. The sum of these two components gives us the overall turnover.

On the same line, the information regarding the sales margin is obtained by comparing the turnover with the purchase of goods for resale. This information is of vital importance as it supplies a taxable index offered by a commercial exchange at a wholesale level, influencing prices.

Figure 2: Template of the data base ECOFISCOM of production, measured according to the positive components of income (IRAP data source) and according to turnover (IVA data source).

Subsequently, the same information is illustrated regarding wholesale prices against retail prices. In this case, more than one market sector is represented, given the lower level of specialization of the goods in retail sales as opposed wholesale sales.

For any further information, on request, the territorial disaggregation is available (the last part of the template).

The database therefore provides a logical path which follows a group of products from the production stage to final consumption. Although supplying important information, the following path discounts certain levels of simplification which, at the present state of information, do not seem to be able to be solved. In the first place, no information exists which allows the first question to be answered "who sells to who?". In other words, we do not know how much of the production in the textile sector is sold to wholesalers and how much is destined for the retail sector.

Another limitation is due to the presence of un-specialized commercial sales networks. This is not actually shown in the template, since due to the high supply in the sector which characterizes it, it is not easily attributable to any specific group of products. This failing can be partially completed in future by integrating fiscal data with the data from the Italian Statistical Institute through a check on sales[3].

[3] Methodological aspects are presented in Biffignandi et al. [3].

Figure 3: Template of the data base ECOFISCOM for the value chain of the group of products: Texture and finishing of textiles

4 Concluding remarks

The ECOFISCOM data base is presented in this paper, which is based on administrative data (fiscal), which has allowed more specific analysis to be generated.

The information is presented following a satellite accountability approach and grants a micro reading of the structural characteristics of internal trade. Regarding studies carried out on the variable definitions, these microanalyses can be linked to the macro approach of national accounting.

The database structure has been developed in an SAS environment, with the application of AF modules for the construction of visual templates and data interrogation. It is important to underline the development of information technology in a user friendly environment, with the creation of innovative contents (such as value chains) and output containing indicators which are useful from an economic point of view (such as the calculation of sales margins). The data base allows key questions to be asked by sector, by territorial areas and by value chain; it is also possible to obtain information of a judicial nature, the territorial spread and the size of the company. Given the perfect comparability of ECOFISCOM with the common software (such as Excel, Dbase, etc.), this tool can also be used to create personalized databases which can supply data to other software applications.

ECOFISCOM is a dynamic database based on data taken from IVA and IRAP tax returns which are drawn from the economic activities, from the country and production bases.

One aspect of the value added to the product which must not be overlooked is the application of metadata associated with it, which allows the informative content to be unquestionably singled out of each variable and to compare this content with international standardized definitions (given by the national accounts).

The database, in its present form, can be accessed only in an SAS form; in future it will be able to be consulted on the web; a version with selected tables may be available on CD-Rom. A further planned development is the widening of the database through its integration with data made available from surveys.

LOCALIZED LOGISTIC CLASSIFICATION WITH VARIABLE SELECTION

Harald Binder and Gerhard Tutz

Key words: Local logistic regression, discrimination, data adaptive tuning parameters, selection of predictors, localized discrimination.

COMPSTAT 2004 section: Classification.

Abstract: The main problem with localized discriminant techniques is the curse of dimensionality, which seems to restrict their use to the case of few variables. In the present paper logistic discrimination is used locally and combined with local variable selection. A robust localized logistic regression method is developed for which all tuning parameters are chosen data-adaptively. The procedure allows to use higher numbers of variables with discrimination performance that is comparable to the best available classifiers. The performance is evaluated in simulation studies and by using real data sets and compared to various alternative procedures such as linear discriminant analysis, nearest neighbourhood classifiers, trees, random forests and variants of boosting.

1 Introduction

In recent years the local fitting of parametric models has become a powerful tool in nonparametric regression, see e.g. Fan & Gijbels [4], Loader [10]. Local binary regression may reveal how covariates determine the binary response. When used in classification problems the decision boundaries are smooth functions instead of hyperplanes as is the case in simple logistic discrimination. A drawback of the method which carries over to the classification problems is the restriction to the low dimensional case. For example Loader [10] applied localized logistic discrimination techniques to cases with two and four variables. The approach presented here deals with the problem of higher dimensions by combining localization with local dimension reduction by localized variable selection.

In a first localization step parameter estimation for the logistic regression model is obtained by maximizing weighted likelihood where the weights are based on Euclidian distances between the observations from the training set and the target value for which prediction is wanted. In a second step we use a simple simultaneous variable selection procedure. In the reduced space of the selected variables the distance-based weights are recalculated and estimation is repeated to obtain the final model for prediction.

This classification approach is observation specific in the sense that a new classifier is computed for each new observation. The same holds for example for nearest neighbourhood classifiers in contrast to procedures like linear or quadratic discrimination where the classification rule is computed once by estimating parameters. Procedures such as linear discrimination may be seen as global approaches.

Alternative approaches to local dimension reduction have been given by Schaal et al. [13], Hastie et al. [6]. In contrast to these approaches variable selection has the advantage that one obtains information about the relevance of variables even if the selection is performed locally. In statistical applications the user is often interested which variables are relevant and have to be collected in the future.

2 Localized logistic discrimination

Let the observations be given by (x_i, y_i), $i = 1, \ldots, n_L$, for $x_i' = (x_{i1}, \ldots, x_{ip})$ being a p-variate predictor variable and $y_i \in \{0, 1\}$ the class indicator. The objective is to predict y for a new observation for which only x is observed. In the following only the case of two classes is considered although the extension to the k class situation is straightforward.

Localized logistic discrimination is based on the fitting of the model

$$\log\left\{\frac{P(y_i = 1|x_i)}{1 - P(y_i = 1|x_i)}\right\} = z_i'\beta$$

where β is a parameter vector of length $m + 1$ and z_i is a design vector built from x_i. For linear logistic discrimination $z_i' = (1, x_i')$ and for quadratic logistic discrimination $z_i' = (1, x_i', x_{i1}^2, \ldots, x_{ip}^2)$ is used.

The model is fitted locally by using weights within the (log-)likelihood. For target value x the weighted log-likelihood is given by

$$l_x(\beta) = \sum_i \left(y_i \log \pi(x_i) + (1 - y_i)\log(1 - \pi(x_i))\right) w_k(z, z_i) \tag{1}$$

where $\pi(x_i) = P(y_i = 1|x_i)$ and z, z_i are the predictor values connected to x, x_i, i.e. $z' = (1, x')$, $z_i = (1, x_i')$ in the linear case and $z' = (1, x', x_1^2, \ldots, x_p^2)$, $z_i' = (1, x_i', x_{i1}^2, \ldots, x_{ip}^2)$ in the quadratic case. By using a loess type localization the locally adaptive weights $w_k(z, z_i)$ are chosen to depend on the (Euclidian) distance between the (transformed) target value z and the (transformed) observation z_i and a kernel window

$$w_k(z, z_i) = K\left(\frac{||z - z_i||}{\lambda(z)}\right) \tag{2}$$

where the kernel width parameter $\lambda(z)$ is chosen as the distance to the kth nearest neighbour $z_{(k)}$ of z, i.e. $\lambda(z) = ||z - z_{(k)}||$. Various kernel functions K can be used. For our investigations we used the tricube kernel which has the computational advantage that in estimation only points in the neighbourhood are included since all other points receive weight zero.

Parameter estimation is performed by solving the local score equation $s_{x,k}(\beta) = 0$ by iterative Fisher scoring of the form

$$\hat{\beta}_x^{(s+1)} = \hat{\beta}_x^{(s)} + F_{x,k}(\hat{\beta}_x^{(s)})^{-1} s_{x,k}(\hat{\beta}_x^{(s)}) \tag{3}$$

where $s_{x,k}(\beta) = \partial l_x/\partial\beta$ is the local score function which for the logistic model has the simple form

$$s_{x,k}(\beta) = \sum_i w_k(z, z_i) z_i (y_i - \pi_i(\beta))$$

with $\pi_i(\beta)$ denoting the response probability evaluated at β and $F_{x,k} = E(-\partial^2 l_x/\partial\beta\partial\beta')$ denoting the weighted Fisher matrix

$$F_{x,k} = \sum_i w_k(z, z_i) z_i z_i' \frac{\partial h(\eta_i)}{\partial\eta}$$

with $\eta_i = z_i'\beta$ and $h(x) = \exp(x)/(1 + \exp(x))$ being the response function of the logistic regression model. The dependence of the parameter estimates on the target value shows in the notation $\hat\beta_x$. For the asymptotic behaviour of local estimates see Fan and Gijbels [4].

3 Local variable selection

In addition to localizing the logistic model the variables which are used for discrimination are locally selected. The underlying assumption is that not all predictors are equally informative on class membership throughout the space spanned by all predictors.

For computational efficiency a one-step selection procedure is used that determines the relevance of predictors by a simple variant of Wald tests. For the local estimates $\hat\beta_x$ at target value x the variance may be approximated by $\hat{\text{cov}}(\hat\beta_x) = F_{x,k}(\hat\beta_x)^{-1}$ (see [8]). Based on the approximation variables are selected by considering the studentized value

$$c_{x,k}(\hat\beta_{x,j}) = \frac{|\hat\beta_{x,j}|}{\sqrt{\hat{\text{var}}(\hat\beta_{x,j})}} \quad , \ j = 1, \ldots, m,$$

where $\beta_x' = (\beta_{x,0}, \beta_{x,1}, \ldots, \beta_{x,m})$. In a single step those predictors are selected for which $c_{x,k}(\hat\beta_j)$ exceeds a threshold c_β. $c_{x,k}(\hat\beta)$ is a localized version of the Wald statistic for testing the null hypothesis $\beta_j = 0$ locally. In the case of linear logistic discrimination where z_i is given by $(1, x_{i1}, \ldots, x_{ip})$ predictor selection refers to the original variables $x_1, \ldots, x_p$ whereas in quadratic logistic discrimination where z_i is given by $(1, x_{i1}, \ldots, x_{ip}, x_{i1}^2, \ldots, x_{ip}^2)$ predictor selection refers to the extended set of variables $x_1, \ldots, x_p, x_1^2, \ldots, x_p^2$.

When the number of predictors has been reduced the weights $w(z, z_i)$ are recalculated for the subspace spanned by the selected predictors and the estimation is performed for the reduced β-vector of the final local model. Prediction for target value x then is based on the reduced and re-estimated model.

In order to avoid instabilities of the estimation procedure it is useful to use some robustified estimator for β_x. We consider a penalized estimator (e.g. Le Cessie & Van Houwelingen [9]) by using the weighted log-likelihood

$$l(\beta) = \sum_i \left(y_i \log \pi(x_i) + (1 - y_i) \log(1 - \pi(x_i))\right) w_k(z, z_i) - \lambda \beta' P \beta. \tag{4}$$

where P is the penalization matrix and λ determines the strength of the penalization. Setting λ to 0 would result in the unpenalized likelihood (1). For the penalty matrix P a simple identity-matrix is used. This leads to a penalization of β_j^2 and is similar to logistic ridge regression [9].

The modifed expression for the penalized weighted local score function and Fisher matrix are

$$s_{x,k}(\beta) = \sum_i w_k(z, z_i) z_i (y_i - \pi_i(\beta)) - 2\lambda P \beta$$

and

$$F_{x,k} = \sum_i w_k(z, z_i) z_i z_i' + 2\lambda P.$$

Special attention has to be given to the intercept parameter β_0. All predictors are centered and standardized in a weighted way and the intercept is kept fixed at the value of the transformed local class membership proportion.

The performance of the algorithm depends on some parameters which have to be chosen. These are: 1. the order k of the nearest neighbourhood used in (2); 2. the threshold c_β which determines how many variables are selected locally; 3. the tuning parameter λ which determines the strength of penalization.

In order to obtain a fully data-adaptive procedure these tuning parameters are chosen by cross-validation. The cross-validation criterion is given by the prediction error rate. Optimization is based on a recently proposed procedure that uses quadratic approximations (see [12]).

4 Simulation study

The simulation study compares the performance of various classification procedures for various types of data structures. The investigated classification procedures are localized logistic regression with variable selection (LLD), linear discriminant analysis (LDA), single-hidden-layer neural networks with five units in the hidden layer and committee voting (NNet), 10-nearest-neighbourhood classification (10-NN), cross-validated classification trees (Tree) and random forests (see [2]). The implementations used are those from the statistical environment R [7] and we used the standard settings for all procedures. The investigated data structures are based on the structure suggested by Friedman [5] and Hastie and Tibshirani [6] denoted by 'Fx' and 'HTx' where 'x' is the number of the example in the respective articles. The size of

Table 1: Mean error rates for different simulated data examples and classification procedures.

the learning data was 200 and the number of observations in the test data was 1000 when not stated otherwise. In both data sets the frequencies of the true classes have been chosen to be equal. The results are based on 50 replications for each example. Table 1 gives the mean error rates for all procedures and all examples.

In example HT1 two covariates are drawn from normal distributions with non-zero covariance and different means for the two classes. Linear discriminant analysis (LDA) is seen to have the best performance. This does not come as a surprise because the decision boundary is a straight line and can be matched very well by LDA. Localized logistic regression (LLD) is similar to LDA in performance. This similarity is also releflected in the selection of large values of k. When 14 noise variables are added (HT2) the performance of LLD degrades but not as much as that of 10-nearest-neighbourhood. It still performs better than tree-based methods.

In examples F1 and F2 the amount of information provided by the variables is systematically varied. For both classes the covariates are drawn from a 10-dimensional normal distribution. For one of the two classes the mean and the variance depend on the variable index. In example F1 the covariates with the higher index j are intended to be more relevant. The good performance of procedures using linear combinations of predictors (LLD, LDA and neural networks) indicates that the Bayes decisions boundary can be approximated very well by hyperplanes. In the second example (F2) the mean structure of the second class is changed in that the variables with lower index contain more relevant information on class membership due to the mean and the variables with higher index due to the variance. Again a hyperplane approximation of the Bayes decision boundary seems to be efficient.

In example F5 the class boundary is defined by a linear combination of ten covariates. The procedures that utilize a linear combination of predictors clearly have the best performance (with LLD among them). With a quadratic combination of covariates and training sample size of $n_L = 500$ and $n_T = 1000$ (F4) the performance of the linear procedures LDA and neural networks degrades. LLD shows good performance performance, with only random forests being better. When a weighted contribution of the variables is used (F3) the performance of linear LLD degrades to the level of neural networks. This indicates that the class boundary is too complicated to be approximated very well by local linear models.

In the examples HT5 there are four covariates drawn from standard normal distributions that define a spherical class region augmented with a varying number of noise variables. When no noise is present LLD performs very well here. When adding six noise variables the performance of LLD decreases relative to procedures like random forest and decreases even more with 16 noise variables.

In the two examples with extremely fractioned class regions (HT3 and HT4) the distribution of each of the two classes is defined as a mixture of six spherical bivariate normal subclasses with extremely scattered means. There are 20 observations drawn from the distribution of each subclass and so there are 140 observations per class with a total of $n_L = 240$ observations ($n_T = 960$). With no noise (HT3) all procedures (except LDA) perform very similar on this data. When we augmented the two variables carrying information on class membership with eight noise covariates (HT4) the performance of LLD degrades compared to the partition-based classification tree and random forest procedures. The latter procedures seem to perform very well in seperating informative variables from noise variables.

4.1 Summary of simulation results

It is seen that for different situations different classification methods turn out to be the best choice, but some procedures react more flexibly to varying data structures. Given that it cannot be expected that one method is superior in all data situations LLD performs rather well on a variety of different data structures.

LLD shows better performance than LDA and the 10-nearest neighbourhood approach in almost all examples. Neural networks as used here perform distinctly better only in two examples, despite the fact that in contrast to LLD they can model interactions of covariates directly. The same holds for simple trees. For data with fractioned class structure with noise variables tree-based approaches perform very well in particular if noise variables are included. Although LLD performs better without noise variables it is outperformed if much noise is present. Advanced tree methodology as present in random forests clearly performs best in this case.

* from Bühlmann and Yu [3]

Table 2: Error rates for real data and various classification procedures. The numbers are mean error rates for 50 random splits into a 90% training and 10% test set.

5 Application to real data

We use the Australian credit data from the Statlog project [11] and the breast cancer and the sonar data from the UCI machine learning repository [1]. One reason for this selection of data sets is that they have been used in recent work on boosting methods [3] and so information on error rates is available for a class of procedures that is considered to perform very well.

Each data set has been split 50 times randomly into a 90% training and 10% test set and all procedures used in the simulation study have been applied. Table 2 shows the error rates for the three data sets and all procedures used in the simulation study. In addition the error rates for several boosting procedures as given in Bühlmann and Yu [3] are shown.

For the Australian credit data 10-nearest neighbourhood classification rules yield very bad performance while the rest of the procedures are well comparable. For the breast cancer example LLD, 10-nearest neighbourhood classification and random forests distinctly outperform the rest. For the sonar data LLD is distinctly the best performer. As is seen LLD performs well for all three data sets.

6 Concluding remarks

A localized discrimination procedure has been proposed which in combination with local selection of predictors shows promising results, that might be even improved by different parameter selection schemes. Although a method cannot be expected to be best for all potential data structures the performance is surprisingly good over a wide range of data structures. While it outperforms advanced tree methodology for simple structures, the latter dominate at least a linear version for quadratically separated classes with many noise variables. For real data sets, the localizing methodology works very well with the best performance for two of the considered data sets. This shows the high potential in statistical applications.

NEW STAR MODELS OF TIME SERIES AND THEIR APPLICATION IN FINANCE

Tomáš Bognár, Jozef Komorník and Magda Komorníková

Key words: Time series, regime-switching autoregressive models, transition functions.

COMPSTAT 2004 section: Time series analysis.

Abstract: A new class PSTAR of Smooth Transition Autoregressive models, based on cubic spline type transition functions, has been recently introduced in [1] subjected to comparation with LSTAR models based on the traditional logistic functions. A very high degree of similarity between both classes of models has been demonstrated. PSTAR models can be slightly preferable because of their more simple formal and geometrical structure that may enable users more convenient manipulation in statistical inference procedures.

In this paper, a general approach to construction of STAR models that covers both PSTAR and LSTAR classes is suggested.

An interesting application to modeling exchange rates time series, where the threshold variable has delay 5 (corresponding to the number of business days in 1 week), has been found.

1 Introduction

Smooth transition autoregressive models (STAR) have been extensively analyzed and applied by many authors during the last two decades. They have been introduced in [3] as a smooth alternative to Treshold Autoregressive models (representing nonlinear generalizations of autoregressive models) that assume different autoregressive models describing behaviour of an investigated time series y_t in different regimes. Many interesting applications of STAR and other nonlinear models have been presented in [2].

2 New STAR models

A formal representation of a 2-regimes STAR can be expressed by

$$y_t = \Phi_1(B) y_t [1 - G(y_{t-d}; \gamma, c)] + \Phi_2(B) y_t G(y_{t-d}; \gamma, c) + \epsilon_t \qquad (1)$$

(see [4]), where

ϵ_t is a white noise sequence with variance σ^2,

the autoregressive polynomials

$$\Phi_i(B) = \phi_{i,0} + \phi_{i,1} B + \cdots + \phi_{i,p_i} B^{p_i}, \qquad i = 1, 2$$

in the shift operator B (defined by $By_t = y_{t-1}$) are related to regimes that are determined by values of a threshold variable y_{t-d} and its treshold level value c.

The original LSTAR models proposed in [3], [4] are based on the logistic transition function.

A logistic transition function has the form

$$G(y_{t-d}; \gamma, c) = \frac{1}{1 + \exp(-\gamma[y_{t-d} - c])} \tag{2}$$

where γ is the smoothness parameter.

It is obvious that $G(c; \gamma, c) = \frac{1}{2}$ and $G(y; 0, c) = \frac{1}{2}$ for any $y, c \in R$ and $\gamma \geq 0$.
If we put $q_t = y_{t-d} - c$
and

$$\begin{aligned} G^*(q; \gamma) &= G(c + q; \gamma, c) - \frac{1}{2} = \frac{1}{1 + \exp(-q\gamma)} - \frac{1}{2} = & (3) \\ & & (4) \\ &= \frac{1 - \exp(-q\gamma)}{2(1 + \exp(-q\gamma))} = \frac{1}{2}\text{tgh}(-q\gamma) & (5) \end{aligned}$$

we can rewrite (1) in the form (see [2])

$$y_t = \frac{1}{2}[\Phi_1(B) + \Phi_2(B)]y_t + [\Phi_2(B) - \Phi_1(B)]y_t G^*(q_t; \gamma) + \epsilon_t \tag{6}$$

which can be applied for testing linearity of the model (the hypothesis $\Phi_1(B) = \Phi_2(B)$ which is equivalent to the hypothesis $H_0 : \gamma = 0$ in (3)). For this test, the following third-order Taylor polynomial approximation to $G^*(q; \gamma)$ in the right neighborhood of $\gamma = 0$ was utilized in [2] (where an error in the sign of the third-order term occurred).

For any $\gamma > 0$, G^* as a function of q is convex for $q < 0$ and concave for $q > 0$, thus the partial derivative $\frac{\partial G^*(q;\gamma)}{\partial q}$ attains its maxima $\frac{\gamma}{4}$ for $q = 0$:

$$T_3(q, \gamma) = \gamma \left[\frac{\partial G^*(q; \gamma)}{\partial \gamma}\right]_{\gamma=0} + \frac{1}{6}\gamma^3 \left[\frac{\partial^3 G^*(q; \gamma)}{\partial \gamma^3}\right]_{\gamma=0} = \frac{1}{4}\gamma q - \frac{1}{48}\gamma^3 q^3 \tag{7}$$

Note that $T_3(q, \gamma)$ as well as G^* and G are symmetric in the pair of variables q and γ since they depend only on the product $x = q\gamma$.

For a new STAR model, we can deal with any even non-decreasing smooth surjective function

$$\mathcal{G} : [-\infty, +\infty] \to \left[-\frac{1}{2}, \frac{1}{2}\right]$$

which will be called a *shape function.*

For $\gamma \geq 0$ we will so deal with

$$H^*(q;\gamma) = g(\gamma.q).$$

Then our transition function is given by

$$H(y_{t-d};\gamma;c) = g(\gamma.(y_{t-d} - c)) + \frac{1}{2}$$

Typical examples of shape functions are:

$$g(x) = \frac{1}{\pi} \text{ arctg } \text{ x};$$

$$g(x) = \begin{cases} -\frac{1}{2} & \text{if } x < -\frac{1}{\sqrt{2}} \\ (x + \frac{1}{\sqrt{2}})^2 - \frac{1}{2} & \text{if } -\frac{1}{\sqrt{2}} \leq x < 0 \\ -(x - \frac{1}{\sqrt{2}})^2 + \frac{1}{2} & \text{if } 0 \leq x \leq \frac{1}{\sqrt{2}} \\ \frac{1}{2} & \text{if } x > \frac{1}{\sqrt{2}} \end{cases} \quad \text{(quadratic spline);}$$

$$g(x) = \begin{cases} -\frac{1}{2} & \text{if } x < -\frac{\pi}{2} \\ \frac{1}{2} sin \text{ x} & \text{if } -\frac{\pi}{2} \leq x \leq \frac{\pi}{2} \\ \frac{1}{2} & \text{if } x > \frac{\pi}{2} \end{cases}$$

In [1] a third-order spline shape function P^* has been introduced

$$g(x) = \text{ min } \left(\frac{1}{2}, \text{ max } \left(-\frac{1}{2}, \frac{1}{4}x - \frac{1}{108}x^3 \right) \right).$$

Then

$$P^*(q,\gamma) = \begin{cases} -\frac{1}{2} & q < -\frac{3}{\gamma} \\ \frac{1}{4}q\gamma - \frac{1}{108}q^3\gamma^3 & -\frac{3}{\gamma} \leq q \leq \frac{3}{\gamma} \\ \frac{1}{2} & q > \frac{3}{\gamma} \end{cases} \tag{8}$$

Each shape function H^* has the following properties:

a)

$$H^*(0,\gamma) = 0 \qquad \text{for any } \gamma > 0.$$

b)

$$H^*(q,\gamma) + H^*(-q,\gamma) = 0 \qquad \text{for any } q \in R \text{ and } \gamma > 0.$$

c)

$$\frac{\partial H^*(q;\gamma)}{\partial q} > 0 \qquad \text{for all } q \in R \text{ and } \gamma > 0.$$

d) For any $\gamma > 0$

$$\lim_{q\to\infty} H^*(q;\gamma) = \frac{1}{2} \qquad \text{and} \qquad \lim_{q\to-\infty} H^*(q;\gamma) = -\frac{1}{2}.$$

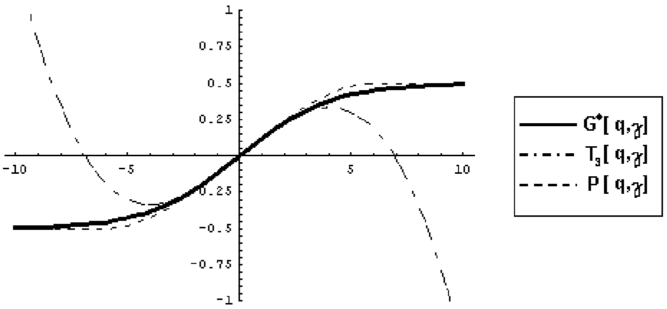

Figure 1: $\gamma = 0.5$

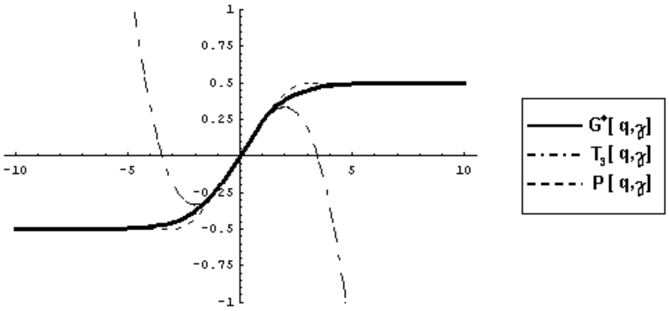

Figure 2: $\gamma = 1$

e) For any $q > 0$, $H^*(q;\gamma)$ is nondecreasing in γ,

$$\lim_{\gamma\to\infty} H^*(q;\gamma) = \frac{1}{2} \qquad \text{and} \qquad \lim_{\gamma\to-\infty} H^*(-q;\gamma) = -\frac{1}{2}.$$

f) For any $q \in R$

$$\lim_{\gamma\to 0} H^*(q;\gamma) = 0.$$

In case of cubic splines, we can see in the Figures 1-3, the polynomials $P^*(q,\gamma)$ provide much better global approximations to $G^*(q,\gamma)$ than $T_3(q,\gamma)$.

Moreover, the function $P^*(q,\gamma)$ is identical with its third-order Taylor polynomial approximation in the right neighborhood of $\gamma > 0$ for $|q| < \gamma^{-1}$ which guarantees higher precision of the same test of linearity that has been applied for logistic models.

Moreover

$$\frac{\partial G^*(0;\gamma)}{\partial\gamma} = \frac{\partial P^*(0;\gamma)}{\partial\gamma} = \frac{\gamma}{4}$$

Inspecting behaviour of the difference $\frac{\partial P^*(q;\gamma)}{\partial\gamma} - \frac{\partial G^*(q;\gamma)}{\partial\gamma}$ we conclude that for any $\gamma > 0$ the difference $P^*(q,\gamma) - G^*(q,\gamma)$ is positive for $q > 0$, increasing on

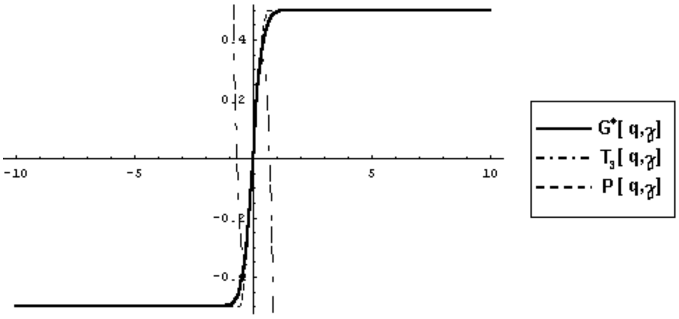

Figure 3: $\gamma = 5$

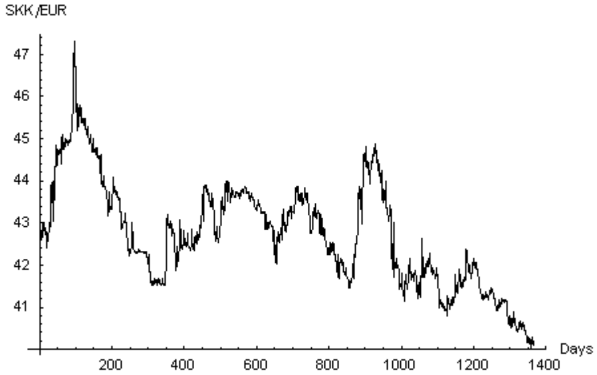

Figure 4: The time series daily exchange rates of Slovak Crown to Euro.

the interval $(0, q_0)$, where $q_0 \approx \frac{2.58}{\gamma}$, and decreasing on (q_0, ∞). The maximal difference $P^*(q_0, \gamma) - G^*(q_0, \gamma) \approx 0.056$ independently on γ.

Similarly we can obtain that the difference $G^*(q, \gamma) - T_3(q, \gamma)$ is positive for any $\gamma > 0, q > 0$.
$T_3(q, \gamma)$ is better approximation to $G^*(q, \gamma)$ than $P^*(q, \gamma)$ on the interval $(0, q_1)$, where $q_1 \approx \frac{1.966}{\gamma}$ and $G^*(q_1, \gamma) - T_3(q_1, \gamma) = P^*(q_1, \gamma) - G^*(q_1, \gamma) \approx 0.044$ independently on γ.

The maximum of differences $[(P^*(q, \gamma) - G^*(q, \gamma)) - (G^*(q, \gamma) - T_3(q, \gamma)]$ is obtained in $q = q_2 \approx \frac{1.482}{\gamma}$ and its value is 0.013 independently on γ.

3 Application

We have investigated the time series daily exchange rates of Slovak Crown to Euro in the period January 1, 1999 - April 22, 2004 (see Figure 4).

The partial autocorrelation function for this time series (see Figure 5)

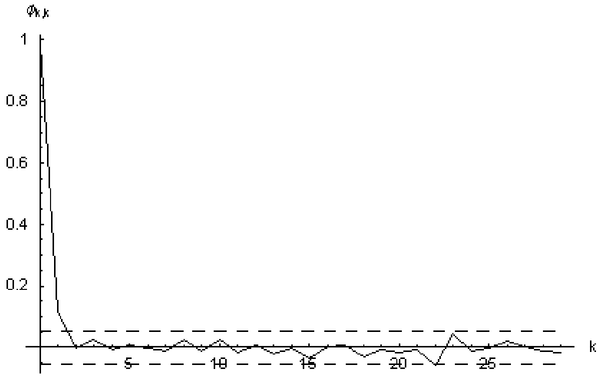

Figure 5: Partial autocorrelation function for time series daily exchange rates of Slovak Crown to Euro.

Table 1: Test of nonlinearity for AR(2).

suggests that in the class of linear AR(p) models are preferable low order models. Stepwise tests of AR(p) agains submodels AR(p-1) showed that the optimal AR(p) model is AR(2).

Further we continued by investigating 2-regimes models of the class AR(2) with threshold variables y_{t-d} for d = 1, 2, 3, 4, 5, 6. We applied tests of nonlinearity (see [2] based on the Taylor polynomial approximation mentioned above. From the Table 1 we conclude that only for d = 5 the linear model can be rejected against the general nonlinearity hypothesis.

These results can be related to the fact that there are typically 5 working days in a week and Mondays' and Fridays' trading may exhibit certain specific features.

The following Table 2 sumarizes the results of computations for different LSTAR and PSTAR models with threshold variable y_{t-5}.

We see that for all pairs (p1, p2) PSTAR models provide slightly better fit than their LSTAR alternatives. However the value of coefficients of corresponding PSTAR and LSTAR models are very similar and differences in

PSTAR	(3, 3)	42	15,5	{0.384, 0.966, 0.009, 0.015}	{0.463, 0.811, 0.190, -0.011}	0.15886

Table 2: The results of computations for different LSTAR and PSTAR models with threshold variable y_{t-5}.

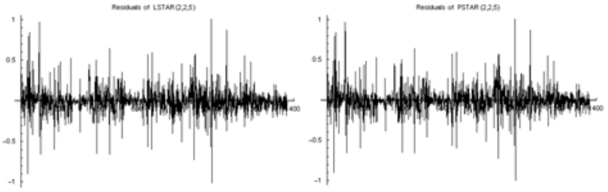

Figure 6: Residuals of LSTAR and PSTAR models.

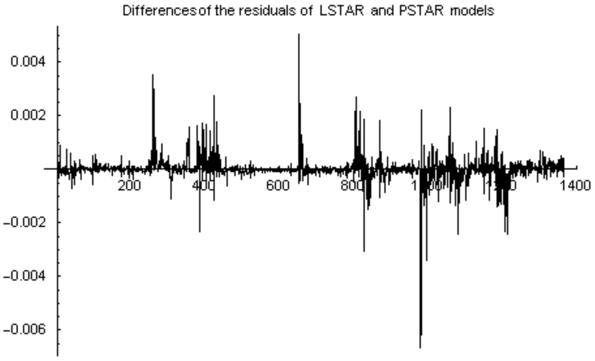

Figure 7: Differences of the residuals of LSTAR and PSTAR models.

their residual variances are small. The best fit is obtained for the model of the class PSTAR(2,2). A surprising phenomenon that higher order models do not provide lower values of estimates of residual variance can be explained by the fact that higher order models deal with smaller number of residulas. Note that the scale for differences of the residulas of optimal PSTAR(2, 2) and LSTAR(2, 2) is smaller by almost three orders than the ones for these residuals (see Figures 6 and 7).

COMPSTAT'2004 Symposium

THE TRADE-OFF BETWEEN GENERATIVE AND DISCRIMINATIVE CLASSIFIERS

Guillaume Bouchard and Bill Triggs

Key words: Statistical computing, numerical algorithms.

COMPSTAT 2004 section: Classification.

Abstract: Given any generative classifier based on an inexact density model, we can define a discriminative counterpart that reduces its asymptotic error rate. We introduce a family of classifiers that interpolate the two approaches, thus providing a new way to compare them and giving an estimation procedure whose classification performance is well balanced between the bias of generative classifiers and the variance of discriminative ones. We show that an intermediate trade-off between the two strategies is often preferable, both theoretically and in experiments on real data.

1 Introduction

In supervised classification, inputs x and their labels y arise from an unknown joint probability $p(x, y)$. If we can approximate $p(x, y)$ using a parametric family of models $\mathcal{G} = \{p_\theta(x, y), \theta \in \Theta\}$, then a natural classifier is obtained by first estimating the class-conditional densities, then classifying each new data point to the class with highest posterior probability. This approach is called *generative* classification.

However, if the overall goal is to find the classification rule with the smallest error rate, this depends only on the conditional density $p(y|x)$. *Discriminative* methods directly model the conditional distribution, without assuming anything about the input distribution $p(x)$. Well known generative-discriminative pairs include Linear Discriminant Analysis (LDA) vs. Linear logistic regression and naive Bayes vs. Generalized Additive Models (GAM). Many authors have already studied these models e.g. [3], [4]. Under the assumption that the underlying distributions are Gaussian with equal covariances, it is known that LDA requires less data than its discriminative counterpart, linear logistic regression [2]. More generally, it is known that generative classifiers have a smaller variance than.

Conversely, the generative approach converges to the best model for the joint distribution $p(x, y)$ but the resulting conditional density is usually a biased classifier unless its $p_\theta(x)$ part is an accurate model for $p(x)$. In real world problems the assumed generative model is rarely exact, and asymptotically, a discriminative classifier should typically be preferred [6], [3]. The key argument is that the discriminative estimator converges to the conditional density that minimizes the negative log-likelihood classification loss against the true density $p(x, y)$ [1]. For finite sample sizes, there is a bias-variance tradeoff and it is less obvious how to choose between generative and discriminative classifiers.

In this paper, we will first consider the parameter estimation problem, focusing on the theoretical distinction between generative and discriminative classifiers. Then we propose a new technique for combining the two classifiers: the Generative-Discriminative Trade-off (GDT) estimate. It is based on a continuous class of cost functions that interpolate smoothly between the generative strategy and the discriminative one. Our method assumes a joint density based parametrization $p_\theta(x, y)$, but uses this to model the conditional density $p(x|y)$. The goal is to find the parameters that maximize classification performance on the underlying population, but we do this by defining a cost function that is intermediate between the joint and the conditional log-likelihoods and optimizing this on training and validation sets.

Given that the generative model based on maximum likelihood (ML) produces minimum variance — but possibly biased — parameter estimates, while the discriminative one gives the best asymptotic classification performance, there are good reasons for thinking that an intermediate method such as the GDT estimate should be preferred. We illustrate this on simulations and on real datasets.

2 Preliminaries

Using independent training samples $\{x_i, y_i\}, i = 1, \ldots, n$, $x_i \in \mathbb{R}^d$,and $y_i \in \{1, \ldots, K\}$ sampled from the unknown distribution $p(x, y)$, we aim to find the rule that gives the lowest error rate on new data. This is closely related to estimating the conditional probability $p(y|x)$.

For each of the K classes, the class-conditional probability $p(x|y = k)$ is modeled by a parametric model f_k with parameters θ_k. The y follows a multinomial distribution with parameters $p_1, \ldots, p_K$. The full parametrization of the joint density is $\theta = (p_1, \ldots, p_K, \theta_1, \ldots, \theta_K)$. Given θ, new data points x are classified to the group k giving the highest posterior probability

$$P_\theta(Y = k|X = x) = \frac{p_k f_k(x; \theta_k)}{\sum_{l=1}^{K} p_l f_l(x_i; \theta_l)}. \tag{1}$$

The generative and the discriminative approaches differ only in the estimation of θ.

Generative classifier. Given data $\{x_i, y_i\}$, $i = 1, \ldots, n$, a standard way to estimate the parameters of densities is the Maximum Likelihood (ML) estimate (we assume that the solution is unique):

$$\hat{\theta}_{GEN} = \arg\max_{\theta \in \Theta} \mathcal{L}_{GEN}(\theta), \qquad \mathcal{L}_{GEN}(\theta) = \textstyle\sum_{i=1}^{n} \log p_{y_i} f_{y_i}(x_i; \theta). \tag{2}$$

Discriminative classifier. Let $\mathcal{D} = \{p_\theta(y|x) = p_\theta(x,y)/\sum_z p_\theta(x,z), \theta \in \Theta\}$ be the set of conditional densities derived from the generative model. Our aim is to find the conditional density in $\mathcal{D}$ that minimizes a classification loss function on the training set. Here, we consider only the negative conditional log-likelihood $-\mathcal{L}_{DISC}$, which can be viewed as a convex approximation to the error rate:

$$\hat{\theta}_{DISC} = \arg\max_{\theta\in\Theta} \mathcal{L}_{DISC}(\theta), \qquad \mathcal{L}_{DISC}(\theta) = \sum_{i=1}^n \log \frac{p_{y_i} f_{y_i}(x_i;\theta)}{\sum_k p_k f_k(x_i;\theta)}. \tag{3}$$

The discriminative approach allows to eliminate parameters that influence only $p(x)$,not $p(y|x)$ (e.g. shared covariance matrix in Gaussian distributions), leading to logistic regression over lower dimensional parameter spaces. However, we will not use this reduction, as we need to maintain a common parametrization for the discriminative and generative cases. thus, the solution (3) of the discriminative classifier may not be unique — there may exist infinitely many parameters that give the same conditional distribution $p_\theta(x|y)$. However, the classification performance is the same for all such solutions.

Relationship. The quantity $\mathcal{L}_{DISC}$ can be expanded as follows:

$$\mathcal{L}_{DISC}(\theta) = \underbrace{\sum_{i=1}^n \log p_{y_i} f_{y_i}(x_i;\theta)}_{\mathcal{L}_{GEN}(\theta)} - \underbrace{\sum_{i=1}^n \log \sum_{k=1}^K p_k f_k(x_i;\theta)}_{\mathcal{L}_x(\theta)} \tag{4}$$

The difference between the generative and discriminative objective functions $\mathcal{L}_{GEN}$ and $\mathcal{L}_{DISC}$ is thus $\sum_{i=1}^n \sum_k \log p_\theta(x_i,k)$, the log-likelihood of the input space probability model $p_\theta(x)$. Equation (4) shows that compared to the discriminative approach, the generative strategy tends to favor parameters that give high likelihood on the training data.

3 Between generative and discriminative classifiers

To get a natural trade-off between the two approaches, we can introduce a new objective function $\mathcal{L}_\lambda$ based on a parameter $\lambda \in [0,1]$ that interpolates continuously between the discriminative and generative objective functions:

$$\begin{aligned} \mathcal{L}_\lambda(\theta;\boldsymbol{x},\boldsymbol{y}) &= \mathcal{L}_{GEN}(\theta;\boldsymbol{x},\boldsymbol{y}) - (1-\lambda)\mathcal{L}_x(\theta;\boldsymbol{x}) \qquad (5)\\ &= \lambda\mathcal{L}_{GEN}(\theta) + (1-\lambda)\mathcal{L}_{DISC}(\theta). \qquad (6)\end{aligned}$$

For $\lambda \in [0,1]$, the GDT estimate is

$$\hat{\theta}_\lambda \quad = \arg\max_{\theta\in\Theta} \mathcal{L}_\lambda(\theta). \tag{7}$$

Taking $\lambda = 0$ leads to the discriminative estimate $\hat{\theta}_{DISC}$, while $\lambda = 1$ leads to the generative one $\hat{\theta}_{GEN}$. We expect that the GDT estimates $\hat{\theta}_\lambda$ $(0 < \lambda < 1)$ will sometimes have better generalization performances than these two extremes. Even if the discriminative estimate (3) is not unique, the maximum of (7) is unique for all $\lambda \in [0, 1)$ if the ML estimate $\hat{\theta}_{GEN}$ is unique.

Computation of $\hat{\theta}_\lambda$. Since we use a differentiable classification loss, the maximization problem (7) can be solved by any gradient ascent method. The Newton algorithm converges rapidly, but requires the computation of the Hessian matrix, The Conjugate Gradient (CG) algorithm may be more suitable for large scale problems: it needs only the first derivative and it is possible to avoid the storage of the quasi-Hessian matrix which can be huge when the number of parameters is large.

For simplicity, we assume that the parameters θ_k of the different class densities are independent. Taking the derivative of (5) with respect to θ_k and π_k, we get

$$\left\{ \begin{array}{l} \frac{\partial}{\partial \theta_k} \mathcal{L}_\lambda(\theta_k) = \sum_{i=1}^n (\mathbf{I}_{\{y_i = k\}} - (1 - \lambda) \tau_{ki}) \frac{\partial \log f_k(x_i; \theta_k)}{\partial \theta_k} \\ \frac{\partial}{\partial \pi_k} \mathcal{L}_\lambda(\theta_k) = \frac{1}{\pi_k} \left(n_k - (1 - \lambda) \sum_{i=1}^n \tau_{ki} \right) \end{array} \right. \tag{8}$$

with $n_k = \sum_{i=1}^n \mathbf{I}_{\{y_i = k\}}$ and $\tau_{ki} = \frac{\pi_k f_k(x_i; \theta_k)}{\sum_{l=1}^K \pi_l f_l(x_i; \theta_l)}$. The optimal parameters are zeros of the equations (8) for $k = 1, \ldots, K$.

For a given class k, these equations are analogous to the ML equations on weighted data, although unlike ML, the weights can be negative here Each point has a weight $\mathbf{I}_{\{y_i = k\}} - (1 - \lambda) \tau_{ki}$. The examples that have most influence on the θ_k-gradient are those that belong to the class k but have a low probability to be in it (τ_{ki} is small), and conversly those that do not belong to the class k but that are assigned to it with a high probability. The influence of the assignment probabilities is controlled by the parameter λ. This remark may ultimately help us to link our approach to boosting, and similar algorithms that iteratively re-weight misclassified data. It also shows that the generative estimator (λ=1) is not affected by the classification rate of the data points.

Choice of λ. The GDT estimate contains a tuning parameter to set, which functions like the smoothing parameter in regularization methods. λ cannot be set on the basis of minimum classification loss on the training set, since by definition, $\lambda = 0$ gives the optimal θ for training set classification. Instead, λ is set to the value $\hat{\lambda}$ that minimizes the cross-validation error rate.

If the optimal $\hat{\lambda}$ is close to one, the generative classifier is preferred. This suggests that the bias in $p_\theta(x, y)$ (if any) does not affect the discrimination of the model too much. Similarly, if $\hat{\lambda}$ is close to 1, it suggests that the model $p_\theta(x, y)$ does not fit the data well, and the bias of the generative classifier is too high to provide good classification results. In this case, a more complex model — i.e. with more parameters, or less constrained — may be needed to reduce the bias. For other $\hat{\lambda}$, there is an equilibrium between the bias and the variance, meaning that the model complexity is well adapted to the amount of training data.

4 Simulations

To illustrate the behavior of the GDT method, we study its performance on two synthetic test problems. We define the true distributions of the data as follows: In the first experiment, the class conditional probabilities are gaussian with identity covariance matrix and means $m_1 = (1.25, 0, 0, 0)$ and $m_0 = (-1.25, 0, 0, 0)$. In the second case, we simulate x according to a uniform density with correlated covariates : $x^{(1)} \sim \mathcal{U}[0; 1]$ and $x^{(d)} \sim \mathcal{U}[x^{(d-1)}; 1 + x^{(d-1)}]$ with $d \in \{2, 3, 4\}$ and $x^{(i)}$ denotes the i^{th} covariate. Then $y|x$ is simulated according to a Bernoulli distribution with parameter $1/\exp(-2.5x^{(1)})$. Note that the linear logistic model is true in the two experiments.

The assumed model is a Gaussian distribution for each class with shared diagonal covariance matrices and prior probabilities equal to $\frac{1}{K}$. Hence, the model does not correspond exactly to the true density in the second experiment, but it can provide a good approximation when the differences between the variances are small.

In each case, we estimated the true error rate of the classifiers learned on training samples of size 50, 100 and 200. The results are plotted in figure 1. We used standard plug-in estimates for $\lambda = 1$ and closed form logistic regression for $\lambda = 0$. For intermediate estimates, the conjugate gradient method was used. The first row illustrates the fact that the generative classifier performs better than the other estimates, but this difference tends to decrease when the sample size increases. In the second row, the best performance is from the BDG estimate for all training set sizes, and the optimal value of λ (the one that minimizes the expected loss) decreases with n since we know that the discriminative approach becomes optimal when n tends to infinity.

5 Experiments

We tried our classification method on some of the publically available Statlog datasets. In our implementation of the GDT estimates, the parameter dimension is limited due to the size of the optimization problem (7). To make the computation feasible, we reduced the dimension of the data by computing the first four Fisher discriminant variables and using them as inputs (when the number of classes was less than 5, so that there were fewer than four discriminant directions, we computed the remaining directions by PCA on the residuals). These directions are computed using the training data and do not involve the test data.

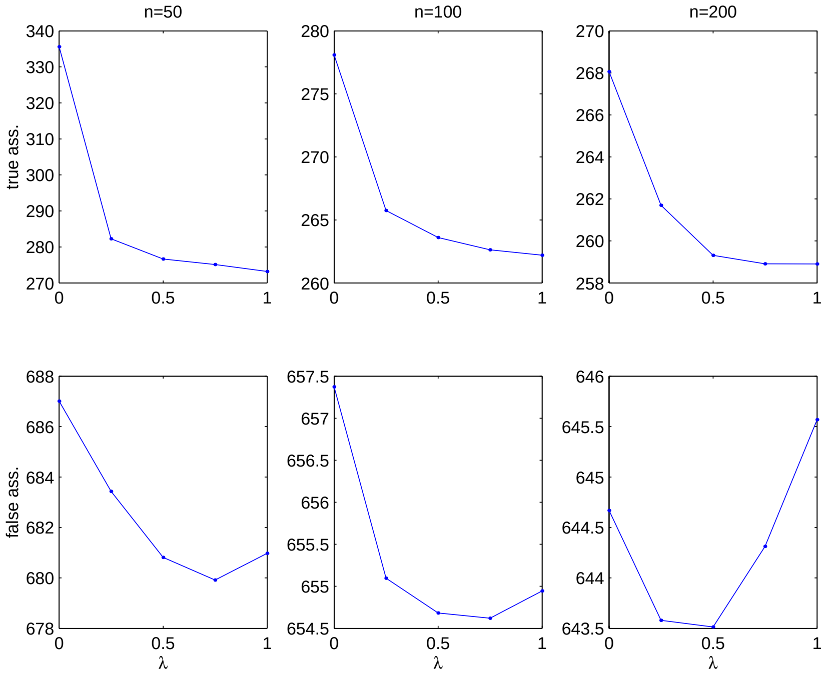

Figure 1: The full lines plot logistic loss computed on test sets of size 10^5 against the tuning parameter λ. Each plotted value is the median of 200 experiments. The rows correspond to the first and second simultations. The columns correspond to different training sample sizes.

We tried four types of density for the class-conditional distributions: 1. Gaussian densities with common covariance matrix (LDA), 2. Gaussian densities with unconstrained covariance (QDA), 3. Gaussian densities with spherical covariance matrix (Balls1), 4. Mixture of two Gaussian densities with spherical covariance matrix (Balls2). These distributions do not exactly fit the data, but they are distributions that are often used to approximate real datasets. Therefore, when the training sample is small, the generative approach may still behave better than the discriminative one. Training sample sizes were set to 50 times the number of classes so the discriminative classifiers should not have reached their asymptotic behavior.

We used a Cholesky-based parametrization of the inverse covariance matrix, so there was no need for a separate positivity constraint on the parameters. Derivatives with respect to this parametrization were obtained for each density, and we used the generative solution — which is explicit for densities 1-3 and obtained by the EM algorithm for the densities 4 — to initialize the CG algorithm.

Table 1 shows the generalization performance for each dataset and each

Table 1: Test error rate on real datasets, averaged over 100 trials. For each trial, training data were randomly chosen and the error rate was computed on the remaining data. In the *heart* dataset, a misclassified heart disease has a cost of 5 instead of 1.

model with different values of λ. These results show that substantial improvements in the classification rate can be obtained for intermediate values of λ. However, they do not directly show the performance of the GDT estimate because we fixed λ rather than selecting it by cross-validation on the training set. The evaluation of the cost as a function of λ could be used as a model selection criterion. For example, on the vehicle dataset, the simple Gaussian model (Balls1) gives an optimal λ equal to 0. This suggests that the bias is dominating the error, and indeed the results are improved by using two Gaussian densities for each class (Balls2).

One can object that the gain in error rate in these experiments is not sufficient to really conclude the usefulness of the GDT estimator.

6 Conclusion

In this study, the relationship between generative and discriminative classifiers has been clarified: they correspond to two different maximizations in the parameter space. By interpolating linearly between the two objective functions, we introduced the GDT estimator. This can be seen either as a less biased variant version of the discriminative solution, or as an improvement of the generative classifier. The regularization is "natural" in the sense that the parameters are encouraged to fit the inputs. Our preliminary results on real data showed that the intermediate model often gives better classification performances than the discriminative and generative classifiers.

The real interest of the GDT estimate resides in its application to generative models. Probabilistic models already exist in many areas: time series models, mixed models and graphical models — including Markov Random Fields and Hidden Markov Models — are examples of widely used generative models. When class-conditional probabilities are modelled generatively, then the GDT estimator should often improve the classification performances.

Currently, the main difficulty with the GDT method is the choice of the tuning parameter, as this requires an expensive cross-validation computation. We believe that more computationally efficient criteria can be developed by analyzing the solutions on the training set, in the spirit of the Bayesian Information Criterion [5].

PRINCIPAL COMPONENTS ANALYSIS IN THE FREQUENCY DOMAIN

Alain Boudou, Olivier Caumont and Sylvie Viguier-Pla

Key words: Principal components analysis, time series, stationarity, random measure, spectral analysis, applications.

COMPSTAT 2004 section: Functional data analysis.

Abstract: This paper shows how to overcome some problems arising when summarizing a p-dimensional time series by a q-dimensional one. An application on meteorological data is given.

1 Introduction

David Brillinger [5] proposes a method in order to summarize a $p-$dimensional times series $(X_n)_{n\in\mathbb{Z}}$ by a $q-$dimensional times series $(X'_n)_{n\in\mathbb{Z}}$, $q < p$, where $X'_n = \sum_m C'_m X_{n-m}$.

This method is performed with a principal components analysis (PCA) of each spectral component, so it combines harmonic analysis and PCA However, when the spectrum is continuous, it cannot be put into practice because it would need the diagonalization of an infinity of matrices, and so we cannot compute the coefficients $\ldots, C'_{-1}, C'_0, C'_1, \ldots$.

We get round this difficulty by using a discretization of the spectrum and we substitute for this analysis an analysis which requires the diagonalization of a finite set of matrices. We show that under the assumption that the mesh spacing of the discretization tends to 0 the quality of the approximate solution tends to the quality of the summary $(X'_n)_{n\in\mathbb{Z}}$.

2 The PCA in the frequency domain

A series $(X_n)_{n\in\mathbb{Z}}$ (in the following, a series $(X_n)_{n\in\mathbb{Z}}$ will be noted $(X_n)_n$) composed of $p-$dimensional random vectors X_n is said to be stationary when $\mathbb{E}(X_n\, {}^t\overline{X_m}) = \mathbb{E}(X_{n-m}\, {}^t\overline{X_0})$ for all pair (n, m) of elements of $\mathbb{Z}$.

A second q-dimensional stationary time series $(X'_n)_n$ is said to be stationarily correlated with $(X_n)_n$ when $\mathbb{E}(X_n\, {}^t\overline{X'_m}) = \mathbb{E}(X_{n-m}\, {}^t\overline{X'_0})$ for all pair (n, m) of elements of $\mathbb{Z} \times \mathbb{Z}$.

If $P_{H_{X'}}$ designates the orthogonal projector from $L^2_{\mathbb{C}^p}(\Omega, \mathcal{A}, P)$ onto $H_{X'}=$ $\overline{\text{vect}}\{K\, X'_n;\ n \in \mathbb{Z},\ K\ p \times q \text{ matrix}\}$, we can assert that the $p-$dimensional series $(P_{H_{X'}} X_n)_n$ is a filtered of $(X'_n)_n$. From this fact, it is stationary and stationarily correlated with $(X_n)_n$. The stationary properties allow us to deduce that, for all integer n, $\|X_n - P_{H_{X'}} X_n\| = \|X_0 - P_{H_{X'}} X_0\|$.

We can then consider this last quantity in order to measure, when $q < p$, the quality of the summary $(X'_n)_n$ of $(X_n)_n$. We will note it $r((X'_n)_n)$. Of course, among all the possible $q-$dimensional summaries which are stationary and stationarily correlated with $(X_n)_n$, we will choose the one which is, from this point of view, the most powerful. So it follows the

Definition. *We call principal components analysis of order q in the frequency domain, of the $p-$dimensional stationary series $(X_n)_n$, the research of the $q-$dimensional stationary series $(X'_n)_n$, stationarily correlated with $(X_n)_n$, such that $\|X_0 - P_{H_{X'}}X_0\|$ is the smallest possible.*

3 Mathematical context

We will briefly develop the mathematical context for the resolution of the problem we have just exposed. A more extensive and rigourous mathematical discussion may be found in [2] and [3].

A $p-$dimensional random measure ($p-$r.m.) Z is a vector measure defined on $\mathcal{B}$, Borel $\sigma-$field of $[-\pi,\,\pi[$, with values in $L^2_{\mathbb{C}^p}(\mathcal{A})$, such that $\mathbb{E}(Z\,A^t\overline{Z\,B}) = 0$ for all pair (A,B) of disjoint elements of $\mathcal{B}$.

We easily verify that the applications $M_Z\,:\,A\in\mathcal{B}\mapsto\mathbb{E}(ZA\,{}^t\overline{ZA})\in HS(p,p)$ and $t_Z\,:\,A\in\mathcal{B}\mapsto \text{trace}\,\mathbb{E}(ZA\,{}^t\overline{ZA})\in\mathbb{R}^+$ are measures, $HS(p,q)$ being the vector space of $q\times p$ matrices which, with the inner product $< K_1, K_2 >= \text{trace}\,K_1^t\overline{K_2}$, has a $\mathbb{C}-$Hilbert space structure.

When a $\sigma-$finite measure η dominates t_Z, we can establish the existence of an application $\frac{dM_Z}{d\eta}$ from $[-\pi,\,\pi[$ into $HS(p,p)$, measurable, whose norm is $\eta-$integrable, and for which $M_Z(A) = \int 1_A\frac{dM_Z}{d\eta}\,d\eta$, for all A of $\mathcal{B}$.

A relation of equivalence, related to M_Z, may be defined on a subspace of $HS(p,p)^{[-\pi,\,\pi[}$ and we will denote by $(p,q)-L^2(M_Z)$ the set of classes of equivalence. We will use the same notation for an element of $(p,q)-L^2(M_Z)$, that is a class of equivalence, and one of its representatives, that is an application from $[-\pi,\,\pi[$ into $HS(p,q)$. The application $(\varphi,\psi)\in((p,q)-L^2(M_Z))^2\mapsto\int\text{trace}\,\{\varphi(\lambda)\frac{dM_Z}{d\eta}(\lambda)\,{}^t\overline{\psi(\lambda)}\}\,d\eta(\lambda)\in\mathbb{C}$ is an inner product which gives to $(p,q)-L^2(M_Z)$ a $\mathbb{C}-$Hilbert space structure.

The stochastic integral, relatively to Z, may be defined as the unique isometry from $(p,q)-L^2(M_Z)$ onto $\overline{\text{vect}}\,\{K\,Z(A)\,;\,A\in\mathcal{B},\ K\,q\times p\text{ matrix}\}$ which with 1_AK associates $K\,Z(A) = \int 1_AK\,dZ$ for all A of $\mathcal{B}$ and for all $q\times p$ matrix K.

The $p-$dimensional series $(\int e^{i.n}I_{\mathbb{C}^p}\,dZ)_n$ is stationary. Conversely, with each $p-$dimensional stationary series $(X_n)_n$ we can associate a $p-$r.m., and only one, Z, such that $X_n = \int e^{i.n}I_{\mathbb{C}^p}\,dZ$ for all integer n.

The $q-$dimensional series $(\int e^{i.n}\varphi(.)\,dZ)_n$ is the image of $(X_n)_n$ by the filter φ, element of $(p,q)-L^2(M_Z)$. It is stationary and stationarily correlated with $(X_n)_n$, its associated q-r.m. is $Z_\varphi\,:\,A\in\mathcal{B}\mapsto\int 1_A\varphi\,dZ\in L^2_{\mathbb{C}^q}(\mathcal{A})$.

Under certain conditions, the image by a filter is a moving average :
PROPRIETY 1. *Let Z be a $p-$r.m. for which μ, Lebesgue measure, dominates t_Z and such that $\frac{dM_Z}{d\mu}(.)$ is bounded. If φ is an application from $[-\pi,\,\pi[$ into $HS(p,q)$ measurable and bounded, then the family $\{C_mX_{n-m}\,;\,m\in\mathbb{Z}\}$, where $C_m = (2\pi)^{-1}(\int e^{i\,\cdot\,m}\varphi(.)\,d\mu(.))$, is summable of sum $\int e^{i.n}\varphi\,dZ$.*

4 Solution of the PCA problem

If we denote by $\sum_{j=1}^{p} \mu_j(.)A_j(.)^t\overline{A_j(.)}$ a measurable Schmidt decomposition of $\frac{dM_Z}{d\eta}$ and by F_j the column matrix associated with the j^{th} element of the canonical basis of $\mathbb{C}^q$:

PROPRIETY 2. *The image of $(X_n)_n$ by the filter $\alpha(.) = \sum_{j=1}^{q} F_j^t\overline{A_j(.)}$ is the stationary $q-$dimensional series, stationarily correlated with $(X_n)_n$, solution of the PCA problem of order q of $(X_n)_n$ in the frequency domain.*

We can prove that the series $(X''_n)_n$, where $(X''_n)_n = (P_{H_{X'}}X_n)_n$, is the image of $(X'_n)_n$ by the filter ${}^t\overline{\alpha(.)}$. It is also the image of $(X_n)_n$ by the filter ${}^t\overline{\alpha(.)}\alpha(.)$. This series may be named, a “series reconstitution of data”.

In the particular case where Z is concentrated on a finite set $\{\lambda_1, \ldots, \lambda_k\}$ of elements of $[-\pi, \pi[$, it may be written $Z = \sum_{l=1}^{k} \delta_{\lambda_l}(.)Z_l$, where δ_l is the Dirac measure concentrated on λ_l and $\{Z_1, \ldots, Z_k\}$ a family of elements of $L^2_{\mathbb{C}^p}(\mathcal{A})$ such that $\mathbb{E}(Z_j\,{}^t\overline{Z_{j'}}) = 0$ when $j \neq j'$.

For all φ of $(p,q) - L^2(M_Z)$, it comes $\int \varphi\, dZ = \sum_{l=1}^{k} \varphi(\lambda_l)Z_l$. So the series $(\int e^{i.n} I_{\mathbb{C}^p}\, dZ)_n$ is the sum of stationary uncorrelated series $(e^{i\lambda_l n}Z_l)_n$.

If we denote by λ_{jl} (resp. A_{jl}) the j^{th} eigenvalue (resp. the j^{th} unit eigenvector) of $\|Z_l\|^2\mathbb{E}(Z_l^t\overline{Z}_l)$, a measurable Schmidt decomposition of $\frac{dM_Z}{dt_Z}$ is $\sum_{l=1}^{k} 1_{\{\lambda_l\}} \sum_{j=1}^{p} \lambda_{jl}A_{jl}{}^t\overline{A}_{jl}$.

The series $(X'_n)_n$ and $(X''_n)_n$ corresponding to the PCA of order q in the frequency domain of $(\sum_{l=1}^{k} e^{i\lambda_l n}Z_l)_n$ are respectively
$(\sum_{l=1}^{k} e^{i\lambda_l n} \sum_{j=1}^{q} F_j^t\overline{A}_{jl}Z_l)_n$, image of $(X_n)_n$ by the filter
$\alpha(.) = \sum_{l=1}^{k} 1_{\{\lambda_l\}}(.) \sum_{j=1}^{q} F_j^t\overline{A_{jl}}$, and $(\sum_{l=1}^{k} e^{i\lambda_l n} \sum_{j=1}^{q} A_{jl}\,{}^t\overline{A}_{jl}Z_l)_n$, image of $(X'_n)_n$ by ${}^t\overline{\alpha(.)}$ or equivalently of $(X_n)_n$ by ${}^t\overline{\alpha(.)}\alpha(.)$. This analysis is equivalent to the PCA of each random vector Z_l, that is why we call it PCA in the frequency domain.

5 The particular case of absolutely summable autocovariance function

We propose to perform the PCA in the frequency domain of a p-dimensional stationary time series $(X_n)_n$ of associated p-r.m. Z and of autocovariance function absolutely summable : $\sum_n \|\mathbb{E}(X_n\,{}^t\overline{X_0})\| < +\infty$. This assumption implies the fact that the Lebesgue measure μ dominates t_Z, and consequently that a spectral density $\frac{dM_Z}{d\mu}$ exists (and is equal to $(2\,\pi)^{-1}\sum_n e^{-i.n}$ $\mathbb{E}\,X_n^t\overline{X_0}$). From this, the PCA in the frequency domain, which might be performed by the diagonalization of $\frac{dM_Z}{d\mu}(\lambda)$, for all λ of $[-\pi,\, \pi[$, cannot be obtained in practice. We get round this difficulty by using a discretization of the spectrum.

More precisely, k designating an integer parameter which will tend to infinity, we consider the measurable application from $[-\pi,\, \pi[$ into itself :

$f_k = \sum_{l=-k}^{k-1} \frac{\pi\, l}{k}\, 1_{B_{lk}}$, where $B_{-k,k} = \{-\pi\}$, $B_{lk} = [\frac{\pi\, l}{k} - \frac{\pi}{k}, \frac{\pi\, l}{k}[$ for $l = -k+1, \ldots, -1$, $B_{0k} =]-\frac{\pi}{k}, \frac{\pi}{k}[$, and $B_{lk} = [\frac{\pi\, l}{k}, \frac{\pi\, l}{k} + \frac{\pi}{k}[$ for $l = 1, \ldots, k-1$.

The application $Z_k \ : A \in \mathcal{B} \mapsto Z f_k^{-1} A \in L^2_{\mathbb{C}^p}(\mathcal{A})$ is the $p-$m.a. image of Z by f_k and is equal to $\sum_{l=-k+1}^{k-1} \delta_{\frac{\pi\, l}{k}}(.)\, Z\, B_{lk}$. The PCA in the frequency domain of this last series needs only the diagonalization of the matrices $\mathbb{E}\,(Z\, B_{lk}\, {}^t\overline{B_{lk}})$, $l = -k+1, \ldots, k-1$.

If A_{jlk} denotes the j^{th} unit eigenvector of $\mathbb{E}\,(Z\, B_{lk}\, {}^t\overline{B_{lk}})$, from § 4, the filter, element of $(p,q) - L^2(M_{Z_k})$ that corresponds to the PCA of order q in the frequency domain of $\left(\sum_{l=-k+1}^{k-1} e^{i\frac{\pi\, l}{k} n}\, Z\, B_{lk}\right)_n$ is

$\alpha_k(.) = \sum_{l=-k+1}^{k-1} 1_{\{\frac{\pi\, l}{k}\}}(.) \sum_{j=1}^{q} F_j\, {}^t\overline{A_{jlk}}$.

Let $(X'_n)_n$ denote the $q-$dimensional solution of the problem of PCA of order q in the frequency domain of $(X_n)_n$. This series is of the form $X'_n = \sum_m C'_m X_{n-m}$. Let $(X'^k_n)_n$ be the image of $(X_n)_n$ by the filter $\alpha_k(f_k(.))$. This last series, also stationary and stationarily correlated with $(X_n)_n$, may be considered as a $q-$dimensional summary. If we suppose that, for all λ of $[-\pi, \pi[$, the p eigenvalues of $\frac{d\, M_Z}{d\, \mu}(\lambda)$ are distinct, then we can (cf. [1]) establish that $\lim_{k\to\infty} r((X'^k_n)_n) = r((X'_n)_n)$, what legitimates the discretization.

Of course, as a "series reconstitution of data", one can choose $(X''^k_n)_n$ which is either the image of $(X'^k_n)_n$ by ${}^t\overline{\alpha_k(f_k(.))}$ or the image of $(X_n)_n$ by ${}^t\overline{\alpha_k(f_k(.))}\alpha_k(f_k(.))$.

For all m of $\mathbb{Z}$, we define $C'_{m,k}$, $C''_{m,k}$ and $D_{m,k}$ such that $2\pi\, C'_{m,k} = \int e^{i\,.m} \alpha_k \circ f_k\, d\,\mu = \sum_{l=-k+1}^{k-1} (\int_{B_{lk}} e^{i\,.m}\, d\,\mu) \sum_{j=1}^{q} F_j\, {}^t\overline{A_{jlk}} = 2\pi\, {}^t\overline{C''_{m,k}}$ and $D_{m,k} = (2\pi)^{-1} \sum_{l=-k+1}^{k-1} (\int_{B_{lk}} e^{i\,.m}\, d\mu)\ \sum_{j=1}^{q} A_{jlk}\, {}^t\overline{A_{jlk}}$.

From § 3, we can affirm that
$X'^k_n = \sum_m C'_{m,k} X_{n-m}$ and $X''^k_n = \sum_m C''_{m,k} X'^k_{n-m} = \sum_m D_{m,k} X_{n-m}$.

Then it is obvious that the various "coefficients" $C'_{m,k}$, which can be computed as soon as we know the vectors A_{jlk}, i.e. the matrices $\mathbb{E}\,(Z\, B_{jl}\, {}^t\overline{Z\, B_{jl}})$, allow us to obtain the series (X'^k_n) which is a $q-$dimensional summary all the more powerful as k is large.

If the series $(X_n)_n$ is strictly stationary, in [1] we prove that, almost surely:

$$\lim_m \frac{1}{2\,\pi\, m} \sum_{u=1}^{m} \sum_{v=1}^{m} (\int_{B_{lk}} e^{i\,.(u-v)}\, d\mu) X_v\, {}^t\overline{X_u} = \mathbb{E}(Z\, B_{jl}\, {}^t\overline{Z\, B_{jl}}).$$

Thus, the matrices $\mathbb{E}(Z\, B_{jl}\, {}^t\overline{Z\, B_{jl}})$ can be estimated by
$\frac{1}{2\,\pi\, m} \sum_{u=1}^{m} \sum_{v=1}^{m} (\int_{B_{lk}} e^{i\,.(u-v)}\, d\mu) X_v\, {}^t\overline{X_u}$.
The data being real, we establish $\mathbb{E}(Z\, B_{j,-l}\, {}^t\overline{Z\, B_{j,-l}}) = {}^t\overline{\mathbb{E}(Z\, B_{jl}\, {}^t\overline{Z\, B_{jl}})}$, what allows us to save computing time.

6 A worked example

6.1 The meteorological data of the application

We consider the average annual temperatures in 6 French towns, that is Aix, Biarritz, Toulouse, Bourges, Lille and Lyon, from 1950 to 2000. Then the random vector X_n has values in $\mathbb{C}^6$, and we have $m = 51$ observations. The data are preliminarily centered.

6.2 Convergence when k grows

The results of the PCA in the frequency domain depend on the discretization parameter k of the spectrum $[-\pi, \pi[$. The larger k is, the more the error of reconstitution (square root of the mean square errors) is low (figure 1).

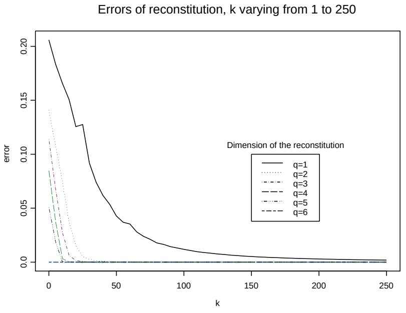

Figure 1. Errors of reconstitution

Let us notice that the usual PCA corresponds to $k = 1$. Hence, it is clear that the PCA in the frequency domain gives best results.

The coefficients $C'_{r,k}$, $C''_{r,k}$ and $D_{r,k}$ seem to converge when k grows (to our knowledge, that is not proved mathematically). For example, for $q = 1$, we obtain

$$C'_{0,5} = \begin{pmatrix} 0.3577 \\ 0.3787 \\ 0.3986 \\ 0.4578 \\ 0.3657 \\ 0.4371 \end{pmatrix} \quad C'_{0,100} = \begin{pmatrix} 0.2809 \\ 0.2986 \\ 0.3001 \\ 0.3888 \\ 0.3171 \\ 0.3956 \end{pmatrix} \quad C'_{0,200} = \begin{pmatrix} 0.2774 \\ 0.2990 \\ 0.2983 \\ 0.3849 \\ 0.3080 \\ 0.3935 \end{pmatrix} \quad C'_{0,300} = \begin{pmatrix} 0.2773 \\ 0.2963 \\ 0.2954 \\ 0.3833 \\ 0.3066 \\ 0.3932 \end{pmatrix} \quad C'_{0,400} = \begin{pmatrix} 0.2767 \\ 0.2955 \\ 0.2947 \\ 0.3828 \\ 0.3064 \\ 0.3931 \end{pmatrix}$$

In figure 2, we see the values of the $C'_{r,k}$ norms, at a stage where convergence can be considered as reached (k=400), whereas figure 3 shows how, for a reconstitution in dimension 1, these norms vary with k.

In [4], we establish that $q = \sum_{n \in \mathbb{Z}^*} \|C'_n\|^2 + \|C_0\|^2$. Hence, from the figure 2, the quantity $\sum_{n \in \mathbb{Z}^*} \|C'_n\|^2$ is not negligible. We also prove that $\sum_{n \in \mathbb{Z}^*} \|C'_n\|^2 = (2\,\pi)^{-1} \int \|\alpha(\lambda) - C'_0\|^2 d\,\mu(\lambda)$. Hence, when $\sum_{n \in \mathbb{Z}^*} \|C'_n\|^2$

is small, $\alpha(\lambda)$ is near C'_0 (for all λ of $[-\pi,\, \pi[$). That means that the various spectral components have very close systems of principal axes. We also prove that, when $(X_n)_n$ is a white noise, $\int \|\alpha(\lambda) - C'_0\|^2 d\,\mu(\lambda) = 0$.

We do not need all of the coefficients $C'_{n,k}$, $C''_{n,k}$ and $D_{n,k}$ for the reconstitution, because they are small when $|n| > 2$ (see figures 2 and 3). Note that they all can be computed. We can prove the equality $\lim_n C'_n = 0$.

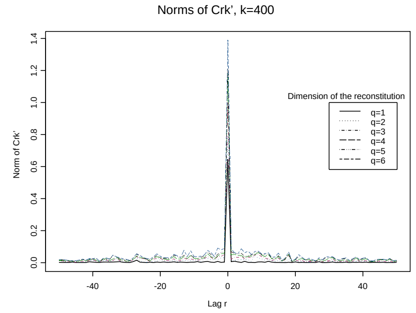

Figure 2. Norms of the $C'_{r,k}$'s for $k = 400$

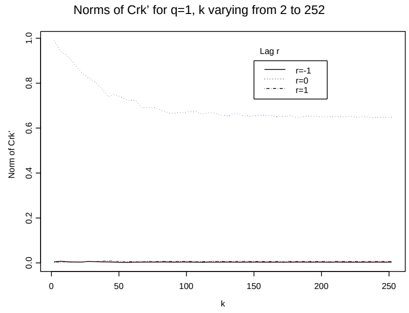

Figure 3. Norms of $C'_{r,k}$'s, k varying

6.3 Reconstitution of data from principal components

When the PCA is used as method of voluminous data storage, one uses, for reconstituting data, the principal components and the reconstitution formula, which is a filter from $\mathbb{C}^q$ into $\mathbb{C}^p$.

From the figure 1, when $k > 50$, the PCA of order 1 in the frequency domain is reaching as good results, from the quality of the reconstitution point of view, as the 5 first steps of the usual PCA. It is the reason why we will compare the quantities of data it is necessary to store in order to "reconstitute" a time series of m observations, according to whether one or the other of the two methods is used.

In the first case, the transformation of the unidimensional series $(X'_{n,k})_n$ into a series reconstituted of dimension 6 $(X''_{n,k})_n$ is made, formally, by the way of a moving average $X''_{n,k} = \sum_l C''_{n-l,k} X'_{l,k}$.

Insofar as we wish to obtain $(X''_{n,k})_{n=1,2,\ldots,m}$, only from the time series $(X'_{n,k})_{n=1,2,\ldots,m}$, the previous formula is approximated by
$X''_{n,k} = \sum_{l=1}^m C''_{n-l,k} X'_{l,k}$. That requires to know $C''_{l,k}$ for $l = 1-m$ to $m-1$.

Taking into account that, for an integer R large enough, when $|l| > R$, $C'_{l,k}$ is very small, the interesting matrices are only $2R+1$: $C''_{-R,k}, \ldots, C''_{R,k}$ (of course, if $m-1 > R$). So this requires the storage of $6(2R+1)$ data. Broadly speaking, adding the 6 data of the mean vector and the m data of $X'_{n,k}$, it is necessary to store $m + 12(R+1)$.

In the usual PCA case, it is necessary to know m values of a 5−dimensional vector, that is $5m$ data, plus the matrix that allows the reconstitution in the dimension 6, that is a matrix of 5×6 data, and the mean vector of

6 data. That adds up $5m + 36$ data. The ratio between these two quantities is $\frac{5m+36}{m+12(R+1)}$, which is all the larger as m is large.

This means that the PCA in the frequency domain is more powerful than the usual PCA, from the data storage point of view.

Let us note that, with the same way of computation, for any number of variables p, q denoting the number of steps selected in the PCA, m still denoting the number of time observations, the compression ratio is $\frac{2Rpq+p+mq}{mp}$. For $q = 1$ (it is often enough to restitute more than 97% of the inertia), this ratio becomes $\frac{(2R+1)p+m}{mp}$. For $R = 5$, this ratio in our example is 38.2%.

Figure 4 indicates the mean square error induced by the reconstitution from the principal components $(X'_{n,k})_{n=1,\dots,m}$. The minimal error is 0.038, for R to its maximum, that is 50. We notice that the error seems to be independent of q. That is because the error of reconstitution with principal components is always larger than the error due to the projection.

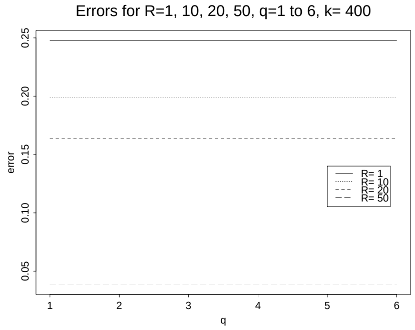

Figure 4. Errors of reconstitution for $R = 1$, 10, 20 et 50 and $k = 400$

We must notice that the more m is large, better the compression ratio is, for a constant error of reconstitution.

6.4 Elements of interpretation

From the fact that, for the PCA of order 1, ${}^tC'_0 = (2\pi)^{-1} \int A_1(\lambda) d\mu(\lambda)$, this matrix $p \times 1$ may be termed "mean of the first latent vectors $A_1(\lambda)$", and can be interpreted as a first latent vector. The other steps of the PCA may be interpreted in a same way.

For this example, the reconstitution ratio of the first principal axis is 97.8% for a total inertia of 2.611. When considering $R = 10$, that is 21 coefficients $C'_{r,k}$ instead of 101, the reconstitution ratio becomes 82.3%.

This allows us to focus on the first step of the PCA for the interpretation.

We can see on figure 5 that this first axis is linked to the mean annual temperature in all the 6 towns. On the left hand of the scatter plot are the colder years, as on the right the warmer ones.

This interpretation is copied from a usual interpretation from a usual PCA. Let us recall that the usual PCA is a particular case ($k = 1$) of the PCA in the frequency domain.

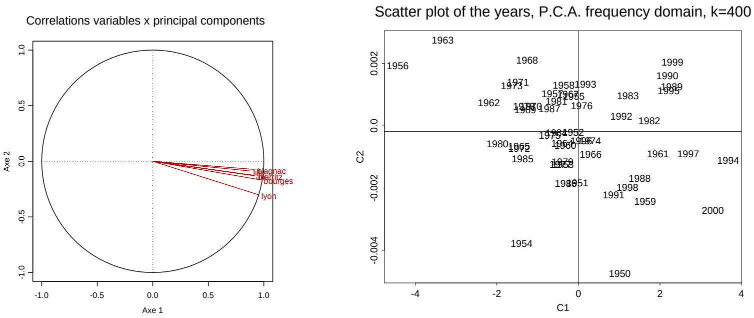

Figure 5. Correlations variables x principal components and scatter plot for principal components 1 and 2

For $k > 1$, instead of reconstituting a data at time t by a linear combination of data at the same t, this reconstitution is obtained by a moving average of linear combinations of data at times $t + n$, $n \in \mathbb{Z}$. This is logically more adequate for times series not necessarily independent in time. When $k = 2$, the reconstitution ratio is slightly higher than $k = 1$ one (90.73% instead of 90.26%), and when $k = 200$, this ratio reaches 99.70%.

COMPSTAT'2004 Symposium

FINITE SPATIAL SAMPLING DESIGN AND "QUANTIZATION"

Kamal Boukhetala and Sadoun Ait-Kaci

Key words: Spatial sampling, genetic algorithm, "quantization", localization.

COMPSTAT 2004 section: Spatial statistics.

Abstract: A Spatial Genetic Algorithm (SGA) is proposed to design a finite optimal spatial sampling. A geostatistical application is studied for a problem of optimal localization of meteorological stations. The "quantization" is used to improve the performance of the SGA.

1 Introduction

Optimal sampling of estimation of random quantities is an actual problem for practical and theoretical statistical considerations. For example, real situations where the observed quantities are accompanied by measurement errors.

Whenever errors are correlated, both of sampling problem and methodologies of global search have been studied. In scalar case, this problem has been discussed by [1], using the heuristics methods like genetic algorithms and annealing search algorithms. For a scalar finite sampling, we have confirmed in [4] the performance of the "quantization" (adequate transformation for compression of data), for the used algorithms. For a large sample size, [2] has proved that one may reduce the rate of convergence of mean quadratic error, from n^{-2} to $n^{-1,5}$.

In [3], we have generalized the previous studies in the spatial case by developing an adapted search algorithm. In our work, we propose a generalization of studies of [4], that concern spatial optimal sampling with "quantization", by developing for the spatial case, an adequate global search algorithm. The proposed algorithm is a *Spatial Genetic Algorithm*, that is a powerful heuristic to solve hard combinative problems. We describe two new crossover operators, called: global and local crossover operators. This type of crossover operators explores the spatial aspect and gives better results than [3]. On the other hand, we show that the "quantization" of spatially correlated errors, improve clearly the quality of results, for a small number of sampling points (k), but gives bad results when $k \to \infty$ which is theoretically proved by [2].

We may conclude that the "quantization" has a positive effect with the proposed *Spatial Genetic Algorithm* for a small number of sampling points, that presents a practice interest for different problems encounter in hydrological and environmental sciences.

2 Spatial genetic algorithm

Generally, Genetic Algorithms (GA) represents an enough rich and very interesting family of stochastic algorithms of optimization, that are founded on mechanisms of the natural selection and genetics. Fields of application are very varied; theory of the picture compression, automatic and others. The principle of these algorithms is to proceed by a stochastic research on an important space through "a population" of Pseudo- Solutions. These algorithms are simple and very efficient, because they are not like at hypotheses on the function to optimize, as the continuity and the differentiability. They operated directly one the explored space, after a coding of feasible solutions of the function. They processes on a population of points, instead of an unique point and use values of the studied function only without another auxiliary knowledge and rules of transition probabilistic.

In order to well to fear the genetic algorithm dynamics, let's introduce the main elements of the jargon, used in the literature.

- *Individual or Chromosome: a potential solution.*
- *Population: a set of chromosomes or of points of the space of research.*
- *Environment: the space of research;*
- *Fitness or Function of assessment: the function that one seek to maximize (minimize).*

The working of the GA is based on different basis operators. These operators are inspired directly from the natural selection mechanism and the genetic phenomenon. It consists to evolve the population in order to adapt individuals to the environment. Technically, a new generation gets himself at the end of a cycle by using of three main standard operators, namely, operators of reproduction, crossover, and mutation. For a reason of implementation adapted to computers, a chromosomal representation or coding of individuals (feasible solutions) is necessary. We propose in the case of our problem:

- A spatial coding of the solution,
- Two operators of crossover and mutations appropriated.

What permits us to propose a new Genetic Algorithm adapted to the Spatial case, denoted *SGA*.

2.1 Coding of the solution (CS)

One considers a spatial n-sample, in a space of research, of dimension $L < n$, that is a matrix of real, of the following form:

$$X = \begin{bmatrix} x_{11} & x_{12} & \dots & x_{1L} \\ \vdots & & \dots & \vdots \\ \vdots & & \dots & \vdots \\ x_{n1} & x_{n2} & \dots & x_{nL} \end{bmatrix}$$

Thus, a population of solutions in this space is a set of real matrixes $M_{(n\times L)}$. We adept coding relatively to a matrix; it is given for individual i, by a vector of real of size $n * L$:

$$X_i = ((x_{1l}, \dots x_{1L})_i, (x_{2l}, \dots x_{2L})_i, \dots, (x_{nl}, \dots x_{nL})_i) \,.$$

2.1.1 Operator of crossover (OC) One consider two coded real configurations:

$$X = (x_1, x_2, \dots, x_L) \quad \text{and} \quad Y = (y_1, y_2, \dots, y_L)$$

A classic crossover, that we call global crossover produced of the new configurations thereafter. The uniform crossover corresponds here to interchange, at random, a subset of points of IR^L. Without losing generality, we consider an example for the case of the plan in order to illustrate the process of crossover. For two parents X_p and Y_p, such that:

$$\begin{aligned} X_p : &= (x_1, x_2, \dots, x_7) = ((x_1^1, x_1^2), (x_2^1, x_2^2), \dots, (x_7^1, x_7^2)) \\ Y_p : &= (y_1, y_2, \dots, y_7) = ((y_1^1, y_1^2), (y_2^1, y_2^2), \dots, (y_7^1, y_7^2)) \end{aligned}$$

an uniform crossover products two individuals children, X_e and Y_e, with a appropriate Jong schema. We has a difficulty, when we applied this operators with a low probability for the mutation, in accordance with the theory of the AG. What gives a little changes in the diversity of the individuals population relatively to the initial population. On the other hand, the defined crossover operator has for simple role to change indication of components. A first idea was to increase the probability of mutation to maintain a diversity being sufficient, and so to preserve the improvement. The works of Jong clearly demonstrate that this method is not efficient. An uncontrolled increase of the rate of mutation can damage the performance of the genetic algorithm. Therefore, we introduced a new operator, says local crossover, that acts locally on couples of two individual components to cross.

2.1.2 Operator of local crossover (OLC) From a couple $X_1, X_2)$ of individuals, we choose a sample (x_i^1, x_i^2) . We proceed as following to define the OLC operator, by generating a new sample $(x_i^{1'}, x_i^{2'} \in [a,b] \times [a,b]$, with:

$$\begin{cases} x_i^{1'} = P_E\left(\frac{(b-a)}{\text{pas}} \times U\right) \times \text{pas} + \text{pas}/2\,; \\ x_i^{2'} = x_i^1 + x_i^2 - x_i^{1'} \end{cases}$$

for

$$\begin{aligned} a &= \max(x_i^1, x_i^2) - \min(x_i^1, x_i^2) \\ b &= \min(x_i^1, x_i^2, \mathrm{Sup}) \end{aligned}$$

The quantities, denoted by pas, P_E et U, are respectively the increment of sampling space, integer part and a random value, taken from $[0,1]$.

At the time of the research of optimal sample, it can contain two identical samples, because the combinative nature of the problem. For it, one introduces an operator of diversity that is defined as following by increasing or creasing of the gene:
we set

$$\begin{cases} x_i' = x_i & \mathrm{Sgn} \quad \mathrm{pas} \\ y_i' = y_i & \mathrm{Sgn} \quad \mathrm{pas} \end{cases} \qquad (x_i, y_i) \in [a_1, b_1] \times [c_1, d_1] \, .$$

a_1, b_1, c_1, d_1 are some constants, and Sgn is defined by:

$$\mathrm{Sgn} = \begin{cases} + \text{ if} & (x_i = a_1 \text{ or } y_i = c_1) \\ - \text{ if} & (x_i = b_1 \text{ or } y_i = d_1) \\ (+ \; rmor \; -) & \text{with probability } \frac{1}{2} \end{cases}$$

Finally, local crossover is for our problem, an adaptation very interesting of the crossover classic multi-site on chromosomes, produced by the concatenation of binary code.

2.1.3 Operator of Mutation (OM) The operator of mutation that we propose to our spatial sampling problem proceeds as following:
We operate on a gene $S_k = (x_k, y_k)$, to mute it to a new gene $S_k' = (x_k', y_k')$, as following:

$$\begin{cases} x_k' = x_k & \mathrm{Sgn} \quad U \\ y_k' = y_k & \mathrm{Sgn} \quad V \end{cases}$$

such that:

$$\begin{aligned} U &\in \begin{cases} P_E\left(\frac{U_{[x_k, b_1]}}{\mathrm{pas}}\right) \times \mathrm{pas} & \text{if} \quad x_k \geq \frac{a_1+b_1}{2} \\ P_E\left(\frac{U_{[a_1, x_k]}}{\mathrm{pas}}\right) \times \mathrm{pas} & \text{if} \quad x_k < \frac{a_1+b_1}{2} \end{cases} \\ V &\in \begin{cases} U_{[y_k, d_1]} & \text{si} \quad y_k \geq \frac{c_1+d_1}{2} \\ U_{[c_1, y_k]} & \text{si} \quad y_k < \frac{c_1+d_1}{2} \end{cases} \end{aligned}$$

$U_{[a_1,b_1]}$ is a random value from $[a_1, b_1]$.

2.2 Stopping criteria (SC)

The number of iterations is fixed, after some tests on the fitness function. It satisfies a compromise between constraints of convergence of the population, the CPU time and the precision.

Therefore we are now able to propose the following Spatial Genetic Algorithm:

```
SGA algorithm:
Begin
Stage 1 - Function of fitness
Stage 2 - Coding: CS
Stage 3 - Generation of the feasible solutions set
Stage 4 -
        Do
            $OC$, $OLC$ and $OM$
        until SC.
End
```

3 Application

The goal is the installation of a rainfall optimal network, that permits to observe a quantity M of rain data taken on a region D with a number reduces of stations k.

We have:

$$D = \{(x, y, z) \,|\, x \in [540, 800],\ y \in [150, 400],\ z \in [456, 1250]\}$$

where $s = (x, y, z)$ is a point of the rainfall site in the region D, with z is the altitude. The rainfall annual data, obtained from the domain D, permits to give the following regression model, relatively to the observed data of a site $S_i = (x_i, y_i, z_i)$ $Q_{S_i} = \langle \tilde{\alpha\alpha}, S_i \rangle + d + m \cdot \varepsilon(S_i)$ (/millimeter). $\tilde{\alpha} = \begin{pmatrix} a \\ b \\ c \end{pmatrix}$, d and m are some real parameters. The parameters a, b, c and d are estimated by:

$$\hat{a} = 60.05.10^{-3} \quad \hat{b} = 0.701 \quad \hat{c} = 0.29 \quad \hat{d} = 94.44$$

with a value of $R62 = 0.89$.

The observations errors are modeled by spatial random process ε_S, by taking in consideration the characteristic of variability, uncertainty and heterogeneity of the real rainfall process. We suppose that the spatial random process of errors associated to each site, is a spatial homogenous Gaussian process, with mean μ_ε and covariance $C(\varepsilon_i, \varepsilon_j)$. Therefore, one determine the optimal sites by the research of the optimal sample of finite size k, relatively to a optimality criteria: $E(\overline{Q} - M)^2$, with $\overline{Q}$ is the mean quantity of rainfall of the k sites $\left(\overline{Q} = \frac{1}{k} \sum_{i=1}^{k} Q_{S_i}\right)$.

3.1 Mathematical formulation of the problem

Let $S = \{s_i \in D \subset IR^3, i = 1, \ldots, k\}$, be a set of sample of sites of size $k = |S| \leq n$, where n is the size of the domain D. The optimality criteria is given by:

$$\sigma^2(S^*/\varepsilon) = \min_{S\in D}\left\{E\left(\sum_{i=1}^{k}\frac{Q(s_i)}{k} - M\right)^2\right\}$$

k: Size of S.
S: Set of sample of size k.
$Q_{S_{ii}}$: Quantity of rainfall observed on site S_i.
$s_i^* = (x_i^*, y_i^*, z_i^*)$ $i = 1, 2, \ldots, k$: coordinates of optimal spatial sample S^*,
$\varepsilon = (\varepsilon(s_i))_{i=1,\ldots,k}$: Vector of correlated observations errors in each site, with mean zero and covariance function $\mathrm{Cov}(s_i, s_j)$ of a Gaussian spatial process, of analytical type. $E(\cdot)$ is mathematical mean, defined relatively to the law of ε.

3.2 Function of fitness

We have:

$$\sigma^2(S^*;\varepsilon) = \min\left\{\frac{1}{k^2}\left[(\mathrm{Cst})^2 + m^2\cdot\sum_{i=1}^{k}\sum_{j=1}^{k}\mathrm{Cov}\left(\varepsilon(s_i)\varepsilon(s_j)\right)\right]\right\}\ldots(I)$$

such that: $\{s_i \in S : i = 1, \ldots, k\}$ and $\{s_j \in S : j = 1, \ldots, k\}$ and Cst is an appropriate determined constant.

We applied our SGA algorithm for following choice of parameters, that are fixed by the expert:

- M: mean quantity of rainfall: 337.9 mm
- k: number of rainfall stations: 5
- Selection by ranging (Pressure of selection: 1.4)
- Crossover: OC and OLC are used, with adequate probabilities P_{OC} and P_{OLC}, receptively
- Mutation: OM is used with an adequate probability P_{OM}
- Spatial Covariance $\mathrm{Cov}(s_i, s_j) = \exp(-\theta\|s_i - s_j\|^2$, with $\theta = 0.05$

The initial choice of individual has an effect on the precision of solution. A positive effect, when this choice is a bad individual. For $\sigma^2(S^*/\varepsilon) = 0,62$, the corresponding optimal spatial configuration is given by the following figure.

The following table give the obtained results of the SGA, for optimum parameters and relatively to a regular sampling, by a repetition of 80 times of the SGA.

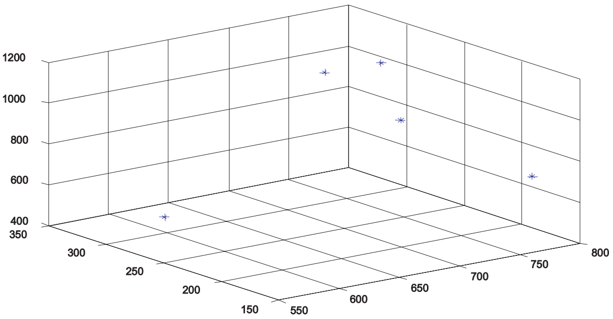

Figure 1: Optimal spatial Localization, obtained by the SGA.

P_{CG}	P_{CL}	**Absolute Error (AE):** $\|\overline{Q} - M\|$	**Confi. Interval of (AE)**
0.9	0.01	4.43, 3.98, 0.52, 1.81, 2.02, 1.4, 0.3, 1.26, 0.76, 0.11, 5.10, 2.41, 3.46, 9.07, 1.81, 0.651, 0.34, 0.41, 2.19, 0.00, 0.94, 0.75, 5.17, 2.80, 7.14, 2.79, 0.19, 1.78, 0.03, 0.19, 8.28, 0.63, 1.44, 7.59, 8.84, 1.42, 2.14, 0.58, 4.09, 2.46, 7.54, 1.42, 4.62, 2.02, 4.14, 0.39, 11.85, 0.11, 0.26, 1.11, 0.56, 1.81, 2.39, 0.84, 2.01, 0.01, 0.98, 1.58, 7.71, 3.28, 1.07, 2.16, 0.07, 0.21,0.95,4.56, 0.92, 0.03, 0.43, 1.22,1.46, 13.74, 7.81, 1.27, 5.51, 1.64, 0.90, 5.31, 1.18, 0.99.	[4.02, 9.96]

4 "Quantization"

The use of a "quantization" operator reduce the variability of the estimator of $\overline{Q}$ and improve the performance of the SGA, as it is shown by the following table:

P_{CG}	P_{CL}	**Absolute Error (AE):** $\|\overline{Q} - M\|$	**Confi. Interval of (AE)**
0.9	0.01	0.35 2.09 1.31 0.22 2.57 0.7 0.56 0.26 0.43 0.61 0.56 2.38 5.58 0.93 5.53 2.70 0.32 0.80 0.441 0.47 6.63 1.95 1.03 1.17 1.67	[2.43, 5.79]

5 Implementation

The SGA is implemented by the MATLAB language. The object procedure of this language are used in generation of Gaussian spatial measure errors and by simulation operators OC, OLC and OM.

6 Conclusion and comments

A Spatial Genetic Algorithm is proposed. The obtained results of sampling are improved by "quantization" of errors, for small size of sample. It justifies itself by the fact that the "quantization" has an effect on the regularity of function fitness, by creating a configuration of picks, desirable for an algorithm of type genetic. The perspective works will be devoted to improve parameters and operators of Spatial Genetic Algorithm, in order to decrease the size of errors and to obtain realistic confidence intervals more adapted to practical applications.

USING PRINCIPAL COMPONENTS ANALYSIS FOR DIMENSION REDUCTION PRIOR TO COMPOSITIONAL ANALYSIS

Mark John Brewer, David A. Elston, Lorna A. Dawson and Robert W. Mayes

Key words: Compositional analysis, principal components.

COMPSTAT 2004 section: Dimensional reduction.

Abstract: We investigate the use of principal components analysis (PCA) as an aid to compositional analysis. We study a data set concerning measurements of chemical markers (*n-alkanes* and *alcohols*) on artificially-created mixtures of grass and clover shoots. We go on to apply our procedure to mixture data sets based on actual Fourier Transform Infrared (FTIR) spectroscopy measurements on soil, where the very large number of markers recorded means that some form of dimension reduction is a necessity.

1 Introduction

We are concerned with data arising from research into the use of chemical markers for apportioning samples of mixtures of plant materials, faeces, soils, etc. into constituent components—i.e. *compositional analysis*. We assume that samples of the original components, here termed (*pure*) *sources* are also available, and that measurements on the chemical markers are made on both mixtures and sources. Note that it is the *problem*, not the *data set*, which is compositional, and that [2] and [3] introduce a Bayesian model for compositional analysis in these contexts.

The numbers of markers involved may be large. For example, spectroscopic methods return traces often comprising over a thousand variables. Consequently, we cannot conduct a compositional analysis without employing some form of dimension reduction. As the number of samples is likely to be relatively low, canonical variates analysis (CVA), an obvious choice where different groups occur in the data, will not be feasible (at least directly).

We first investigate the effectiveness of using PCA prior to compositional analysis on data sets with 15 markers measured on plant shoots, and compare the results with analyses on the full (non-rotated) sets of markers. We then study simulated mixture data sets based on real FTIR source measurements on three different soil types.

2 Compositional analysis

As our model has been introduced elsewhere ([2] and [3]), we provide only a brief description here. We assume there are N sources, for which there are A markers. We have direct measurements of markers for each source, denoted x_j^i for $j = 1, \dots, N$ with $i = 1, \dots, n_j$ samples from each source, and where x_j is a vector of length A. We assume multivariate normality of x_j with mean vectors μ_j and covariance matrices Σ_j, $j = 1, \dots, N$, hence

$$x_j^i \sim \mathrm{MVN}_A(\mu_j, \Sigma_j), \qquad j = 1, \dots, N, \quad i = 1, \dots, n_j. \tag{1}$$

Also, we have measurements on mixture samples, denoted similarly by z^k for $k = 1, \dots, n_z$ samples (z^k being another A-vector).

Further, we assume that each mixture sample is comprised of a weighted combination of *latent* draws from the source distributions at (1); we denote these latent quantities by y_j^k, and hence

$$y_j^k \sim \mathrm{MVN}_A(\mu_j, \Sigma_j), \qquad j = 1, \dots, N, \quad k = 1, \dots, n_z;$$

in addition, the weights are the source proportions, and hence we can model the mixture samples via

$$z^k = \sum_{j=1}^{N} p_j^k y_j^k + \epsilon^k, \quad k = 1, \dots, n_z;$$

where ϵ^k is an A-vector of measurement errors having zero mean (vector) and covariance Σ_ϵ. To model the composition proportions p_j, we use *log-ratios* [1] $q_j^k \equiv \log(p_j^k / p_N^k)$ for $j = 1, \dots, N-1$, and the overall log-ratio compositional $(N-1)$-vector q^k is also assumed multivariate normal, with

$$q^k \sim \mathrm{MVN}_{N-1}\left(\mu_q, \Sigma_q\right), \qquad k = 1, \dots, n_z,$$

for the mean vector μ_q on the log-ratio scale, and covariance Σ_q.

We complete the model definition by defining appropriate diffuse priors: multivariate normal for the mean vectors μ; and Wishart priors on the reciprocals of the covariance matrices Σ. We make inferences on the model via Markov chain Monte Carlo methods using the WinBUGS [5] package.

3 Analysis of plant shoot mixtures

3.1 Background

Chemical markers known as *n-alkanes* have been used in compositional analysis for some time now; [6] considered their use in determining diet composition using matrix methods. Another application using n-alkanes appeared in [3], where they were used to recover the proportions of artificially-mixed samples of grass and clover shoots ($N = 2$). Twelve sets of mixture samples were created at different mean/standard deviation (SD) combinations of clover proportions, shown in columns 1 and 2 of Table 1, expressed as percentages. For each of the twelve sets, 40 “target” clover proportions were generated

Percentages		Non-PCA Analysis		PCA, Mean-only Scaling			
Mean	SD	All 15	Best 3	1 PC	2 PCs	3 PCs	4 PCs
10	1	0.0200	0.0132	0.0324	0.0116	0.0125	0.0126

Table 1: Root mean square errors for estimated plant compositions.

to have the stated mean percentage and SD. There were $n_j = 140$ samples each of grass and clover. There were 9 n-alkanes considered in [3], and some attempt was made to determine important subsets of n-alkanes in terms of prediction accuracy measured by root mean square errors (RMSEs, recorded throughout on the *proportion* scale) of the estimates of the individual $n_z = 40$ target proportions for each mixture set.

This paper considers, in addition to the data of [3], measurements of 6 other chemical markers (*alcohols*), giving $A = 15$ markers in total. Columns 3 and 4 of Table 1 give the RMSEs for analyses using all 15 markers, and for the best subset of size 3 respectively. Note the overall superior performance of the subset relative to the full set; several other subsets have been studied (the selection informed by a discriminant analysis) which gave inferior RMSE performance, and which also included larger subsets of markers.

3.2 Dimension reduction

We consider here the use of PCA to reduce the dimensionality of the problem. We have noted how better results are obtained using only a subset of the markers, but that selection of this subset required considerable effort via discriminant analysis and compositional analyses on subjectively-chosen candidate subsets. We would hope that PCA might simplify this process, in a sense, by drawing out the important projections for apportionment. For this reason, we choose a PCA on the source samples *only*, and hence use the same projection for each set of mixture data.

A PCA was conducted on the 280 pure grass and clover samples; we used a mean-centred transform of the data, since transforming to unit variance

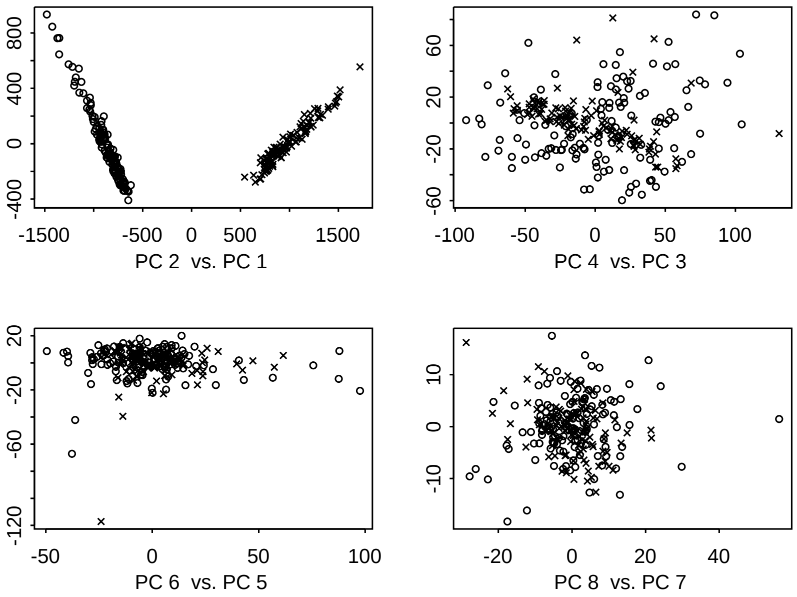

Figure 1: Plots of the first 8 PCs for the plant shoots data: grass (circles) and clover (crosses)

in addition proved less successful in terms of RMSE. The PCA suggested 94.5% of the variation was explained by the first PC, 99.7% by the first two, reaching 99.9% by the first four principal components (PCs). Figure 1 shows pairwise plots of the first 8 PCs. It is clear that the first PC separates the sources very well, the 2nd less well. The plot of PC4 vs. PC3 suggests a difference of scale in a diagonal direction, while the remaining plots show little distinction between grass and clover shoots. It is possible, therefore, that compositional analysis might benefit from the use of the first 4 PCs, while any more than this would be unnecessary. However, we evaluate this objectively below.

3.3 Compositional analysis

Following the PCA, we apply the rotation obtained from the source analysis to the mixed samples, and perform the compositional analysis on any chosen number of PCs. The final 4 columns of Table 1 contain the RMSEs for analyses using from (the first) 1 to 4 PCs. The results for 1 PC are poor; note that the first PC was almost identical to the first (and only) canonical variate (CV) here, and hence using 1 CV gave no improvement. Broadly speaking, it seems that for the mixture sets with the lowest SD, using 2 PCs provided the greatest accuracy; for the 2 sets with the largest SDs, 4 PCs appear to perform best; while for the rest, 3 PCs may be optimal. Results were not improved by using more than 4 PCs; beyond 4, the within-source variance becomes large relative to the between-source variance, and hence we are merely adding more uncertainty into our analysis.

Here, it seems that the larger the variance of the individual sample proportions, the more PCs are required to estimate the composition as best we can. Comparing the analysis of the PCs with the non-PCA analysis, we see that apart from the 30% mean, 12 SD case, use of the PCA-rotated data gives better or equivalent results for one or more numbers of PCs, and on the whole, might be described as doing better.

4 Analysis of FTIR soil data

4.1 Background

Our second example concerns the use of FTIR spectroscopy, where some form of dimension reduction is a *necessity* prior to compositional analysis. FTIR gives information on specific functional chemical groups present in mineral or organic matter by measuring the absorption pattern obtained in the infrared spectrum. The whole spectrum (fingerprint) may also contain information that relates to more general chemical or biological properties related to the influence of vegetation on soil, for example ([4]). FTIR is a rapid procedure, and as such has advantages where chemical or biological analyses are time-consuming or require fresh material.

We have FTIR readings on $N = 3$ sets of source samples of soils—these soils are broadly classified as Brown Earth, Alluvial and Cultivated Podzols. The FTIR spectroscopy returns trace plots which have been summarised by 1894 readings at particular wavelengths. For some regions of the traces, there is no meaningful information, and once these have been removed we are left with $A = 1264$ variables for analysis, with $n_j = 4$ samples of each source. We consider the situation where we might have mixtures of the three soil types, and wish to determine the relative proportions of each.

4.2 Dimension reduction

A PCA analysis of the FTIR source data suggests 61.9% of the variability is explained by the first PC, 92.6% by the first two and 96.6%, 98.4%, 99.3%, 99.8% by the first 3,4,5,6 PCs respectively. (We use the mean-centred transform, since again this provided better results.) We also consider obtaining the two CVs—on the 12 PCs, since the number of original variables is too large for sensible direct application of CVA. Figure 2 shows scatterplots of the first 8 PCs; the sources are well-separated for lower PCs, but the separation becomes less clear beyond the 6th. Thus, 6 PCs might represent the most information to be gained from the data for a compositional analysis; again, we investigate this by attempting to recover known proportions.

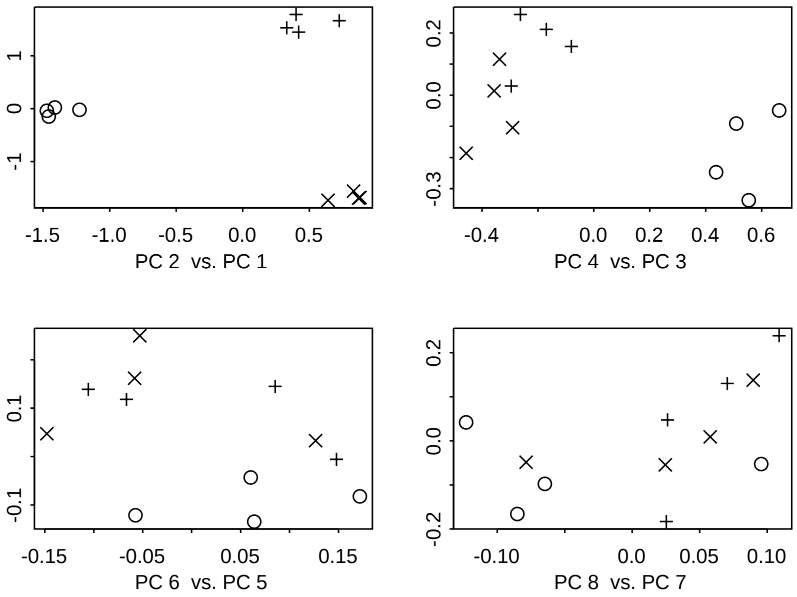

Figure 2: Plots of first 8 PCs for the FTIR soils data: Brown Earth (circles), Alluvial (addition signs), Cultivated Podzols (crosses).

Since no physical mixtures of the soils are as yet available, we obtained numerical mixtures of the source soils stochastically. We achieved this by repeatedly sampling randomly one of the 4 samples from each source, and then combining the FTIR values in the proportions indicated by the first three columns of Table 2. In fact, to obtain $n_z = 40$ mixture samples for each row of the table, we generated 40 uniform random numbers on prop $\pm\, 0.05$ (prop± 0.025 for the bottom six rows, which all include 0.05 as a proportion), and rescaled to ensure summation to 1. We also allowed for slight randomness on the FTIR values, but experiments without this produced similar results. Thus, for each set of mixture proportions, we have a sample of size 40 for analysis, and we can compare the estimated individual p^k with the proportions used in generating the mixture data via RMSEs as before.

4.3 Compositional analysis

The results from use of the first 3, 4, 5 and 6 PCs are shown in Table 2, along with those from use of the 2 CVs. Note that with 3 sources, we require at least 2 variables.

The results for 2 PCs are not shown as they were comparatively poor. For the top 7 proportion combinations in the table the best accuracy appears to occur when using 5 or 6 PCs, although the estimates themselves seem fairly stable with regard to the precise number. For the bottom 6 combinations, where the variability is less, this stability is even more evident, with good

Table 2: Root mean square errors for estimated soil compositions.

results being found using only 3 or 4 PCs. Comparing the RMSE values between the top 7 rows of the table, the accuracy of the estimates is lowest for the 10/10/80-split mixture sets, suggesting that apportionment is harder for cases where the proportions are more uneven.

Note that including more than 6 PCs did not produce further improvements; again, results worsened since variability along projections came to be dominated by within-source variance. Finally, the last column of Table 2 shows the RMSEs from use of the two CVs; perhaps surprisingly, the results are poor—even more so than the 2 PCs case, in fact.

5 Discussion

We have demonstrated the application of PCA as a tool for reducing the dimensionality of data sets in a compositional analysis context. For a relatively small example in terms of number of markers, we found results from analysing a PCA-rotated data set to be as good as or better than those from analysing a non-rotated data set in most cases. For a simulated mixture (from real source components) having well over a thousand markers, we found compositions accurate in all cases to less than 1%.

It was by no means a certainty that PCA would be useful in this context; PCA is concerned with projections maximising variation of a data set taken as whole, not making any distinctions between subsets of the data. Indeed, the procedure relies on source separation occurring in low-numbered PCs; if this does not happen, then the possibility exists of using a different selection of PCs in the analysis than simply the first n. PCA would not work for data where separation of sources was dwarfed by within-source variance, but then it is doubtful whether compositional analysis would be at all sensible.

The decision as to the number of PCs to use is aided by inspection of scatterplots of PCs, using different symbols or colours for each source. We try to find the point at which the separate sources appear indistinguishable. A scree plot is unlikely to be informative; in our examples, we found gains in compositional RMSE accuracy well beyond the point at which the "elbow" would have occurred.

Finally, we note the poor performance of CVA-derived data in this paper. This seems to be due to limitations on the number of CVs which can be derived, whereas the greater number of PCs available allow more subtle features of the compositions to be uncovered.

A ROBUSTIFICATION OF THE JARQUE-BERA TEST OF NORMALITY

Guy Brys, Mia Hubert and Anja Struyf

Key words: Robustness, skewness, tail weight, goodness-of-fit tests.

COMPSTAT 2004 section: Robustness.

Abstract: Many statistical tests have been proposed to find out whether a sample is drawn from a normal distribution or not. Here we discuss the Jarque-Bera test [1] which is based on the classical measures of skewness and kurtosis. As these measures are based on moments of the data, this test has a zero breakdown value. In other words, a single outlier can make the test worthless. In this paper we propose normality tests based on robust measures of skewness and tail weight. We investigate their power and their robustness by means of simulations and examples. We also outline how this approach can be extended to test for other distributions than the normal.

1 Introduction

The third and fourth moments of a distribution are called the skewness and kurtosis. For any distribution F with finite central moments μ_k $(k \leq 3)$, the *skewness* is defined as

$$\gamma_1(F) = \frac{\mu_3(F)}{\mu_2(F)^{3/2}}.$$

Skewness describes the asymmetry of a distribution. A symmetric distribution has zero skewness, an asymmetric distribution with the largest tail to the right has positive skewness, and a distribution with a longer left tail has negative skewness.

For any distribution F with finite central moments μ_k $(k \leq 4)$, the *kurtosis* is defined as

$$\gamma_2(F) = \frac{\mu_4(F)}{\mu_2(F)^2}.$$

There is no agreement on what it really measures. Strictly speaking, kurtosis measures both peakedness and tail heaviness of a distribution relative to that of the normal distribution. Consequently, its use is restricted to symmetric distributions. Finite-sample versions of γ_1 and γ_2 will be denoted by b_1 and b_2.

The classical skewness and kurtosis coefficient have some common disadvantages. They both have a zero breakdown value, and so they are very sensitive to outlying values. One single outlier can make the estimate become very large or small, making it hard to interpret. Another disadvantage is that they are only defined on distributions having finite moments.

In Section 2 we propose several measures of skewness and of left and right tail weight for univariate continuous distributions. Their interpretation is clear and they are robust against outlying values. Contrary to the kurtosis coefficient, the tail weight measures can be applied to symmetric as well as asymmetric distributions. In Section 3 we describe the Jarque-Bera test and introduce some robust normality tests. Section 4 includes simulation results while Section 5 applies the tests on real data. Finally, Section 6 concludes and gives outlines for future research.

2 Robust measures of skewness and tail weight

Assume we have independently sampled n observations $X_n = \{x_1, x_2, \ldots, x_n\}$ from a continuous univariate distribution F. We will consider the *medcouple* (MC), a robust skewness measure, proposed in Brys et al. [2] and extensively discussed in Brys et al. [3]. It is defined as

$$MC(F) = \operatorname*{med}_{x_1 \leq m_F \leq x_2} h(x_1, x_2)$$

with x_1 and x_2 sampled from F, $m_F = F^{-1}(0.5)$ and the kernel function h given by

$$h(x_i, x_j) = \frac{(x_j - m_F) - (m_F - x_i)}{x_j - x_i}.$$

Furthermore, we consider the *left medcouple* (LMC) and *right medcouple* (RMC), respectively the left and right tail weight measure, as defined in Brys et al. [4]. To construct these measures we have applied the medcouple to respectively the left and right half of the samples:

$$\mathrm{LMC}(F) = -\mathrm{MC}(x < m_F) \quad \text{and} \quad \mathrm{RMC}(F) = \mathrm{MC}(x > m_F).$$

Finite sample versions will be denoted by MC_n, LMC_n and RMC_n. These measures can be computed at any distribution, even when finite moments do not exist. Their computation can be performed in $\mathrm{O}(n \log n)$ time due to the fast algorithm described in Brys et al. [3]. They satisfy all natural requirements of skewness or tail weight measures including location and scale invariance. Moreover, they have good robustness properties. More details can be found in the cited references.

3 Normality tests

In this section we discuss four normality tests for the following null and alternative hypothesis:

$$\begin{cases} H_0 : \text{The data are sampled from a normal distribution} \\ H_1 : \text{The data are not sampled from a normal distribution} \end{cases}$$

First, the Jarque-Bera normality test (JB) uses the classical skewness and kurtosis coefficient. As been stated in Moors [7], under the normality assumption ($\gamma_1 = 0$ and $\gamma_2 = 3$) we can write:

	JB	MC1	MC2	MC3
ω	$\begin{pmatrix} 0 & 3 \end{pmatrix}$	$\begin{pmatrix} 0 \end{pmatrix}$	$\begin{pmatrix} 0.199 & 0.199 \end{pmatrix}$	$\begin{pmatrix} 0 & 0.199 & 0.199 \end{pmatrix}$
Σ_k	$\begin{pmatrix} 6 & 0 \\ 0 & 24 \end{pmatrix}$	$\begin{pmatrix} 1.25 \end{pmatrix}$	$\begin{pmatrix} 2.62 & -0.0123 \\ -0.0123 & 2.62 \end{pmatrix}$	$\begin{pmatrix} 1.25 & 0.323 & -0.323 \\ 0.323 & 2.62 & -0.0123 \\ -0.323 & -0.0123 & 2.62 \end{pmatrix}$

Table 1: Asymptotic mean ω and covariance matrix Σ_k of the (joint) distribution of several measures of skewness and tail weight.

$$\sqrt{n}\begin{pmatrix} b_1 \\ b_2 \end{pmatrix} \rightarrow_{\mathcal{D}} N_2\left(\begin{pmatrix} 0 \\ 3 \end{pmatrix}, \begin{pmatrix} 6 & 0 \\ 0 & 24 \end{pmatrix}\right)$$

which leads to the Jarque-Bera test statistic:

$$T = n\left(\frac{b_1^2}{6} + \frac{(b_2-3)^2}{24}\right) \approx \chi_2^2.$$

This test can be viewed as a special case of the following generalization. Let $w = (w_1, w_2, \ldots, w_k)$ be estimators of $\omega = (\omega_1, \omega_2, \ldots, \omega_k)$, such that

$$\sqrt{n}\begin{pmatrix} w_1 & \ldots & w_k \end{pmatrix} \rightarrow_{\mathcal{D}} N_k\left(\omega, \Sigma_k\right)$$

then the generalized test statistic T

$$T = n(w-\omega)^t \Sigma_k^{-1}(w-\omega) \approx \chi_k^2.$$

We can thus easily expand the number of goodness-of-fit tests. Taking $k = 2$, $w_1 = b_1$ and $w_2 = b_2$ leads to the JB test with $\omega_1 = \gamma_1 = 0$ and $\omega_2 = \gamma_2 = 3$. A test based on the medcouple (MC1) given in Brys et al. [3] has $k = 1$ and $w_1 = \text{MC}$. Tests solely based on one robust tail weight are proposed in Brys et al. [4]. In the latter paper also a comparison is included with a robust test proposed in Schmid and Trede [8] based solely on quantiles of the data. However as the power of these tests appeared to be rather low, we here construct tests that are based on the joint distribution of several robust measures of skewness and tail weight. First, we define a test based on the left and right medcouple (MC2) with $k = 2$, $w_1 = \text{LMC}$ and $w_2 = \text{RMC}$. Next, we propose a normality test based on MC, LMC and RMC (MC3) where $k = 3$, $w_1 = \text{MC}$, $w_2 = \text{LMC}$ and $w_3 = \text{RMC}$. Table 1 shows the values of ω and Σ_k under the null hypothesis of normality for the proposed normality tests. They are derived from the influence function of the estimators, as described in Brys et al. [3] and in Brys et al. [4].

Note that a robust test of normality could also be obtained by removing the outliers from the data, using an outlier detection rule such as provided by the boxplot or a rule based on robust estimators of location and scale. When the majority of the data are indeed normally distributed, this is a valuable alternative to our robust tests as both the boxplot and the most popular robust estimators of location and scale (such as M-estimators) are based on this normal assumption and thus will indicate the correct set of outliers. However it becomes more complicated when even the majority of the data points do not come from a normal distribution. A boxplot for example then typically shows too many outliers, and to construct an outlier rule one should have knowledge about the underlying distribution of the regular observations. Robust tests, such as the ones presented in Schmid and Trede [8], Moors [7] and in this paper, are based on characteristics of the majority of the data points, and hence they do not require an outlier detection procedure. Consequently, these tests are less powerful to detect non-normality than classical tests, but they are less sensitive to outlying values. This will be demonstrated in the next sections.

4 Simulation study

We investigate the performance of the four normality tests at Tukey's class of gh-distributions [6]. When a random variable Z is standard gaussian distributed, then

$$Y_{g,h} = \begin{cases} \frac{(e^{gZ}-1)}{g} e^{\frac{hZ^2}{2}} & g \neq 0 \\ Ze^{\frac{hZ^2}{2}} & g = 0 \end{cases}$$

is said to follow a gh-distribution $G_{g,h}$ with parameters $g \in \mathbb{R}$ and $h \geq 0$. The parameter g controls the skewness of the distribution, whereas h effects the tail weight. We generated 1000 samples of size 1000 from some $G_{g,h}$ distributions, and summarized the results in Table 2 by calculating the fraction of 1000 samples on which the null hypothesis of normality was rejected at the 5% significance level. In this way, the first column depicts the actual size of the tests, while the other columns represent their power.

It is straightforward to see that the JB test outperforms the other normality tests, followed by MC3 which is much more conservative. The poor performance of MC1 at fat tailed but symmetric distributions $G_{0,h}$, is due to the fact this test is based solely on the skewness of the distribution. Although MC2 is based on tail weight only, it also detects deviations from symmetry, which is a consequence of considering both the left and the right tail weight. Nevertheless, the power values of MC1 and MC2 are mostly lower than those of their combined test MC3.

We now compare the robustness of the normality tests using contaminated normal samples. Contaminated samples were created by taking normal samples of size $1000(1-\varepsilon)$, and adding a normal sample of outliers N(a,σ^2=1) of size 1000ε with $a = 7$ (right contamination, RC) and $a = -7$ (left contamination, LC). With central contamination (CC) a normal sample N(0,σ^2=0.05) of size 1000ε was added. We have also studied a more dispersed symmetric contamination (SC) by adding a normal sample N(0,σ^2=5) of size 1000ε. Here, we take ε equal to 1% and 5%. In Table 3 the fraction of 1000 samples on which the null hypothesis of normality was rejected is given. These values should remain close to the prescribed significance level of 5%.

	$G_{0,0.0}$	$G_{0,0.1}$	$G_{0,0.2}$	$G_{0,0.3}$	$G_{0.1,0.0}$	$G_{0.1,0.1}$	$G_{0.3,0.0}$	$G_{0.3,0.1}$
JB	0.038	0.999	1.000	1.000	1.000	1.000	1.000	1.000
MC1	0.038	0.058	0.063	0.076	0.225	0.235	0.965	0.941
MC2	0.036	0.218	0.688	0.939	0.064	0.254	0.425	0.560
MC3	0.030	0.196	0.617	0.914	0.223	0.383	0.986	0.991

Table 2: Fraction of 1000 samples of data size 1000 from several distributions $G_{g,h}$ on which the null hypothesis of normality was rejected at the 5% significance level.

	RC(1%)	RC(5%)	LC(1%)	LC(5%)	SC(1%)	SC(5%)	CC(1%)	CC(5%)
JB	1.000	1.000	1.000	1.000	0.991	1.000	0.058	0.162
MC1	0.061	0.319	0.067	0.338	0.039	0.072	0.028	0.033
MC2	0.056	0.359	0.044	0.362	0.058	0.094	0.041	0.046
MC3	0.050	0.588	0.052	0.598	0.058	0.092	0.031	0.047

Table 3: Fraction of 1000 samples of data size 1000 from several contaminated normal samples on which the null hypothesis of normality was rejected.

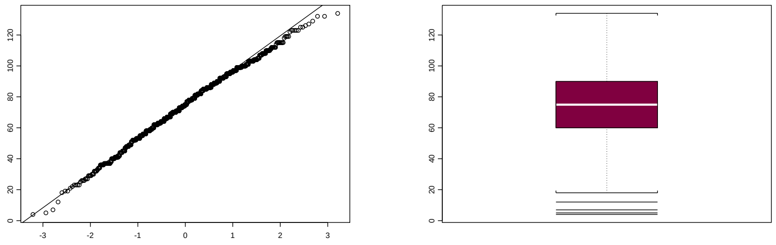
We notice that the JB test is very sensitive to outlying values, especially at right, left and symmetric contamination. The robust normality tests perform better in all cases. Their performance is very comparable except at 5% left and right contamination where MC1 and MC2 are more robust than MC3.

5 Examples

In this section we analyse two data sets which illustrate the robustness of our tests compared to the JB test.

The first data set comes from the Associated Examining Board in Guilford [5] and contains a sample of 1000 scores of students on the writing of a paper. From the normal QQ-plot of Figure 1(a) and the boxplot in Figure 1(b) the assumption of normality seems appropriate. Only a few minor outliers are visible on the boxplot. In Table 4 the non-robustness of the JB test is illustrated. Normality is rejected at the 5% significance level when the outliers from the boxplot are included, but is accepted when they are excluded. On the contrary, the robust normality tests are based on the majority of the data and so they behave the same in both situations. As could be expected, they all detect normality in this data set. Note also the higher significance values of the robust tests compared to the JB test.

Our second example is the speed of light data set [9] which measures the time required for light to travel from a laboratory to a mirror and back, over a total distance of 7400m. This data set contains 66 observations, which is low compared with our simulation study, but we will see that also in this situation the Jarque-Bera test may fail. From the normal QQ-plot and the boxplot in Figure 2 we have the impression that these data come from a normal



(a) (b)

Figure 1: The Guilford data: (a) normal QQ-plot; (b) boxplot.

	JB	MC1	MC2	MC3
Guilford, outliers included	0.039	1.000	0.901	0.975
Guilford, outliers excluded	0.087	1.000	0.967	0.995
Speed of light, outliers included	0.000	1.000	0.308	0.492
Speed of light, outliers excluded	0.855	1.000	0.957	0.992

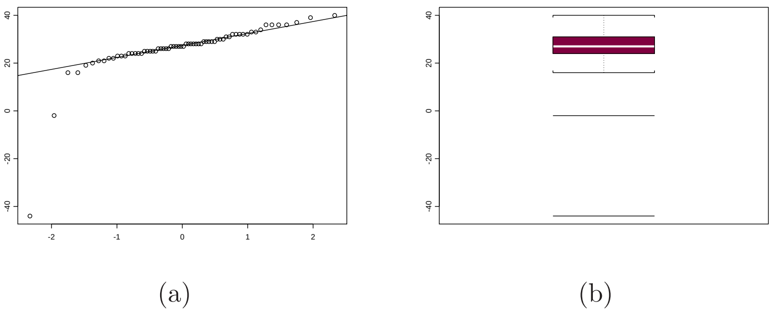
Table 4: Significance of the tests JB, MC1, MC2 and MC3 at the Guilford and speed of light data set, both with outliers included or excluded.

distribution, apart from two clear outliers. As can be seen from Table 4, the JB test applied on the full data rejects the null hypothesis at any significance level, a result which is due to the two outlying values. Excluding those outliers again leads to the opposite conclusion. The robust normality tests detect in both situations the normal behavior which is present in the large majority of the observations.

Of course we do not know whether the so-called outliers in these two data sets are contaminated observations, or whether the true distribution has a long left tail. We therefore recommend to apply both the robust and the classical test. If they contradict each other, the researcher is stimulated to study the nature of these ‘outliers’ in detail.

6 Conclusions

In this paper we have discussed the Jarque-Bera test of normality which is not able to detect normality in the presence of outlying values. Therefore, three robust normality tests have been proposed, which are all based on the medcouple, a robust measure of skewness. The test MC3 which combines the medcouple with a left (LMC) and a right (RMC) measure of tail weight is seen to give the best overall result.



(a) (b)

Figure 2: The speed of light data: (a) normal QQ-plot; (b) boxplot.

In our future research, we will investigate the power of these tests at smaller sample sizes and we will generalize our approach to test whether data are sampled from another distribution than the normal (where again, outlier detection rules become complicated). We then only need to compute the asymptotic mean and covariance matrix as in Table 1. This can be done quickly using a Mathematica program which is available from our website (`www.agoras.ua.ac.be`). Note that the Jarque-Bera test can only be generalized for distributions where the third and fourth moment exist, an assumption which often doesn't hold.

These generalized robust tests will then be used to test distributional assumptions of robust procedures. If, for example, a robust covariance matrix is computed, the underlying assumption is multivariate normality for the majority of the data. A robust test can then be applied to the Mahalanobis distances from the robust fit. The same idea applies to check normality of the residuals from a robust regression procedure.

COMPSTAT'2004 Symposium

A GENERALISED PAV ALGORITHM FOR MONOTONIC REGRESSION IN SEVERAL VARIABLES

Oleg Burdakow, Anders Grimwall and M. Hussian

Key words: Statistical computing, numerical algorithms, monotonic regression, nonparametric regression, pool-adjacent-violators algorithm.

COMPSTAT 2004 section: Nonparametrical statistics.

Abstract: We present a new algorithm for monotonic regression in one or more explanatory variables. Formally, our method generalises the well-known PAV (pool-adjacent-violators) algorithm from fully to partially ordered data. The computational complexity of our algorithm is $O(n^2)$. The goodness-of-fit to observed data is much closer to optimal than for simple averaging techniques.

1 Introduction

Monotonic regression is a nonparametric method that is appropriate to use when a response variable (y) is increasing or decreasing in one or more explanatory variables ($x_1, \ldots, x_p$). Over the past decades, several numerical algorithms have been developed to facilitate practical application of this method. However, all the algorithms that are currently in use have considerable drawbacks.

The most widespread computational method for monotonic regression is the so-called pool-adjacent-violators (PAV) algorithm [1], [2], [8]. When $p = 1$, this algorithm is computationally efficient and provides solutions that are optimal in the sense that the mean square error is minimised. However, if $p > 1$, the PAV algorithm is less useful. Special cases in which the values of the explanatory variables can be grouped into a moderate number of classes can be handled by repeatedly applying the PAV algorithm to different subsets of data [4], [6], [15], [16]. Other approaches are required for typical multiple regression data in which at least one of the explanatory variables is continuous.

Simple averaging techniques constitute another widespread group of methods. The main idea is to form a weighted mean of two monotonic functions that embrace all observed values of the response variable [11], [12], [16]. In contrast to the PAV algorithm, simple averaging techniques can easily accommodate several explanatory variables. On the other hand, the latter techniques are sensitive to outliers, and the goodness-of-fit can be far from optimal.

Quadratic programming provides yet another approach to monotonic regression [3], [7]. Given a set of observations $\{(x_{1i}, \ldots, x_{pi}, y_i), i = 1, \ldots, n\}$, we shall find a set of fitted values $\{z_i, i = 1, \ldots, n\}$ such that

$$S = \sum_{i=1}^{n} (z_i - y_i)^2$$

is minimised under the constraints induced by the partially ordered data, namely

$$z_i \leq z_j, \text{ if } x_{ki} \leq x_{kj} \text{ for } k = 1, \dots, p.$$

All available algorithms for such solutions entail a considerable computational burden, even for moderately large data sets. The best known computational complexity is $O(n^4)$, and it refers to an algorithm introduced in [10]. Development of more efficient algorithms remains an open problem.

Here, we generalise the PAV algorithm from fully to partially ordered data, and we show how this algorithm can be used for monotonic regression in one or more explanatory variables. In addition, we examine the performance of this algorithm with respect to computational burden and goodness-of-fit to observed data.

2 Main characteristics of the PAV algorithm

Let $M_n = \{(x_i, y_i), i = 1, \dots, n\}$ denote a set of n observations of one explanatory variable (x) and one response variable (y), and assume that the x-values are sorted in increasing order. Then the PAV algorithm computes a non-decreasing sequence of values $\{z_i, i = 1, \dots, n\}$ such that

$$S = \sum_{i=1}^{n} (z_i - y_i)^2$$

is minimised. The cited algorithm is recursive in the sense that the optimal solution for the data set M_n is constructed by starting from the solution for M_1, which is subsequently modified into the solution for M_2, and so on. Moreover, it has the following characteristics:

(i) M_{r+1} is formed by extending M_r with a data point (x_{r+1}, y_{r+1}), such that $x_{r+1} \leq x_i$ for all $i > r + 1$.

(ii) If the values $z_1, \dots, z_r$ denote the solution obtained for M_r, then a preliminary solution for M_{r+1} is formed by setting $z_{r+1} = y_{r+1}$. Thereafter, the final solution for M_{r+1} is derived by pooling adjacent z-values that violate the monotonicity constraints. To be more precise, $z_{r+1}, \dots, z_{r+1-k}$ are assigned the common value $(z_{r+1} + \dots + z_{r+1-k})/(k + 1)$, where k is the smallest non-negative integer such that the new values of $z_1, \dots, z_{r+1}$ form a non-decreasing sequence.

(iii) The optimal solution $\{z_i, i = 1, \dots, n\}$ for M_n is composed of clusters of identical z-values.

3 An alternative formulation of the PAV algorithm

The removal of monotonicity violators implies that adjacent clusters of identical z-values are joined to form new and larger clusters. To achieve a more precise reformulation of the PAV algorithm, we introduce the notation $I = \{i_1, \ldots, i_m\}$ for a cluster consisting of a set of adjacent indices $i_1, \ldots, i_m$. Furthermore, we use $|I|$ for the number of elements in I, and the symbol $z(I)$ for the common value of all $z_i, i \in I$. When two adjacent clusters I_1 and I_2 are joined to form a new cluster $I_1 \cup I_2$, the associated z-value is given by the expression

$$z(I_1 \cup I_2) = \frac{|I_1|z(I_1) + |I_2|z(I_2)}{|I_1| + |I_2|}.$$

If the clusters $I_1, \ldots, I_q$ and their associated values $z(I_1), \ldots, z(I_q)$ compose the optimal solution for M_r, then a preliminary solution for M_{r+1} is formed by introducing the cluster I_{q+1} consisting of the integer $r + 1$, and setting $z(I_{q+1}) = y_{r+1}$. Thereafter, the final solution for M_{r+1} is obtained by joining I_{q+1} with adjacent left-neighbour clusters, one by one, until the z-values violating the monotonicity constraints have been removed.

4 A generalised PAV algorithm for partially ordered data

In our generalisation of the PAV algorithm to partially ordered data, we use the notions introduced in the previous sections. Let $M_n = \{(x_{1i}, \ldots, x_{pi}, y_i),$ $i = 1, \ldots, n\}$ denote a set of n observations of p explanatory variables and one response variable. Also, let $x_i = (x_{1i}, \ldots, x_{pi}), i = 1, \ldots, n$, denote the elements in R^p that are defined by the explanatory variables. Then we can define a partial order on the set $U_n = \{x_i, i = 1, \ldots, n\}$ by setting

$$x_i \preceq x_j \text{ if } x_{ki} \leq x_{kj}, k = 1, \ldots, p,$$

and subsequently sort the elements of U_n (and M_n) in such a way that, for each i, x_i is a minimal element of the set $V_i = \{x_j, j = i, \ldots, n\}$. Furthermore, we can compute the lower cover L_i of each x_i. The latter set consists of all elements x_j, such that

$$x_j \preceq x_i$$

and the inequalites

$$x_j \preceq x_k \preceq x_i$$

are satisfied only if $x_j = x_k$ or $x_k = x_i$.

Like the original PAV algorithm, our generalisation is recursive. Furthermore, it has the following features:

(i) M_{r+1} is formed by extending M_r with a data point (x_{r+1}, y_{r+1}), such that, for all $i > r+1$, either $x_{r+1} \preceq x_i$, or x_{r+1} is incomparable with x_i.

(ii) If the clusters $I_1, \ldots, I_q$ and their associated values $z(I_1), \ldots, z(I_q)$ denote a solution for M_r, then a preliminary solution for M_{r+1} is formed by introducing the cluster I_{q+1} consisting of the integer $r + 1$, and setting $z(I_{q+1}) = y_{r+1}$. Thereafter, the final solution for M_{r+1} is obtained by joining I_{q+1} with left-neighbour clusters, one by one, until the z-values violating the monotonicity constraints have been removed. A cluster I_j is called a left neighbour of I_l if there exists an $i \in I_j$ and a $k \in I_l$ such that x_i belongs to the lower cover of x_k.

(iii) The solution $\{z_i, i = 1, \ldots, n\}$ obtained for M_n is composed of clusters of identical z-values.

Due to their construction, the solutions obtained by using the generalised PAV algorithm are monotonic in the explanatory variables. However, two ambiguities should be noted:

(i) a cluster may have several different left neighbours;

(ii) the pre-sorting which ensures that, for each i, x_i is a minimal element of the set $V_i = \{x_j, j = i, \ldots, n\}$ may be done in different ways.

The first ambiguity is easy to remove. The goodness-of-fit will be improved, if the largest violator of monotonicity is removed first, whenever a cluster has several left neighbours. The second ambiguity is more intricate, and our generalised PAV algorithm will not necessarily attain the minimal value of the mean square error.

5 Computational burden

The computations can be divided into pre-calculations and a recursive establishment of solutions for the data sets $M_r, r = 1, \ldots, n$. The pre-calculations have three major components: (i) establishment of a partial order on the set $\{x_i, i = 1, \ldots, n\}$; (ii) sorting of the observations to ensure that, for each i, x_i is a minimal element of the set $V_i = \{x_j, j = i, \ldots, n\}$; (iii) calculation of the lower cover of each x_i.

Test runs of a VisualBasic implementation of the algorithm showed that data sets consisting of several hundred observations can be processed in less than a second using an ordinary PC. Most of the computer time was usually spent on the calculation of lower covers, followed by the establishment of a partial order and the removal of monotonicity violators. It is also noteworthy that with our generalised algorithm, after the partial order has been established, the number of explanatory variables does not influence the computational burden.

A theoretical analysis of the proposed algorithm showed that its complexity is $O(n^2)$. This result will be proved in a separate paper. The proof is based on the following observations. The pre-calculations can be carried out in $O(n^2)$ elementary arithmetic operations. Each operation of joining clusters is preceded by the search of the largest violator among the left neighbours.

Correlation	Mean square error			
	Normally distr. errors		Exponentially distr. errors	
	GPAV	SA	GPAV	SA
0	0.72	0.80	0.77	1.05
0.9	0.75	0.90	0.75	1.15
-0.9	0.75	0.88	0.75	1.12

Table 1: Mean square error for monotonic regression in two explanatory variables using the generalised PAV algorithm (GPAV) and a simple averaging technique (SA). The table shows mean values for 100 data sets, each consisting of 400 observations.

Such search requires at most n comparisons. The complexity of joining clusters is also $O(n)$. Since the total number of joinings cannot exceed n, the overall complexity related to joining is $O(n^2)$. The number of cases, in which the search of the largest among the left neighbours does not result in joining of clusters, is below n. Thus, the contribution of these cases to the complexity does not exceed $O(n^2)$.

When the structure of partially ordered data is a tree, the algorithm is guaranteed to produce the optimal solution, and it has the same complexity as the algorithm introduced in [13], namely $O(n \log n)$.

6 Goodness-of-fit

A simulation study was undertaken to compare the goodness-of-fit that could be achieved by applying (i) the generalised PAV algorithm and (ii) the simple averaging technique described by Mukarjee in [11]. All of the analysed data sets were generated according to the equation

$$y = x_1 + x_2 + \epsilon$$

where $(x_1, x_2)^*$ was normally distributed with mean zero, variance one, and correlation ρ. The error terms ϵ were either normally or exponentially distributed with variance 1. Table 1 shows that, regardless of the distribution of the error terms or the correlation between the two explanatory variables, the generalised PAV algorithm performed better than the simple averaging technique. Furthermore, the difference in goodness-of-fit was particularly large for heavy-tailed (exponentially distributed) error terms.

7 Discussion

Models of monotonic responses in two or more explanatory variables have a large number of applications in many areas. Thus far, use of monotonic regression has been hampered by the lack of algorithms suitable for typical multiple regression data. With the generalised PAV algorithm, it is feasible to handle data sets that include hundreds or even thousands of observations of one response variable and an arbitrary number of explanatory variables. For moderately large data sets, it is possible to combine monotonic regression with general model selection techniques, such as cross-validation.

The test runs described in this article show that our generalisation of the PAV algorithm has high efficiency from the viewpoint of both its accuracy (goodness-of-fit) and computational time. Two recent conference contributions [5], [9] involving further numerical experiments and applications in environmental science confirm the main results. The present version of the generalised PAV algorithm is superior to simple averaging techniques, but it may not always provide least squares solutions. Further work is needed to determine the extent to which the goodness-of-fit can be improved by removing or reducing the non-optimal performance.

CONDITIONAL QUANTILES WITH FUNCTIONAL COVARIATES: AN APPLICATION TO OZONE POLLUTION FORECASTING

Hervé Cardot, Christophe Crambes and Pascal Sarda

Key words: Functional data analysis, conditional quantiles, robustness, B-spline functions, weighted least squares, backfitting algorithm, Ozone forecasting.

COMPSTAT 2004 section: Functional data analysis.

Abstract: We are interested in estimating conditional quantiles when the covariariates are functions. We modelize the conditional quantiles as a continuous linear functional of the covariates and we propose a spline estimator of the coefficient which minimizes a L^1-type penalized criterion. Then we give some insights on the asymptotic behaviour of this estimator. This approach is illustrated on pollution data in the area of Toulouse.

1 Presentation of the pollution data

Pollution forecasting is nowadays of primary importance, particularly for prevention. In the city of Toulouse (France), the ORAMIP [1] gets measures, in six different places, of specific pollutants. These measures, as well as meteorological measures, are made each hour. So we have functional variables (see Ramsay and Silverman [13], [14]) known in some discretisation points.

More precisely, the data consist in hourly measurements during the period going from the 15th May to the 15th September for the years 1997, 1998, 1999 and 2000. Measurements are obtained for the following variables: Nitrogen Monoxide, Nitrogen Dioxide, Dusts, Ozone, Wind Direction, Wind Speed, Temperature, Humidity and Sun Radiance. Some data are missing, mainly because of breakdowns or missing measurement apparatus.

A PCA of these data has shown that the behaviour of these variables does not vary much from one station to another. This allows us to handle the problem of missing data by considering a "mean" station, taking the functional mean over the stations for each variable.

The aim of the study is to predict the maximum of Ozone for a day knowing the (functional) values of the above five variables the day before. We present in section 2 a generalization of the model proposed by Koenker and Bassett [9] which allows to estimate a conditional quantile for several functional predictor. Estimates are built by a B-splines expansion and the minimization of a L^1-type penalized criterion. Our methodology is illustrated in section 3 with the prediction of Ozone in the area of Toulouse.

2 Quantile regression for functional covariates

2.1 Conditional quantiles for functional covariates

Let us consider a sample $(X_i, Y_i)_{i=1,\ldots,n}$ of pairs of random variables, independent and identically distributed, with the same distribution as (X, Y), with X belonging to the functional space $L^2([0,1])$ of square integrable functions defined on $[0,1]$, and Y belonging to $\mathbb{R}$. Without loss of generality, we suppose that X is a centered variable, that is to say $\mathbb{E}(X) = 0$. Assume that H, the range of X, is a closed subspace of $L^2([0,1])$. Let α be a real number in $]0,1[$ and x a function in H. The *conditional α-quantile* of Y given $[X = x]$ is defined as the scalar $g_\alpha(x)$ such that

$$P(Y \leq g_\alpha(x)|X = x) = \alpha, \tag{1}$$

where $P(.|X = x)$ is the conditional probability given $[X = x]$.

Provided that $\mathbb{E}|Y| < \infty$, $g_\alpha(x)$ can be defined in an equivalent way as the solution of the minimization problem

$$\min_{a \in \mathbb{R}} \mathbb{E}(l_\alpha(Y - a)|X = x), \tag{2}$$

where l_α is the function defined by $l_\alpha(u) = |u| + (2\alpha - 1)u$ (see [9]).

We assume now that g_α is a linear and continuous functional. This condition can be seen as the direct generalization of the model introduced by Koenker and Bassett, the difference being that here, the covariates are functions. Then, there exists a unique function $\Psi_\alpha \in L^2([0,1])$ such that

$$g_\alpha(X) = \langle \Psi_\alpha, X \rangle = c + \int_0^1 \Psi_\alpha(t) X(t)\, dt, \tag{3}$$

where the notation $\langle ., . \rangle$ refers to the usual inner product of $L^2([0,1])$. The norm of $L^2([0,1])$ induced by this inner product is denoted by $\|.\|$.

2.2 Spline estimator of Ψ_α

Our goal is to introduce now an estimator of the function Ψ_α. When the covariate X is real, Koenker and Bassett [9] have proposed an estimator based on the minimization of the empirical version of (2); for nonparametric modelling, estimators have already been proposed: see for example Bhattacharya and Gangopadhyay [2], Fan, Hu and Truong [6] or Lejeune and Sarda [11]. He and Shi [8] proposed a spline estimator and although our setting is quite different, the estimator of Ψ_α defined below is of the same type as the one introduced by He and Shi (based on regression splines). However in our (functional) case there is a need to introduce a penalization in the criterion to be minimized.

We consider a space of spline functions: for this we choose a degree (fixed) and knots in the interval $[0,1]$. For given integers q and $k = k_n$, with $k \neq 0$, we consider splines of degree q and $k-1$ equispaced knots on $[0,1]$ (see [5]). This space of spline functions is a vectorial space of dimension $k+q$. A basis of this vectorial space is the set of the so-called B-spline functions, that we note $\mathbf{B_{k,q}} = {}^{t}(B_1, \ldots, B_{k+q})$.

We estimate Ψ_α by a linear combination of the B_l functions. This leads us to find a vector $\widehat{\boldsymbol{\theta}} = {}^{t}(\widehat{\theta}_1, \ldots, \widehat{\theta}_{k+q})$ in $\mathbb{R}^{k+q}$ such that

$$\widehat{\Psi}_\alpha = \sum_{l=1}^{k+q} \widehat{\theta}_l B_l = {}^{t}\mathbf{B_{k,q}}\widehat{\boldsymbol{\theta}}, \tag{4}$$

where $\widehat{\boldsymbol{\theta}}$ is the solution of the following minimization problem, which is the penalized empirical version of (2),

$$\min_{\theta \in \mathbb{R}^{k+q}} \left\{ \frac{1}{n} \sum_{i=1}^{n} l_\alpha(Y_i - c - \langle {}^{t}\mathbf{B_{k,q}}\boldsymbol{\theta}, X_i \rangle) + \rho \parallel ({}^{t}\mathbf{B_{k,q}}\boldsymbol{\theta})^{(m)} \parallel^2 \right\}, \tag{5}$$

where $({}^{t}\mathbf{B_{k,q}}\boldsymbol{\theta})^{(m)}$ is the m-th derivative of the spline function ${}^{t}\mathbf{B_{k,q}}\boldsymbol{\theta}$ and ρ is a penalization parameter which role is to control the smoothness of the estimator. This criterion is similar to the one introduced by Cardot et al. [4] for the estimation of the conditional mean in the functional linear model, the quadratic function being replaced here by the loss function l_α. In this case, we have to deal with an optimization problem that does not have an explicit solution, contrary to the case of the functional linear model. That is why we adopted the strategy proposed by Lejeune and Sarda [11]. At first, let us note that the minimization problem (5) is equivalent to

$$\min_{c \in \mathbb{R}, \boldsymbol{\theta} \in \mathbb{R}^{k+q}} \left\{ \frac{1}{n} \sum_{i=1}^{n} \delta_i(\alpha) \mid Y_i - c - \langle {}^{t}\mathbf{B}_{k,q}\boldsymbol{\theta}, X_i \rangle \mid + \rho \parallel ({}^{t}\mathbf{B}_{k,q}\boldsymbol{\theta})^{(m)} \parallel^2 \right\}. \tag{6}$$

where the function δ_i is defined by $\delta_i(\alpha) = 2\alpha \mathbb{1}_{\{Y_i - c - \langle {}^{t}\mathbf{B}_{k,q}\theta, X_i \rangle \geq 0\}} + 2(1-\alpha)\mathbb{1}_{\{Y_i - c - \langle {}^{t}\mathbf{B}_{k,q}\theta, X_i \rangle < 0\}}$. The algorithm for solving (6) described below consists in performing iterative reweighted least squares (see [15]: at step $j+1$, $\delta_i(\alpha)$ is replaced by the value $\delta_i^j(\alpha)$ evaluated at step j and the absolute value is replaced by the ratio of square residuals (at step $j+1$) on the root of residuals computed from step j.

- **Initialization**

  We determine $\boldsymbol{\beta}^1 = {}^{t}(c^1, \boldsymbol{\theta}^1)$ solution of the minimization problem

$$\min_{c \in \mathbb{R}, \boldsymbol{\theta} \in \mathbb{R}^{k+q}} \left\{ \frac{1}{n} \sum_{i=1}^{n} (Y_i - c - \langle {}^{t}\mathbf{B}_{k,q}\boldsymbol{\theta}, X_i \rangle)^2 + \rho \parallel ({}^{t}\mathbf{B}_{k,q}\boldsymbol{\theta})^{(m)} \parallel^2 \right\},$$

  which solution $\boldsymbol{\beta}^1$ is given by $\boldsymbol{\beta}^1 = \frac{1}{n}(\frac{1}{n}\,{}^{t}\mathbf{D}\mathbf{D} + \rho\mathbf{K})^{-1}\,{}^{t}\mathbf{D}\mathbf{Y}$, with

$$\mathbf{D} = \begin{pmatrix} 1 & \langle B_1, X_1\rangle & \dots & \langle B_{k+q}, X_1\rangle \\ \vdots & \vdots & & \vdots \\ 1 & \langle B_1, X_n\rangle & \dots & \langle B_{k+q}, X_n\rangle \end{pmatrix} \quad \text{and} \quad \mathbf{K} = \begin{pmatrix} 0 & 0 \\ 0 & \mathbf{G} \end{pmatrix},$$

where $\mathbf{G}$ is the $(k+q)\times(k+q)$ matrix such that $\mathbf{G}_{jl} =< B_j^{(m)}, B_l^{(m)} >$.

- **Step j+1**

  Knowing $\boldsymbol{\beta}^j = {}^t(c^j, \boldsymbol{\theta}^j)$, we determine $\boldsymbol{\beta}^{j+1} = {}^t(c^{j+1}, \boldsymbol{\theta}^{j+1})$ solution of the minimization problem

$$\min_{c\in\mathbb{R}, \boldsymbol{\theta}\in\mathbb{R}^{k+q}} \left\{ \frac{1}{n}\sum_{i=1}^{n} \frac{\delta_i^j(\alpha)(Y_i - c - \langle {}^t\mathbf{B}_{k,q}\boldsymbol{\theta}, X_i\rangle)^2}{[(Y_i - c - \langle {}^t\mathbf{B}_{k,q}\boldsymbol{\theta}^j, X_i\rangle)^2 + \eta^2]^{1/2}} + \rho \parallel ({}^t\mathbf{B}_{k,q}\boldsymbol{\theta})^{(m)} \parallel^2 \right\},$$

  where η is a strictly positive constant that allows us to avoid a denominator equal to zero. Let us define the $n \times n$ diagonal matrix $\mathbf{W}_j$ with diagonal elements given by

$$[\mathbf{W}_j]_{ll} = \frac{\delta_1^j(\alpha)}{n[(Y_l - c - \langle {}^t\mathbf{B}_{k,q}\boldsymbol{\theta}, X_l\rangle)^2 + \eta^2]^{1/2}}.$$

  Then, $\beta^{j+1} = ({}^t\mathbf{D}\mathbf{W}_j\mathbf{D} + \rho\mathbf{K})^{-1}\ {}^t\mathbf{D}\mathbf{W}_j\mathbf{Y}$.

Let us notice that, at each step of the algorithm, the estimator depends on many parameters: the number k of knots, the degree q of the spline functions, the order m of derivation, and the parameter ρ of the penalization. In our experience, we noticed that the penalization parameter ρ is of primary importance at least when the number of knots is large enough (see also Marks and Eilers [12], Besse et. al. [1]). For this reason, we choose in our study (see section 3) to fix $q = 3$ and $m = 2$, which are values commonly used to reach a sufficient degree of regularity. After several attempts, we fix k to be 8 *i.e.* a number of knots which is not too small. Now, the parameter ρ is chosen by minimizing the generalized cross validation criterion (see [16])

$$GCV(\rho) = \frac{\frac{1}{n}\sum_{l=1}^{n}(Y_l - \widehat{Y}_l)^2}{\left(1 - \frac{1}{n}Tr(\mathbf{H}(\rho))\right)^2}, \tag{7}$$

where $\widehat{\mathbf{Y}} = \mathbf{H}(\rho)\mathbf{Y}$ and $\mathbf{H}(\rho) = \frac{1}{n}\mathbf{D}(\frac{1}{n}\ {}^t\mathbf{D}\mathbf{D} + \rho\mathbf{K})^{-1}\ {}^t\mathbf{D}$.

2.3 Multiple conditional quantiles

Let us notice that this estimation procedure can be easily extended to the case where there is more than one covariate. Considering now v functional covariates $X^1, \ldots, X^v$, we have the following model

$$P(Y_i \leq c + g_\alpha^1(X_i^1) + \ldots + g_\alpha^v(X_i^v)/X_i^1 = x_i^1, \ldots, X_i^v = x_i^v) = \alpha. \quad (8)$$

If we assume as before that $g_\alpha^1, \ldots, g_\alpha^v$ are linear and continuous functionals from a clsoed subspace of $L^2([0,1])$, we can write $g_\alpha^r(X_i^r) = \langle \Psi_\alpha^r, X_i^r \rangle$ for $r = 1, \ldots, v$ with $\Psi_\alpha^1, \ldots, \Psi_\alpha^v$ in $L^2([0,1])$. The estimation of each function Ψ_α^r is obtained using the iterative backfitting algorithm (see [7]) combined with the algorithm described previously.

2.4 An asymptotic result

In this section we give some insights on the asymptotic behavior of $\widehat{\Psi}_\alpha$. As a matter of fact, we give an upper bound for the L^2 convergence: the proof of this result can be found in Cardot et al. [3].

Let us introduce now some notations. If we assume that $\mathbb{E}\|X\|^2 < \infty$, the covariance operator of X, denoted by Γ_X, is defined for all u in $L^2([0,1])$ by $\Gamma_X u = \mathbb{E}\left(\langle X, u\rangle X\right)$. This operator is non-negative, so we can associate a semi-norm noted $\|.\|_2$ and defined by $\|u\|_2^2 = \langle \Gamma_X u, u\rangle$. Using notations from Cardot et al. [4], we consider the $(k+q)\times(k+q)$ matrix $\widehat{\mathbf{C}}$ with general term $\langle \Gamma_n(B_j), B_l\rangle$ where Γ_n is the empirical version of Γ. Moreover, we set $\widehat{\mathbf{C}}_{\boldsymbol{\rho}} = \widehat{\mathbf{C}} + \rho\mathbf{G}$ where the matrix $\mathbf{G}$ is defined in section 2.2. It is possible to find a sequence $(\eta_n)_{n\in\mathbb{N}}$ of non negative reals such that $\Omega_n = \left\{\omega/\lambda_{\min}(\widehat{\mathbf{C}}_{\boldsymbol{\rho}}) > c\eta_n\right\}$, where $\lambda_{\min}(\widehat{\mathbf{C}}_{\boldsymbol{\rho}})$ is the smallest eigenvalue of $\widehat{\mathbf{C}}_{\boldsymbol{\rho}}$, has probability going to 1 when n goes to infinity (see [4])

To prove the convergence result of the estimator $\widehat{\Psi}_\alpha$, we assume that the following hypotheses are satisfied.

$(H.1)$ $\| X_i \| \leq C_0 < +\infty, \quad as.$

$(H.2)$ The function Ψ_α has a continuous p'-th derivative $\Psi_\alpha^{(p')}$ which satisfies a Lipschitz condition of order $\nu \in [0,1]$.

In the following, we set $p = p' + \nu$ and we suppose that $q \geq p \geq m$.

$(H.3)$ The eigenvalues of Γ_X are strictly positive.

$(H.4)$ For $x \in H$, Y has a conditional density function f_Y^x given $[X = x]$ continuous and strictly positive at the α-quantile.

Then, we have the following result.

Theorem 2.1. *Under hypotheses* $(H.1) - (H.4)$*, if we also suppose there exists* β, γ *in* $]0,1[$ *such that* $k_n \sim n^\beta$, $\rho \sim n^{-\gamma}$ *and* $\eta_n \sim n^{-\beta-(1-\delta)/2}$*, then*

(i) $\widehat{\Psi}_\alpha$ *exists except on a set whose probability goes to zero as n goes to infinity,*

(ii) $\mathbb{E}\big(\| \widehat{\Psi}_\alpha - \Psi_\alpha \|_2^2 \,|X_1, \ldots, X_n\big) = O_P\left(\dfrac{1}{k_n^{2p}} + \dfrac{1}{n\eta_n} + \dfrac{\rho^2}{k_n\eta_n} + \rho k_n^{2(m-p)}\right).$

3 Application to Ozone prediction

We want to predict the maximum of the Ozone variable the day i, denoted by Y_i, using the functional covariates observed the day before until 5:00 pm. We consider covariates with length of 24 hours. We can assume that, beyond 24 hours, the effects of the covariate are negligible knowing the last 24 hours, so that each curve X_i begins at 6:00 pm the day $i-2$.

We ramdomly splitted the initial sample $(X_i, Y_i)_{i=1,\dots,n}$ into two subsamples:

- a learning sample $(X_{a_i}, Y_{a_i})_{i=1,\dots,n_l}$ with $n_l = 332$, used to determine the estimators $\widehat{c}$ and $\widehat{\Psi}_\alpha$,
- a test sample $(X_{t_i}, Y_{t_i})_{i=1,\dots,n_t}$ with $n_t = 142$, used to evaluate the quality of the models and to make a comparison.

We use the conditional median to predict the value of Y_i, *i.e.* $\alpha = 0.5$. To judge the quality of the models, we give a prediction of the maximum of Ozone for each element of the test sample,

$$\widehat{Y_{t_i}} = \widehat{c} + \int_D \widehat{\Psi}_\alpha(t) X_{t_i}(t)\, dt.$$

Then, we consider three criteria given by

$$C_1 = \frac{\frac{1}{n_t}\sum_{i=1}^{n_t}(Y_{t_i} - \widehat{Y_{t_i}})^2}{\frac{1}{n_t}\sum_{i=1}^{n_t}(Y_{t_i} - \overline{Y}_l)^2}, \quad C_2 = \frac{1}{n_t}\sum_{i=1}^{n_t} \mid Y_{t_i} - \widehat{Y_{t_i}} \mid,$$

$$C_3 = \frac{\frac{1}{n_t}\sum_{i=1}^{n_t} l_\alpha(Y_{t_i} - \widehat{Y_{t_i}})}{\frac{1}{n_t}\sum_{i=1}^{n_t} l_\alpha(Y_{t_i} - q_\alpha(Y_l))},$$

where $\overline{Y}_l$ is the empirical mean of the learning sample $(Y_{a_i})_{i=1,\dots,n_l}$ and $q_\alpha(Y_l)$ is the empirical α-quantile of the learning sample $(Y_{a_i})_{i=1,\dots,n_l}$. This last criterion C_3 is similar to the one proposed by Koenker and Machado [10]. We remark that, the more these criteria take low values (close to 0), the better is the prediction. After testing all the possible models with one to five covariates, we finally kept the model using the four covariates Ozone, Nitrogen Monoxide, Nitrogen Dioxide and Wind Speed (we have put some of the results obtained in table 1). For this model, figure 1 represents predicted Ozone vs measured Ozone. Except for one outlier, the prediction seems rather good. The most efficient covariate to estimate the maximum of Ozone is the Ozone curve the day before; however, we noticed an improvement adding other covariates.

We can also think that these results could be improved by considering other covariates that were not available, such as for example the curve of temperature. Finally, let us remark that we can similarly estimate conditional quantiles of Y_i or order 0.9 and 0.1 to derive some kind of prediction intervals.

Models	Variables	C_1	C_2	C_3
1 covariate	N2	$0,814$	$16,916$	$0,906$
	O3	**0,414**	**12,246**	**0,656**
	WS	$0,802$	$16,836$	$0,902$
2 covariates	O3, NO	$0,413$	$11,997$	$0,643$
	O3, N2	$0,413$	$11,880$	$0,637$
	O3, WS	$0,414$	$12,004$	$0,635$
3 covariates	O3, NO, N2	$0,412$	$12,127$	$0,644$
	O3, N2, WD	$0,409$	$12,004$	$0,645$
	O3, N2, WS	$0,410$	$11,997$	$0,642$
4 covariates	**O3, NO, N2, WS**	**0,400**	**11,718**	**0,634**
5 covariates	O3, NO, N2, WD, WS	$0,401$	$11,750$	$0,639$

Table 1: Forecast quality for some models of mediane regression.

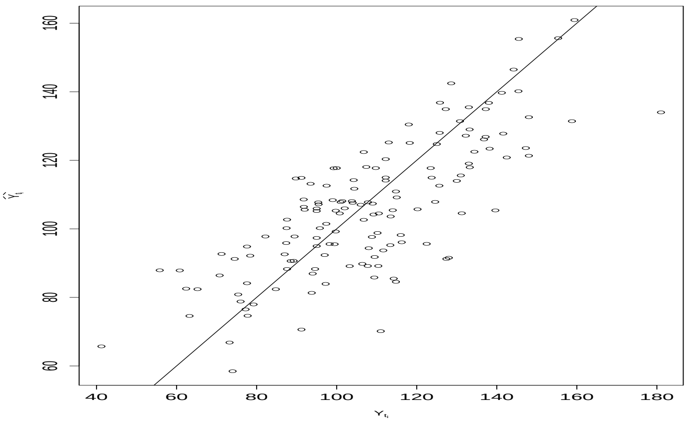

Figure 1: Predicted Ozone vs measured Ozone (prediction with the variables O3, NO, N2 and WS).

COMPSTAT'2004 Symposium

RANDOM EFFECTS VARYING TIME REGRESSION MODELS WITH APPLICATION TO REMOTE SENSING DATA

Hervé Cardot, Robert Faivre and Philippe Maisongrande

Key words: Backfitting, BLUP, covariance operator, ECME, functional data, land use estimation, mixed effects, mixed pixels, splines, unmixing.

COMPSTAT 2004 section: Functional data analysis.

Abstract: The sensor SPOT4/Végétation gives every day satellite images of Europe with medium spatial resolution, each pixel corresponding to an area of 1km×1km. Such data are useful to characterize the development of the vegetation at a large scale. The basic information support units, named *mixed* pixels, aggregate informations of different crops and thus different themes of interest (wheat, corn, forest, ...).

We aim at estimating the local variations of the responses of the different cultures knowing the land use and the temporal evolution of the reflectance of the mixed pixels. We propose an unmixing procedure relying on a random effects varying time regression model. Estimators are based on penalized splines and maximum likelihood. A combination of the backfitting and the ECME algorithms allows us to get a fast estimation procedure. This approach is illustrated in the South-East of France with SPOT4/VGT data obtained during the year 2002.

1 Mixed pixels and characteristic curves expansion

The Végétation sensor of the SPOT4 satellite gives daily images of Europe (high temporal resolution) at a coarse spatial resolution, each pixel corresponding to a ground area of 1 km^2. The information given by this sensor are the reflectances, i.e the proportion of reflected radiation, in a few spectral bands. This information allows to characterize the development of vegetation and crops at the scale of a small country [11]. Nevertheless in Europe, and particularly in France, the size of plots is much less than 1 km^2. Thus the observed reflectances are a mixture of different informations since they contain different agricultural plots (maize, wheat, forest, ...); such pixels are named *mixed pixels*.

When observing mixed pixels, the reflectance is a function of the characteristic reflectances of each particular category. These curves are also called phenological curves when the category is associated to a crop. We can assume the combination is linear so that the reflectance curve $Y_i(t)$ of a pixel i is decomposed as

$$Y_i(t) = \sum_{j=1}^{J} \pi_{ij}\ \rho_{ij}(t) + \varepsilon_{i,t}, \quad t \in [0,T], \tag{1}$$

where π_{ij} is the proportion of land use of crop j, $\rho_{ij}(t)$ is the response curve associated to the category j for the ith pixel and $\varepsilon_{i,t}$ are independent Gaussian random variables with mean zero and variance σ^2. We assume that the land use is fixed during the observation period $[0,T]$, p images are observed at the instants $0 \leq t_1 < \ldots < t_\nu < \ldots < t_p \leq T$. Each image is composed of n pixels so that we get vectors of discretized pixel trajectories $\mathbf{Y}_i = (Y_i(t_1), \ldots, Y_i(t_p))'$, $i = 1, \ldots, n$. In the area under study the land use is supposed to be known and is composed of J different themes (wheat, corn, river, urban, $\ldots$) and we have for each pixel i, the vector of proportions of the surfaces $\boldsymbol{\pi}_i = (\pi_{i1}, \ldots, \pi_{iJ})$ dedicated to each category.

Since agricultural practices may differ from one farmer to another, that the soil properties, the climate, $\ldots$, may also vary with the location, phenological curves which reflect more or less the growth of a culture may be different from one pixel to another. We do not assume anymore that $\rho_{ij}(t) = \rho_j(t)$, as it was done in Cardot et al. [1] to predict the proportion of each crop in a mixed pixel.

Our work deals with the problem of estimating the temporal evolution of the local responses of each crop from the temporal evolution of mixed pixels. Then, it is possible to assimilate the predicted local reflectances of a culture, such as wheat, into a crop growth model in order to predict the total production at a regional scale.

Faivre and Fischer [3] proposed a statistical approach for estimating the local reponses of each crop for a fixed instant t_ν. A random coefficient linear model was built to estimate the distribution of the characteristic reflectances assuming the land use was known; unmixing or disaggregation being done independently on each image, *i.e* at each date. We propose, in section 2, a nonparametric model which can take into account the temporal variations of the responses. It is based on spline decomposition with random coefficients estimated via a penalized maximum likelihood criterion, see section 3. The fixed effects are estimated with a backfitting procedure whereas the ECME algorithm is proposed for the estimation of the random components. A remote sensing application is presented in section 4 and some extensions are proposed in section 5. The method is implemented in the R language and is avalaible on request.

2 A functional random effects model

Assuming the characteristic curves have a Gaussian distribution, we get now, combined with (1), the following model:

$$\begin{cases} Y_i(t) & = & \sum_{j=1}^{J} \pi_{ij}\ \rho_{ij}(t) + \varepsilon_t, \quad t \in [0,T], \\ \rho_{ij} & \sim & \mathcal{N}\left(\rho_j^0, \Gamma_j\right), \quad j = 1, \dots, J, \end{cases} \tag{2}$$

where ρ_j^0 is the mean fonctional response $\rho_j^0(t) = E(\rho_{ij}(t))$ and Γ_j its covariance operator. It is an integral operator whose kernel is $\gamma^j(s,t) = \mathrm{Cov}(\rho_{ij}(s), \rho_{ij}(t))$. We suppose that the noise is not spatially correlated and the response of the different crops are independent, $\mathrm{cov}(\rho_{ij}, \rho_{i'j'}) = 0$ if $i \neq i'$ or $j \neq j'$, so that we do not include cross covariance operators for the conditional variance of the trajectory Y_i.

Model (2) can also be seen as a varying time regression model [4]

$$E\left(Y_i(t)\right) \quad = \quad \sum_{j=1}^{J} \pi_{ij}\ \rho_j^0(t), \tag{3}$$

in which the conditional variance (conditionned to $\boldsymbol{\pi}$) is modelled as follows:

$$\mathrm{Cov}\left(Y_i(s), Y_i(t)\right) \quad = \quad \sigma^2 \delta_{\{s=t\}} + \sum_{j=1}^{J} \pi_{ij}^2\ \gamma^j(s,t)\ . \tag{4}$$

Remark. Models 2 and 4 are extensions of some previous models proposed by Rice and Wu [9], Cardot et al. [1] and Kneip et al. [6]. Rice and Wu [9] have studied nonparametric varying time regression models without explanatory variables whereas Cardot et al. [1] did not include conditional variance terms in a similar model. Kneip et al. [6] studied a semi-parametric model with parametric mean effects and nonparametric random effects but without any covariate.

Spline expansion

Consider two B-splines bases $\{B_1(t), \dots, B_{q+k_1}(t)\}$ and $\{\mathcal{B}_1(t), \dots, \mathcal{B}_{q+k_2}(t)\}$, of order q, with respectively k_1 and k_2 equispaced interior knots [2]. Let us separate the fixed effects from the random ones,

$$\rho_{ij}(t) \quad \approx \quad \sum_{r=1}^{q+k_1} \theta_{r,j}^0 B_r(t) + \sum_{s=1}^{q+k_2} \delta_{s,i}^j \mathcal{B}_s(t) \tag{5}$$

where the coordinates $\theta_{r,j}^0, k = 1, \dots, q+k_1$ are associated to the spline approximation of the mean of the jth phenological curve and $\delta_{s,i}^j$ are the variations from the mean of the trajectory of the pixel i. By hypothesis, $E(\delta_{s,i}^j) = 0$ and we can approximate the mean and the variance of a discretized trajectory $\mathbf{Y}_i$ as follows:

$$\mathrm{E}\left(\mathbf{Y}_i | \boldsymbol{\pi}_i\right) \quad = \quad \mathbf{B}\boldsymbol{\theta}^0 \boldsymbol{\pi}_i' \tag{6}$$

$$\mathrm{Var}\left(\mathbf{Y}_i | \boldsymbol{\pi}_i\right) \quad = \quad \sigma^2 \mathbf{I}_p + \sum_{j=1}^{J} \pi_{ij}^2 \sum_{s,\ell=1}^{q+k_2} \mathrm{Cov}(\delta_{s,i}^j, \delta_{\ell,i}^j) \boldsymbol{\mathcal{B}}_s \boldsymbol{\mathcal{B}}_\ell' \tag{7}$$

where $\mathbf{B}$ is the $p \times (q+k_1)$ matrix whose elements are $[\mathbf{B}]_{\nu,r} = B_r(t_\nu)$, $\boldsymbol{\theta}^0$ is the $(q+k_1) \times J$ matrix whose elements are $[\boldsymbol{\theta}^0]_{r,j} = \theta^0_{r,j}$ and $\boldsymbol{\mathcal{B}}_s = (\mathcal{B}_s(t_1), \ldots, \mathcal{B}_s(t_p))' \in \mathbb{R}^p$.

3 Maximum likelihood estimates

Denote by $\mathbf{V}_i$ the variance of the discretely sampled trajectory $\mathbf{Y}_i$, it is defined in equation (7).

The log-likelihood, equals, up to a constant

$$\mathcal{L} = -\frac{1}{2}\left(\sum_{i=1}^n \log|\mathbf{V}_i| + \sum_{i=1}^n \left(\mathbf{Y}_i - \mathbf{B}\boldsymbol{\theta}^0\boldsymbol{\pi}_i\right)' \mathbf{V}_i^{-1}\left(\mathbf{Y}_i - \mathbf{B}\boldsymbol{\theta}^0\boldsymbol{\pi}_i\right)\right) \quad (8)$$

and the parameters to be estimated are σ^2, the $(q+k_1) \times J$ matrix $\boldsymbol{\theta}^0$ and the J symmetric matrices $\boldsymbol{\gamma}^j$ of size $(q+k_2) \times (q+k_2)$ with $[\gamma^j]_{s,\ell} = \mathrm{Cov}(\delta^j_{s,i}, \delta^j_{\ell,i})$. This latter matrix is independent of i by assumption and has $(q+k_2)(q+k_2+1)/2$ non redundant parameters.

The estimation procedure proposed here is based on combination of the backfitting algorithm and a kind of EM algorithm [7], called ECME which is known to converge faster than the classical EM algorithm [8]. Let us also notice that one major advantage of this approach compared to direct optimization procedures is that the estimated covariance matrices are automatically non negative.

The variance parameters are known

Suppose first that the variance components $\boldsymbol{\gamma}^j, j = 1, \ldots, J$ and σ^2 of the model are known and let us give estimators of the fixed effects.

As in Hoover et al. [4] and Cardot et al. [1], a penalty, tuned by a smoothing parameter λ_j, is added in order to get identifiability and smooth estimators of the mean characteristic curves,

$$J(\lambda, \rho_j) = \lambda_j \times \int_T \left(\frac{d^2\rho_j(u)}{dt^2}\right)^2 du = \lambda_j \; \boldsymbol{\theta}_j'\mathbf{P}_2\boldsymbol{\theta}_j \;, \quad (9)$$

where $[\mathbf{P}_2]_{\ell,r} = \int_T B_\ell^{(2)}(t)B_r^{(2)}(t)dt$ and $B_r^{(2)}(t)$ is the second order derivative of $B_r(t)$. Then maximizing the log likelihood (8) with penalty terms defined in (9) is equivalent to minimize the following criterion:

$$\sum_{i=1}^n \left\|\mathbf{Y}_i - \sum_{j=1}^J \pi_{ij}\mathbf{B}\boldsymbol{\theta}_j\right\|^2_{\mathbf{V}_i^{-1}} + \frac{1}{2}\sum_{j=1}^J \lambda_j \boldsymbol{\theta}_j'\mathbf{P}_2\boldsymbol{\theta}_j, \quad (10)$$

where $\|\mathbf{Y}_i\|^2_{\mathbf{V}_i^{-1}} = \mathbf{Y}_i'\mathbf{V}_i^{-1}\mathbf{Y}_i$. Noticing that minimizing 10) is equivalent to solve the set of equations in $\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_J$

$$\sum_{j'=1}^J \left(\sum_{i=1}^n \pi_{ij}\pi_{ij'}\mathbf{B}'\mathbf{V}_i^{-1}\mathbf{B}\right)\boldsymbol{\theta}_{j'} + \lambda_j\mathbf{P}_2\boldsymbol{\theta}_j \;=\; \sum_{i=1}^n \pi_{ij}\mathbf{B}'\mathbf{V}_i^{-1}\mathbf{Y}_i, \quad (11)$$

for $j = 1, \dots, J$, allows to save computation time by using the backfitting algorithm. It avoids inverting a large $J(q + k_1) \times J(q + k_1)$ matrix. Let us remark that computation time can be saved again by considering the following transformed data, $\widetilde{\mathbf{Y}}_i = \mathbf{B}'\mathbf{Y}_i$. Then we have to deal with $(q+k_1) \times (q+k_1)$ individual variance matrices $\mathbf{W}_i = \mathbf{B}'\mathbf{V}_i\mathbf{B}$ with $q + k_1 < p$.

Variance parameters estimation

Define $\boldsymbol{\delta}_i^j = (\delta_{1,i}^j, \dots, \delta_{q+k_2,i}^j)'$. The individual components $\widehat{\boldsymbol{\delta}}_i^j = E\left(\boldsymbol{\delta}_i^j | \mathbf{Y}_i\right)$ and $\widehat{\boldsymbol{\varepsilon}}_i = E\left(\boldsymbol{\varepsilon}_i \mid \mathbf{Y}_i\right)$ can be deduced using the BLUP formula

$$\widehat{\boldsymbol{\delta}}_i^j = \pi_{ij}\boldsymbol{\gamma}^j\boldsymbol{\mathcal{B}}'\mathbf{V}_i^{-1}\left(\mathbf{Y}_i - \sum_{j=1}^{J}\pi_{ij}\mathbf{B}\widehat{\boldsymbol{\theta}}_j^0\right), \tag{12}$$

$$\widehat{\boldsymbol{\varepsilon}}_i = \mathbf{Y}_i - \sum_{j=1}^{J}\pi_{ij}\left(\mathbf{B}\widehat{\boldsymbol{\theta}}_j^0 + \boldsymbol{\mathcal{B}}\widehat{\boldsymbol{\delta}}_i^j\right). \tag{13}$$

Using these expressions we can get estimates of the variance components

$$\begin{aligned} n\,\widehat{\gamma}^j &= E\left(\sum_{i=1}^{n}\widehat{\boldsymbol{\delta}}_i^j(\widehat{\boldsymbol{\delta}}_i^j)' \mid \mathbf{Y}_i\right) \\ &= \sum_{i=1}^{n}\left\{\widehat{\boldsymbol{\delta}}_i^j(\widehat{\boldsymbol{\delta}}_i^j)' + \mathrm{Var}\left(\boldsymbol{\delta}_i^j \mid \mathbf{Y}_i\right)\right\}. \end{aligned} \tag{14}$$

The variance σ^2 of the noise is estimated by

$$\begin{aligned} np\,\widehat{\sigma}^2 &= E\left(\sum_{i=1}^{n}\boldsymbol{\varepsilon}_i'\boldsymbol{\varepsilon}_i \mid \mathbf{Y}_i, \widehat{\gamma}\right) \\ &= \sum_{i=1}^{n}\left\{\widehat{\boldsymbol{\varepsilon}}_i'\widehat{\boldsymbol{\varepsilon}}_i + \mathrm{tr}\ \mathrm{Var}\left(\boldsymbol{\varepsilon}_i \mid \mathbf{Y}_i\right)\right\}. \end{aligned} \tag{15}$$

Formulas for the expected conditional variances are given in McLachlan and Krishnan [8].

The final algorithm consists in repeating estimation of the fixed effects (11), individual effects (12), (13) and estimations of the variance terms (14), (15) until convergence.

Once the parameters of the model have been estimated, it is easy to get, for every pixel i, the local responses of the different crops applying the BLUP formula (12).

4 An application in remote sensing

We have remote sensing data obtained with the Végétation sensor in the South-East of France. Each pixel correspond to an area of 1 km^2 and we

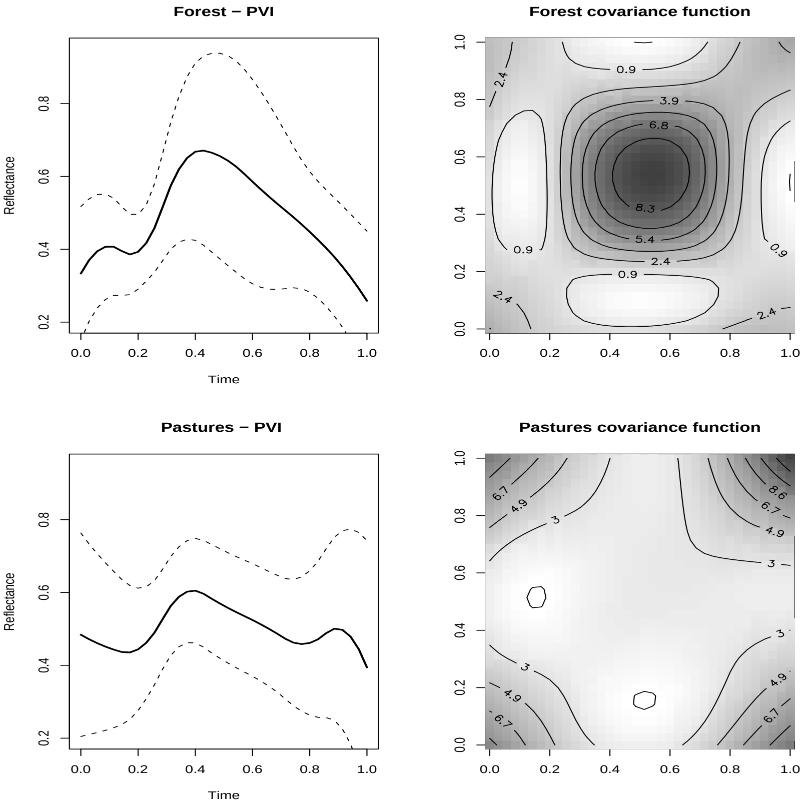

Figure 1: Estimated phenological curves and "normalized" covariance functions for the themes "Forests" and "Pastures". Dotted lines correspond to the mean function ± 1.96 times the standard deviation functions, defined as $\sqrt{\widehat{\gamma}^j(t,t)}$.

observe this region during the year 2002. We have $p = 36$ distinct time instants and $n = 1209$ pixels, corresponding to total area of 1209 km^2.

In this region, the land use is also known thanks the Corine land cover map. We selected the 7th most important themes (forest, pastures, urban, ...) so that we have $J = 8$ classes. We choose B-splines bases of order $q = 3$, with $k_1 = 6$ and $k_2 = 3$ interior knots. The smoothing parameter value is the same for all the phenological curves, it is $\lambda = 10^{-4}$. We deal with the PVI index [10], it is a linear combination of the reflectances in the Red and Near-Infra-Red channels.

It took less than one minute on a PC for the algorithm to converge. The estimated variance of the noise is $\widehat{\sigma}^2 = 0.0022$ whereas the variance of the functions Y_i is about 0.014.

We have drawn in Figure 1 the estimated phenological curves of the themes “Forest” and “Pastures” with their estimated variability as well as discretized estimates of their “normalized” covariance operator defined by $\widehat{\gamma}^j(s,t) = \boldsymbol{\mathcal{B}}'(t)\widehat{\boldsymbol{\gamma}}^j\boldsymbol{\mathcal{B}}(s)$ with $\boldsymbol{\mathcal{B}}'(t) = (\mathcal{B}_1(t), \ldots, \mathcal{B}_{q+k_2}(t))$. Each cell is an estimation of the “normalized” covariance kernel $\widehat{\gamma}^j(s,t)/\widehat{\sigma}^2$ for $s,t \in [0,1]$ and $j \in \{$“forest”,”pastures”$\}$.

Estimated covariance operators can be really different from one class to another as shown in Figure 1. This confirms that different crops are characterized not only by their mean reflectance along time but also by their variations. The largest variations for the theme “Forest” occur during the middle of the year, when the response is close to its maximum, with a strong temporal correlation whereas this is not the case at all for the theme “Pastures”. Furthermore, an eigenanalysis of the estimated covariance operators allows us to exhibit the main modes of variations of the individual responses.

5 Discussion

First notice that we can extend without real difficulties, as in James [5], our estimation procedure with measurements points (sampled time instants) that differ from one pixel to another.

In practice one has to choose the number of knots for the spline basis and values of the smoothing parameters. We prefer a criterion like the AIC criterion compared to cross validation for computation time reasons. James et al. [5] noticed that results were nearly equivalent in a similar study.

Another potential application of this model is land use prediction [1], taking into account the temporal structure of the variability of the crop responses. Indeed, once the parameters have been estimated one can predict the land use in a similar area (assuming the crops have the same modes of variations), that is to say the vector $\boldsymbol{\pi}_{i'}$ of a new pixel i' when observing the trajectory $\mathbf{Y}_{i'} = (Y_{i'}(t_1), \ldots, Y_{i'}(t_p))$. This can be done by maximizing the likelihood criterion, which is equivalent to minimize:

$$\min_{\boldsymbol{\pi}} \ \log|\widehat{\mathbf{V}}_{i'}| + \left(\mathbf{Y}_{i'} - \mathbf{B}\widehat{\boldsymbol{\theta}}^0\boldsymbol{\pi}\right)' \widehat{\mathbf{V}}_{i'}^{-1} \left(\mathbf{Y}_{i'} - \mathbf{B}\widehat{\boldsymbol{\theta}}^0\boldsymbol{\pi}\right) \tag{16}$$

under the constraints that $\pi_j \geq 0$ and $\sum_j \pi_j = 1$, where $\widehat{\boldsymbol{\theta}}^0$ is deduced from the previous estimation procedures and $\widehat{\mathbf{V}}_{i'} = \widehat{\sigma}^2\mathbf{I}_p + \sum_{j=1}^J \pi_j^2 \sum_{s,\ell} \widehat{\gamma}_{s,\ell}^j \boldsymbol{\mathcal{B}}_s\boldsymbol{\mathcal{B}}_\ell'$.

Finally, as it was pointed out by an anonymous referee, we can reasonably think that the spatio-temporal structure of the data is not fully reflected with our model. Incorporating spatial structures would certainly improves the quality of our estimates. It deserves further attention but is beyond the scope of this paper.

CHEMICAL BALANCE WEIGHING DESIGNS FOR $V+1$ OBJECTS WITH DIFFERENT VARIANCES BASED ON TERNARY BALANCED BLOCK DESIGNS

Bronisław Ceranka and Małgorzata Graczyk

Key words: Optimum chemical balance weighing design, ternary balanced block design.

COMPSTAT 2004 section: Statistical software.

Abstract: The paper is studying the estimation problem of individual weights of objects using the chemical balance weighing design under the restriction on the number of times in which each object is weighed. We assume that the errors are uncorrelated and they have different variances. The conditions under which the existence of the optimum chemical balance weighing design for $p=v$ objects implies the existence of the optimum chemical balance weighing design for $p=v+1$ objects are given. The new construction methods for the optimum chemical balance weighing design for $p=v+1$ objects are given. We use the incidence matrices of the ternary balanced block designs for v treatments to construct the design matrix of the optimum chemical balance weighing designs for $p=v+1$ objects.

1 Introduction

The results of n weighing operations to determine the individual weights of p objects with a balance that is corrected for bias will fit into the linear model

$$\mathbf{y} = \mathbf{X}\mathbf{w} + \mathbf{e}, \tag{1}$$

where $\mathbf{y}$ is an $n\times 1$ random observed vector of the recorded results of weights, $\mathbf{X} \in \Phi_{n\times p,m}(-1,0,1)$, where $\Phi_{n\times p,m}(-1,0,1)$ denotes the class of the $n\times p$ matrices with elements $x_{ij}=-1$, 1 or 0 if the jth object is kept on the left pan, right pan or is not included in the particularly weighing, respectively, $i=1,2,\ldots,n,\quad j=1,2,\ldots,p$. Let m be the maximum number of elements equal to -1 and 1 in the columns of the matrix $\mathbf{X}$, $\mathbf{w}$ is a $p\times 1$ column vector representing unknown weights of objects and $\mathbf{e}$ is an $n\times 1$ random vector of errors. We assume that $E(\mathbf{e})=\mathbf{0}_n$ and $Var(\mathbf{e})=\sigma^2\mathbf{G}$, where $\mathbf{0}_n$ is the $n\times 1$ column vector of zeros, $\mathbf{G}$ is the $n\times n$ positive definite diagonal matrix of known elements, $E(\cdot)$ stands for the expectation and $\mathbf{e}^{'}$ is used for transpose of $\mathbf{e}$.

The normal equations estimating $\mathbf{w}$ are of the form

$$\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{X}\hat{\mathbf{w}} = \mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{y}, \tag{2}$$

where $\hat{\mathbf{w}}$ is the vector of the weights estimated by the least squares method.

The chemical balance weighing design is singular or nonsingular depending on whether the matrix $\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{X}$ is singular or nonsingular, respectively. It is obvious that because of the assumption connected with the matrix $\mathbf{G}$ the matrix $\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{X}$ is nonsingular if and only if the matrix $\mathbf{X}^{'}\mathbf{X}$ is nonsingular, i.e. if and only if $\mathbf{X}$ is of full column rank ($= p$). If $\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{X}$ is nonsingular, the least squares estimator of $\mathbf{w}$ is given in the form

$$\hat{\mathbf{w}} = \left(\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{X}\right)^{-1}\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{y} \tag{3}$$

and the variance - covariance matrix of $\hat{\mathbf{w}}$ is given by formula

$$Var(\hat{\mathbf{w}}) = \sigma^2\left(\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{X}\right)^{-1}. \tag{4}$$

Various aspects of the chemical balance weighing designs have been studied by Raghavarao [8] and Banerjee [1]. When $\mathbf{G}$ is the positive definite diagonal matrix of known elements Katulska [7] have showed that the minimum attainable variance of each of the estimated weights for a chemical balance weighing design is $\sigma^2/tr(\mathbf{G}^{-1})$. She proved the theorem that each of the variances of the estimated weights attaines the minimum if and only if $\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{X} = tr(\mathbf{G}^{-1})\mathbf{I}_p$. This design is said to be the optimum chemical balance weighing design. In this case several methods of construction of the optimum chemical balance weighing designs are given in the literature. But the optimality condition implies that the elements of the design matrix $\mathbf{X}$ are equal to -1 and 1, only.

In present paper we consider the generalisation of the problem of choosing the matrix $\mathbf{X}$ of the optimum chemical balance weighing design with nonhomogeneity of variances of errors. We assume that in each column of the design matrix $\mathbf{X}$ are elements equal to 0, i.e. in each measurement operation not all objects are included. We investigate the necessary and sufficient conditions under which the minimum variance is attained for estimated weights. We give new methods of construction of the optimum chemical balance weighing designs for $p = v + 1$ objects. They are based on the incidence matrices of the ternary balanced block designs for $p = v$ treatments.

In a special case when $\mathbf{G} = \mathbf{I}_n$, the methods of construction of the optimum chemical balance weghing designs for $p = v$ objects with homogeneity of variances of errors based on the same set of the incidence matrices were given in Ceranka and Graczyk [4].

2 Variance limit of estimated weights

Let $\mathbf{X}_h \in \Phi_{n_h \times p, m_h}(-1, 0, 1)$ be the $n_h \times p$ matrix of the rank p of the chemical balance weighing design, where $m_h = max(m_{h1}, m_{h2}, \ldots, m_{hp})$, m_{hj} is the number of elements equal to -1 and 1 in the jth column of the matrix $\mathbf{X}_h$, $\quad h = 1, 2$.

Now, we define the matrix $\mathbf{X} \in \Phi_{n\times p,m}(-1,0,1)$ of the chemical balance weighing design as

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \end{bmatrix}, \tag{5}$$

where $n = n_1 + n_2$ and $m = m_1 + m_2$.
Let

$$\mathbf{G} = \begin{bmatrix} \frac{1}{a}\mathbf{I}_{n_1} & \mathbf{0}_{n_1}\mathbf{0}'_{n_2} \\ \mathbf{0}'_{n_2}\mathbf{0}_{n_1} & \mathbf{I}_{n_2} \end{bmatrix}. \tag{6}$$

Ceranka and Graczyk [5] showed that the minimum attainable variance for each of the estimated weights for the chemical balance weighing design with the design matrix $\mathbf{X}$ in the form (5) with the variance-covariance matrix of errors $\sigma^2\mathbf{G}$, where $\mathbf{G}$ is given in (6), is $\sigma^2/(am_1 + m_2)$, i.e. $Var(\hat{w}_j) \geq \sigma^2/(am_1 + m_2)$, $j = 1, 2, \ldots, p$.

Definition 1. *Any nonsingular chemical balance weighing design with the design matrix $\mathbf{X}$ in the form (5) with the variance-covariance matrix of errors $\sigma^2\mathbf{G}$, where $\mathbf{G}$ is given in (6), is called the optimal design for the estimation of individual weights of the objects if $Var(\hat{w}_j) = \sigma^2/(am_1+m_2)$, $j = 1, 2, \ldots, p$.*

Ceranka and Graczyk [5] proved the following theorem

Theorem 1. *Any nonsingular chemical balance weighing design with the design matrix $\mathbf{X}$ in the form (5) with the variance-covariance matrix of errors $\sigma^2\mathbf{G}$, where $\mathbf{G}$ is given in (6), is optimal if and only if*

$$\mathbf{X}'\mathbf{G}^{-1}\mathbf{X} = (am_1 + m_2)\mathbf{I}_p. \tag{7}$$

In the particular case when $m_1 = n_1$ and $m_2 = n_2$ the theorem was given in Katulska [7] and when additionally $\mathbf{G} = \mathbf{I}_n$ the theorem was given in Hotelling [6].

3 Optimum chemical balance weghing designs for $p + 1$ objects

Let $\mathbf{X} \in \Phi_{n\times p,m}(-1,0,1)$ be the matrix of the chemical balance weighing design in the form (5). Based on that matrix we form the design matrix $\mathbf{X} \in \Phi_{n\times(p+1),m}(-1,0,1)$ of the chemical balance weighing design for $p + 1$ objects and we receive

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_1 & \mathbf{1}_{n_1} \\ \mathbf{X}_2 & \mathbf{0}_{n_2} \end{bmatrix}, \tag{8}$$

where $\mathbf{1}_{n_1}$ is the $n_1 \times 1$ column vector of units.

Theorem 2. *If $\mathbf{X}_h$ is the matrix of the $n_h \times p$ chemical balance weighing design, $h = 1, 2$, then the $n \times (p + 1)$ matrix $\mathbf{X}$ given in the form (8) is the matrix of the optimum chemical balance weighing design with the variance-covariance matrix of errors $\sigma^2\mathbf{G}$, where $\mathbf{G}$ is given in (6), if and only if*

$$\mathbf{X}_1^{'}\mathbf{1}_{n_1} = \mathbf{0}_p$$

and

$$am_1 + m_2 = an_1.$$

Proof. For the design matrix $\mathbf{X}$ given in (8) and the matrix $\mathbf{G}$ in the form (6) we have

$$\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{X} = \begin{bmatrix} a\mathbf{X}_1^{'}\mathbf{X}_1 + \mathbf{X}_2^{'}\mathbf{X}_2 & a\mathbf{X}_1^{'}\mathbf{1}_{n_1} \\ a\mathbf{1}_{n_1}^{'}\mathbf{X}_1 & an_1 \end{bmatrix}. \tag{9}$$

Then from (7) and (9) we have $\mathbf{X}_1^{'}\mathbf{1}_{n_1} = \mathbf{0}_p$ and $a\mathbf{X}_1^{'}\mathbf{X}_1 + \mathbf{X}_2^{'}\mathbf{X}_2 = an_1\mathbf{I}_p$ which complet the proof.

4 Ternary balanced block designs

A ternary balanced block design is defined as the design consisting of b blocks, each of size k, chosen from a set of objects of size v, in such a way that each of the v treatments occurs r times altogether and 0, 1 or 2 times in each block, (2 appears at least once) and each of the distinct pairs appears λ times. Any ternary balanced block design is regular, that is, each treatment occurs alone in ρ_1 blocks and is repeated two times in ρ_2 blocks, where ρ_1 and ρ_2 are constant for the design. Let $\mathbf{N}$ be the incidence matrix of the ternary balanced block design. It is straightforward to verify that

$$\begin{aligned}
&vr = bk,\\
&r = \rho_1 + 2\rho_2,\\
&\lambda(v-1) = \rho_1(k-1) + 2\rho_2(k-2) = r(k-1) - 2\rho_2,\\
&\mathbf{NN'} = (\rho_1 + 4\rho_2 - \lambda)\mathbf{I}_v + \lambda\mathbf{1}_v\mathbf{1}_v' = (r + 2\rho_2 - \lambda)\mathbf{I}_v + \lambda\mathbf{1}_v\mathbf{1}_v'.
\end{aligned}$$

5 Construction of the design matrix

Let $\mathbf{N}_h$ be the incidence matrix of the ternary balanced block design with the parameters $v,\quad b_h,\quad r_h,\quad k_h,\quad \lambda_h,\quad \rho_{1h},\quad \rho_{2h},\quad h = 1, 2$. Now, we define the matrix $\mathbf{X}_h$ as $\mathbf{X}_h = \mathbf{N}_h^{'} - \mathbf{1}_{b_h}\mathbf{1}_v^{'}$. Then the matrix $\mathbf{X} \in \Phi_{n\times(p+1),m}(-1,0,1)$ is of the form

$$\mathbf{X} = \begin{bmatrix} \mathbf{N}_1^{'} - \mathbf{1}_{b_1}\mathbf{1}_v^{'} & \mathbf{1}_{b_1} \\ \mathbf{N}_2^{'} - \mathbf{1}_{b_2}\mathbf{1}_v^{'} & \mathbf{0}_{b_2} \end{bmatrix}. \tag{10}$$

In such a design we determine unknown measurements of $p = v + 1$ objects. Thus, each of v first columns of the matrix $\mathbf{X}$ will contain $\rho_{21} + \rho_{22}$ elements equal to 1, $b_1 + b_2 - \rho_{11} - \rho_{12} - \rho_{21} - \rho_{22}$ elements eqaul to -1 and $\rho_{11} + \rho_{12}$ elements eqaul to 0. The last column of $\mathbf{X}$ will contain b_1 elements equal to 1 and b_2 elements equal to zero. Clearly, such a design implies that in $n = b_1 + b_2$ measurement operations the jth object is weighed $b_1 + b_2 - \rho_{11} - \rho_{12}$ times, $j = 1, 2, \ldots, v$, and the $(v + 1)$th object is weighed b_1 times.

Lemma 1. *The chemical balance weighing design* $\mathbf{X}$ *in the form (9) is nonsingular if and only if* $v \neq k_2$.
Proof. Since $\mathbf{G}$ is the positive definite diagonal matrix of known elements then $\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{X}$ is nonsingular if and only if $\mathbf{X}^{'}\mathbf{X}$ is nonsingular. For the design matrix $\mathbf{X}$ given in (9) we have

$$\mathbf{X}^{'}\mathbf{X} = \begin{bmatrix} \theta\mathbf{I}_v + \gamma\mathbf{1}_v\mathbf{1}_v^{'} & (r_1 - b_1)\mathbf{1}_v \\ (r_1 - b_1)\mathbf{1}_v^{'} & b_1 \end{bmatrix},$$

where $\theta = r_1 + 2\rho_{21} - \lambda_1 + r_2 + 2\rho_{22} - \lambda_2$, $\quad \gamma = b_1 + \lambda_1 - 2r_1 + b_2 + \lambda_2 - 2r_2$. It is easy to see that

$$det(\mathbf{X}^{'}\mathbf{X}) = \frac{b_1 b_2}{v}(v - k_2)^2 \left(r_1 + 2\rho_{21} - \lambda_1 + r_2 + 2\rho_{22} - \lambda_2\right)^{v-1}.$$

Evidently $r_1 + 2\rho_{21} - \lambda_1 + r_2 + 2\rho_{22} - \lambda_2$ is positive, hence $det(\mathbf{X}^{'}\mathbf{X}) \neq 0$ if and only if $v \neq k_2$. So, the lemma is proved.

From the theorems (1) and (2) we have

Theorem 3. *Any nonsingular chemical balance weighing design with the design matrix* $\mathbf{X}$ *given in the form (10) with the variance-covariance matrix of errors* $\sigma^2\mathbf{G}$, *where* $\mathbf{G}$ *is of the form (6), is optimal if and only if*

$$a\,(b_1 + \lambda_1 - 2r_1) + (b_2 + \lambda_2 - 2r_2) = 0, \tag{11}$$

$$b_1 = r_1 \tag{12}$$

and

$$b_2 = a\rho_{11} + \rho_{12}. \tag{13}$$

Proof. For the design matrix $\mathbf{X}$ given in (10) and the matrix $\mathbf{G}$ in the form (6) we have

$$\mathbf{X}^{'}\mathbf{G}^{-1}\mathbf{X} = \begin{bmatrix} \delta\mathbf{I}_v + \eta\mathbf{1}_v\mathbf{1}_v^{'} & a(r_1 - b_1)\mathbf{1}_v \\ a(r_1 - b_1)\mathbf{1}_v^{'} & ab_1 \end{bmatrix},$$

where $\delta = a(r_1 + 2\rho_{21} - \lambda_1) + (r_2 + 2\rho_{22} - \lambda_2)$, $\quad \eta = a(b_1 + \lambda_1 - 2r_1) + (b_2 + \lambda_2 - 2r_2)$. The design matrix $\mathbf{X}$ in the form (10) is optimal if and only if the conditions given in the theorems (1) and (2) are fulfieled. From these conditions and relations between parameters we receive the thesis of theorem.

If the chemical balance weighing design given by the matrix $\mathbf{X}$ in the form (10) with the variance-covariance matrix of errors $\sigma^2\mathbf{G}$, where $\mathbf{G}$ is of the form (6), is optimal then

$$Var(\hat{w_j}) = \frac{\sigma^2}{ab_1}, \qquad j = 1, 2, \ldots, v + 1.$$

We have seen in theorem (3) that if parameters of two ternary balanced block designs satisfy the conditions (11), (12) and (13) then the chemical balance weighing design with the design matrix $\mathbf{X}$ given in the form (10) with the variance-covariance matrix of errors $\sigma^2\mathbf{G}$, where the matrix $\mathbf{G}$ is of the form (6), is optimal. Under these conditions we have formulated the theorems following from the papers of Billington [2] and Billington and Robinson [3].

Theorem 4. *Let $a = \frac{1}{2}$. If the parameters of two ternary balanced block designs are equal to*

(i) $v = 5$, $b_1 = 8(s+2)$, $r_1 = 8(s+2)$, $k_1 = 5$, $\lambda_1 = 2(4s+7)$, $\rho_{11} = 8(s+1)$, $\rho_{21} = 4$ *and* $v = 5$, $b_2 = 5(s+2)$, $r_2 = 3(s+2)$, $k_2 = 3$, $\lambda_2 = s+3$, $\rho_{12} = s+6$, $\rho_{22} = s$, $s = 1, 2, \ldots,$

(ii) $v = 9$, $b_1 = 6(s+4)$, $r_1 = 6(s+4)$, $k_1 = 9$, $\lambda_1 = 2(3s-4)$, $\rho_{11} = 2(3s+4)$, $\rho_{21} = 8$ *and* $v = 9$, $b_2 = 3(s+4)$, $r_2 = 2(s+4)$, $k_2 = 6$, $\lambda_2 = s+5$, $\rho_{12} = 8$, $\rho_{22} = s$, $s = 2, 3, \ldots,$

(iii) $v = 11$, $b_1 = 32$, $r_1 = 32$, $k_1 = 11$, $\lambda_1 = 30$, $\rho_{11} = 12$, $\rho_{21} = 10$ *and* $v = 11$, $b_2 = 11$, $r_2 = 7$, $k_2 = 7$, $\lambda_2 = 4$, $\rho_{12} = 5$, $\rho_{22} = 1$,

(iv) $v = 12$, $b_1 = 8(2s+5)$, $r_1 = 8(2s+5)$, $k_1 = 12$, $\lambda_1 = 2(8s+19)$, $\rho_{11} = 2(8s+9)$, $\rho_{21} = 11$ *and* $v = 12$, $b_2 = 3(2s+5)$, $r_2 = 2(2s+5)$, $k_2 = 8$, $\lambda_2 = 2(s+3)$, $\rho_{12} = 6-2s$, $\rho_{22} = 3s+2$, $s = 0, 1, 2,$

(v) $v = 15$, $b_1 = 10(s+4)$, $r_1 = 10(s+4)$, $k_1 = 15$, $\lambda_1 = 2(5s+19)$, $\rho_{11} = 2(5s{+}6)$, $\rho_{21} = 14$ *and* $v = 15$, $b_2 = 3(s{+}4)$, $r_2 = 2(s+4)$, $k_2 = 10$, $\lambda_2 = s+5$, $\rho_{12} = 6-2s$, $\rho_{22} = 2s+1$, $s = 1, 2,$

then the chemical balance weighing design with the design matrix $\mathbf{X}$ given in the form (10) with the variance-covariance matrix of errors $\sigma^2\mathbf{G}$, where $\mathbf{G}$ is given in (6), is optimal.

Proof. It is easy to see that the parameters of the ternary balanced block designs satisfied the equalities (11)-(13).

Theorem 5. *Let $a = \frac{3}{2}$. If the parameters of two ternary balanced block designs are equal to*

(i) $v = 9$, $b_1 = 32$, $r_1 = 32$, $k_1 = 9$, $\lambda_1 = 30$, $\rho_{11} = 16$, $\rho_{21} = 8$ *and* $v = 9$, $b_2 = 27$, $r_2 = 15$, $k_2 = 5$, $\lambda_2 = 6$, $\rho_{12} = 3$, $\rho_{22} = 6$,

(ii) $v = 12$, $b_1 = 28$, $r_1 = 28$, $k_1 = 12$, $\lambda_1 = 26$, $\rho_{11} = 6$, $\rho_{21} = 11$ *and* $v = 12$, $b_2 = 14$, $r_2 = 7$, $k_2 = 6$, $\lambda_2 = 3$, $\rho_{12} = 5$, $\rho_{22} = 1$,

(iii) $v = 15$, $b_1 = 40$, $r_1 = 40$, $k_1 = 15$, $\lambda_1 = 38$, $\rho_{11} = 12$, $\rho_{21} = 14$ *and* $v = 15$, $b_2 = 25$, $r_2 = 15$, $k_2 = 9$, $\lambda_2 = 8$, $\rho_{12} = 7$, $\rho_{22} = 4$,

then the chemical balance weighing design with the design matrix $\mathbf{X}$ *given in the form (10) with the variance-covariance matrix of errors* $\sigma^2\mathbf{G}$, *where* $\mathbf{G}$ *is given in (6), is optimal.*

Theorem 6. *Let* $a = 2$. *If the parameters of the ternary balanced block designs are equal to* $v = 5$, $b_1 = 2(s+4)$, $r_1 = 2(s+4)$, $k_1 = 5$, $\lambda_1 = 2s+7$, $\rho_{11} = 2(s+2)$, $\rho_{21} = 2$ *and* $v = 5$, $b_2 = 5(s+4)$, $r_2 = 3(s+4)$, $k_2 = 3$, $\lambda_2 = s+6$, $\rho_{12} = s+12$, $\rho_{22} = s$, $s = 1, 2, \ldots$, *then the chemical balance weighing design with the design matrix* $\mathbf{X}$ *given in the form (10) with the variance-covariance matrix of errors* $\sigma^2\mathbf{G}$, *where* $\mathbf{G}$ *is given in (6), is optimal.*

Theorem 7. *Let* $a = 3$. *If the parameters of two ternary balanced block designs are equal to*

(i) $v = 9$, $b_1 = 16$, $r_1 = 16$, $k_1 = 9$, $\lambda_1 = 15$ $\rho_{11} = 8$, $\rho_{21} = 4$ *and* $v = 9$, $b_2 = 27$, $r_2 = 15$, $k_2 = 5$, $\lambda_2 = 6$, $\rho_{12} = 3$, $\rho_{22} = 6$,

(ii) $v = 15$, $b_1 = 20$, $r_1 = 20$, $k_1 = 15$, $\lambda_1 = 19$ $\rho_{11} = 6$, $\rho_{21} = 7$ *and* $v = 15$, $b_2 = 25$, $r_2 = 15$, $k_2 = 9$, $\lambda_2 = 8$, $\rho_{12} = 7$, $\rho_{22} = 4$,

then the chemical balance weighing design with the design matrix $\mathbf{X}$ *given in the form (10) with the variance-covariance matrix of errors* $\sigma^2\mathbf{G}$, *where* $\mathbf{G}$ *is given in (6), is optimal.*

A COMPARISON OF TWO METHODS OF PRINCIPAL COMPONENT ANALYSIS

Vartan Choulakian

Key words: Transposition invariance; PCA in L$_1$;PCA; Banach spaces; robustness.

COMPSTAT 2004 section: Multivariate analysis.

Abstract: An invariance property of the classical principal component analysis (PCA) is used to develop a new method of PCA in L$_1$. Using the theory of finite dimensional Banach spaces, we show that the mathematical framework of both methods is similar. The new method is robust compared to the classical PCA, and produces simultaneous dichotomies of the variables and the observations. We compare both methods on a real data set: The new method explains much better the underlying structure of the well known Hearing Loss Data.

1 Introduction

We start with some notation. Let $\mathbf{X}$ be a data set of dimension $n \times m$, where n observations are described by the m variables. Let $\mathbf{Y}$ represent the standardized data set, and $\mathbf{V} = \mathbf{Y}'\mathbf{Y}$ is the correlation or covariance matrix. The p-th vector norm of a vector $\mathbf{v} = (v_1, \ldots, v_n)'$ is defined to be $\|\mathbf{v}\|_p = (\sum_{i=1}^n \|v_i\|^p)^{1/p}$ for $p \geq 1$ and $\|\mathbf{v}\|_\infty = \max_i |v_i|$. Let l_p^n represent the finite n-dimensional Banach space equipped with the norm $\|.\|_p$, similarly we denote l_q^m. The matrix $\mathbf{Y}$ is considered an application from l_q^m to l_p^n. For $p \geq 1$ and $q \geq 1$, we define the matrix norm of $\mathbf{Y}$ to be

$$\|\mathbf{Y}\|_{pq} = \max_{\mathbf{v}} \frac{\|\mathbf{Y}\mathbf{v}\|_p}{\|\mathbf{v}\|_q}$$

In statistics, Galpin and Hawkins [7] proposed the use of $\|\mathbf{Y}\|_{11}$ and $\|\mathbf{Y}\|_{12}$ for L$_1$ estimation of a covariance matrix. Choulakian [4] developed the robust Q-mode principal component analysis (PCA) in L$_1$ based on $\|\mathbf{Y}'\|_{12}$, and Choulakian [5] showed that the centroid method is based on $\|\mathbf{Y}\|_{2\infty} = \|\mathbf{Y}'\|_{12}$. Also, Heiser [8], Benayade and Fichet [3], and, Baccini, Besse and de Falguerolles [2], proposed other formulations of PCA in L$_1$. The method developed in this paper differs from the other methods of PCA in L$_1$ found in the statistical literature by an invariance property: the objective function is transposition invariant with respect to the operator norm $\|\cdot\|_{1\infty}$, that is, $\|\mathbf{Y}\|_{1\infty} = \|\mathbf{Y}'\|_{1\infty}$. For this reason the method is named transposition invariant (TI) PCA in L$_1$. We note that the classical PCA is also transposition invariant and it is based on the norm $\|\mathbf{Y}\|_{22} = \|\mathbf{Y}'\|_{22}$.

The classical PCA is discussed quite in detail in two monographs written by Jackson [9] and Jolliffe [10].

This paper is organized as follows: Section 2 presents the main results, where the classical PCA and the new method are compared. In section 3, we analyze the Hearing Loss Data set, where we show that the TI-PCA in L_1 produces much clearer structure of the natural physical process of the hearing loss in adult males than the classical PCA. Finally, we conclude in section 4.

Here, we stress the fact that the exact principal component weights of TI-PCA in L_1 are calculated by an algorithm based on combinatorial optimization, equations 1 and 2 provided below, whose computational complexity is of the order $\mathrm{O}(\max(m,n)2^{\min(m,n)})$.

2 Main results

In the following we shall enumerate some similar mathematical properties of both methods: Classical PCA and TI-PCA in L_1. Proofs of the first five properties can be found in Choulakian [6].

- Variational definition:

  PCA

  $$\max_{\mathbf{v}} \|\mathbf{Yv}\|_2 \text{ subject to } \|\mathbf{v}\|_2 = 1.$$

  TI-PCA in L_1

  $$\max_{\mathbf{v}} \|\mathbf{Yv}\|_{\mathbf{1}} \text{ subject to } \|\mathbf{v}\|_\infty = 1.$$

- Duality:

  PCA

  $$\max_{\mathbf{u}} \|\mathbf{Y'u}\|_2 \text{ subject to } \|\mathbf{u}\|_{\mathbf{2}} = 1.$$

  TI-PCA in L_1

  $$\max_{\mathbf{u}} \|\mathbf{Y'u}\|_1 \text{ subject to } \|\mathbf{u}\|_\infty = 1.$$

- Bilinear application:

  PCA

  $$\max_{\mathbf{v},\mathbf{u}} \mathbf{u'Yv} \text{ subject to } \|\mathbf{u}\|_{\mathbf{2}} = 1 \text{ and } \|\mathbf{v}\|_2 = 1.$$

  TI-PCA in L_1

  $$\max_{\mathbf{v},\mathbf{u}} \mathbf{u'Yv} \text{ subject to } \|\mathbf{u}\|_\infty = 1 \text{ and } \|\mathbf{v}\|_\infty = 1.$$

- Computation of the first principal component weights $\mathbf{v}_1$ and $\mathbf{u}_1$, and the dispersion measure λ_1 :

PCA: Eigen value method

$$\mathbf{Y}'\mathbf{Y}\mathbf{v}_1 = \lambda_1^2\mathbf{v}_1 \quad \text{and} \quad \|\mathbf{v}\|_2 = 1.$$

$$\mathbf{Y}\mathbf{Y}'\mathbf{u}_1 = \lambda_1^2\mathbf{u}_1 \quad \text{and} \quad \|\mathbf{u}\|_2 = 1.$$

$$\lambda_1 = \mathbf{u}_1'\mathbf{Y}\mathbf{v}_1.$$

TI-PCA in L$_1$: Combinatorial optimization

$$\mathbf{v}_1 = \arg\max_{v_i=\pm 1} \|\mathbf{Y}\mathbf{v}\|_{\mathbf{1}} \quad \text{and} \quad \lambda_1 = \|\mathbf{Y}\mathbf{v}_1\|_{\mathbf{1}}. \tag{1}$$

$$\mathbf{u}_1 = \arg\max_{u_i=\pm 1} \|\mathbf{Y}'\mathbf{u}\|_{\mathbf{1}} \quad \text{and} \quad \lambda_1 = \|\mathbf{Y}'\mathbf{u}_1\|_{\mathbf{1}}. \tag{2}$$

$$\lambda_1 = \mathbf{u}_1'\mathbf{Y}\mathbf{v}_1.$$

- Transitional formulae:

PCA

$$\text{1st pc row scores vector} : \mathbf{s}_1 = \mathbf{Y}\mathbf{v}_1, \tag{3}$$

$$\text{1st pc factor loadings vector} : \mathbf{c}_1 = \mathbf{Y}'\mathbf{u}_1, \tag{4}$$

$$\mathbf{c}_1 = \boldsymbol{\lambda}_\mathbf{1}\mathbf{v}_1 \quad \text{and} \quad \mathbf{s}_1 = \boldsymbol{\lambda}_\mathbf{1}\mathbf{u}_1. \tag{5}$$

TI-PCA in L$_1$

$$\text{1st pc row scores vector} : \mathbf{s}_1 = \mathbf{Y}\mathbf{v}_1, \tag{6}$$

$$\text{1st pc factor loadings vector} : \mathbf{c}_1 = \mathbf{Y}'\mathbf{u}_1, \tag{7}$$

$$sgn(\mathbf{c}_1) = \mathbf{v}_1 \quad \text{and} \quad sgn(\mathbf{s}_1) = \mathbf{u}_1. \tag{8}$$

Where $sgn(.)$ is the coordinatewise sign function, $sgn(x) = 1$ if $x > 0$, and $sgn(x) = -1$ if $x \leq 0$.

- Residual data matrix:

PCA

$$\mathbf{Y}^{(1)} = \mathbf{Y} - \mathbf{s}_1\mathbf{c}_1'/\lambda_1. \tag{9}$$

TI-PCA in L$_1$

$$\mathbf{Y}^{(1)} = \mathbf{Y} - \mathbf{s}_1\mathbf{c}_1'/\lambda_1. \tag{10}$$

Note that in both cases, the rows of $\mathbf{Y}^{(1)}$ are orthogonal to $\mathbf{v}_1$, and the columns of $\mathbf{Y}^{(1)}$ are orthogonal to $\mathbf{u}_1$. From which, we deduce the next property.

- Relationships between the consecutive principal components:

  Let $\mathbf{v}_i, \mathbf{c}_i$, $\mathbf{u}_i$ and $\mathbf{s}_i$ be the ith principal component of weights, loadings and scores, respectively, calculated from $\mathbf{Y}^{(i-1)}$ for $i \geq 2$. Then:

  PCA

$$\mathbf{v}_i'\mathbf{v}_j{=}0 \quad \text{for} \quad i \neq j,$$

$$\mathbf{s}_i'\mathbf{s}_j = 0 \quad \text{for} \quad i \neq j.$$

  TI-PCA in L_1

$$sgn(\mathbf{c}_i')\mathbf{c}_j = \mathbf{v}_j'\mathbf{c}_i = 0 \quad \text{for} \quad i < j, \tag{11}$$

$$sgn(\mathbf{s}_j')\mathbf{s}_i = \mathbf{u}_j'\mathbf{s}_i = 0 \quad \text{for} \quad i < j. \tag{12}$$

Remarks

In the case of TI-PCA in L_1, first, (8) shows that there is a clear distinction between pc weights (± 1) and pc loadings; second, (11) shows that the j-th pc loadings vector is orthogonal to the i-th pc weights vector for $i < j$.

Similar to the singular value decomposition, the matrix $\sum_{i=1}^{k} \mathbf{s}_i \mathbf{c}_i^{'}/\lambda_i$ provides a k rank approximation of the data for $k \leq \min(m, n)$.

The classical PCA presupposes the existence of the variances of the variables in a data set, while the TI-PCA-L_1 presupposes the existence of the means of the variables in a data set. This shows that it is specifically useful for long-tailed data, where the existence of the variances of some of the variables is dubious.

Transition formulae, (3) through (8), between the principal scores and the principal component weights are important for the interpretation of graphical displays. A comparison of the transition formulae sheds further insight into the differences between the two methods: TI-PCA-L_1 is more robust than the classical PCA. In the TI-PCA-L_1, all the variables are included *uniformly* in the construction of a score of an observation, and similarly the component loading of a variable is the sum of *signed uniform* contributions of all the observations.

The calculation of the principal scores and the principal component weights of TI-PCA in L_1 can be accomplished by two algorithms. The first one is based on complete enumeration. The second one is based on iterating the transition formulae (6) and (7), similar to Wold's [11] NILES (nonlinear estimation by iterative least squares) algorithm, which is based on (3) and (4). The rows and the columns of the data can be used as initial values for the iterative algorithm.

Finally, we mention that the same citeria used to select the number of principal components in the classical PCA, such as the scree plot or the percentage of the total dispersion, can be used to select the number of principal components in the TI-PCA in L_1.

Table 1: PCA of hearing loss data.

3 Example: Hearing loss data

The data set of dimension 100 × 8 is found in Jackson [9]. The first four columns represent the hearing measurements on the left ear of an individual, and the last four columns represent the hearing measurements on his right ear. The measuring of hearing is done with an audiometer at 4 different frequencies for each ear: 500Hz, 1000Hz, 2000Hz and 4000Hz. Jackson [9] applied the classical PCA, and he found the first four dimensions to be interpretable. Table 1 displays the 8 principal components obtained by classical PCA and TI-PCA in L_1 applied to the standardized data, $y_{ij} = (x_{ij} - \bar{x}_{.j})/s_j$, where $\bar{x}_{.j}$ and s_j represent the mean and the standard deviation of the jth variable, respectively. We note that the first four principal components are very similar in both approaches. The first principal component is a size factor. The second principal component opposes the low frequencies (500Hz and 1000Hz) to the higher frequencies (2000Hz and 4000Hz). The third principal component contrasts the two extreme frequencies (500Hz and 4000Hz) to the middle frequencies (1000Hz and 2000Hz), and the fourth principal component differentiates the left ear from the right. The remaining principal components obtained by the new method are also interpretable: the fifth principal component shows oppositions between (500Hz and 2000Hz) and (1000Hz and 4000Hz). The last three principal axes reproduce the second, third and fifth principal components but opposing the right ear to the left ear. We conclude that this data set is very well structured, and the complete structure is revealed by the TI-PCA in L_1 and not by the classical PCA. This example provides an empirical substantiation of Arabie [1], where it is argued that the L_1 metric models psychological processes (in this example physiological) better than the L_2 metric.

4 Conclusion

An invariance property of the classical PCA is used to develop a new method named TI-PCA in L_1. The mathematical framework of both methods is similar. The new method is robust compared to the classical PCA, and produces simultaneous dichotomies of the variables and the observations. We compared both methods on a real data set: The new method explained much better the underlying structure of the Hearing Loss Data. In the future, we intend to compare the TI-PCA in L_1 with the other L_1 methods proposed in the statistical literature.

COMPSTAT'2004 Symposium

A LOWER BOUND ON INSPECTION TIME FOR COMPLEX SYSTEMS WITH WEIBULL TRANSITIONS

Stephane Chrétien and F. Corset

Key words: Random networks, random linear programming, reliability, maintenance, Dyer-Frieze-McDiarmid's inequality.

COMPSTAT 2004 section: Reliability.

Abstract: The paper studies the expectation of the inspection time in complex aging systems. Under reasonable assumptions, this problem is equivalent to studying the expectation of the length of the shortest path in the directed degradation graph of the systems where the parameters are obtained from experts. The expectation itself being sometimes out of reach, in closed form or even through Monte Carlo simulations in the case of large systems, we study the bound of Dyer, Frieze and McDiarmid which provides an interesting upper bound in the case of exponential transition times between degradation states. On the other hand, we show that this bound does not hold for Weibull distributions. Another problem is that lower bounds are much more useful in the context of estimating inspection times before failure. Such a rigourous lower bound is presented for the case of Weibull distribution with reasonable values of the shape parameter.

1 Introduction

1.1 Problem statement

Consider a complex system whose n degradation states have been identified by experts. Let node 1 represent the state where the system is considered as new and let node n be the state of unacceptable degradation. All maximum paths from any node of the graph end at node n as in the figure below. The system is supposed to possibly evolve from a degradation state to any neighbor in the corresponding directed graph. The transition time between any two given states is assumed to follow a Weibull distribution whose parameters are given by experts or are estimated if the number of observations is sufficiently large. Using Bayesian statistics both informations can also be merged.

Assume we start with a brand new system. Then, evolution of the system starts in state 1. Maintenance policies require that the system be inspected before reaching state n, i.e. unacceptable degradation. Such examples of complex systems have been studied in [1]. The problem posed in this paper is to provide a lower bound on acceptable inspection times.

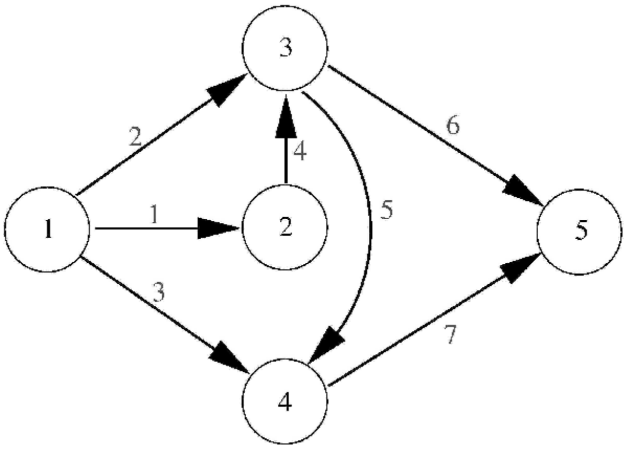

Figure 1: A simple graph.

1.2 Inspection times and shortest paths

In order to simplify the analysis, we assume that evolution inside the degradation graph proceeds following the rule that starting from one node i, the system goes to state j minimizing the transition time among neighbors of state i. Therefore, acceptable inspection times will be the times lower than *the shortest path* from state 1 to state n where each edge is weighted by its transition time. In general situations, we thus may ask for

- an estimator of the expected length of the shortest path from 1 to n,
- a confidence interval for the expected time. path.

This task is in general impossible to achieve because of the huge number of observations this should require in practice. The goal of this paper is to propose a lower bound on the expected length of the shortest path. On the other hand, approximate confidence intervals seem very difficult to obtain. A possible way of doing this may be the use of Talagrand's inequalities but this issue will not be discussed here.

2 The Dyer-Frieze-McDiarmid inequality for exponential transitions

An important step in the search of good bounds for expectations in combinatorial problems was achieved by Dyer, Frieze and Mc Diarmid in [2]; see also [3]. Their bound is an upper bound to the expectation of the optimal value. In comparison, the main objective of our work is to obtain a lower bound but using Dyer-Frieze-McDiarmid's bound gives a first understanding of the problem.

2.1 Linear programming formulation

The main idea is to convert the problem into an equivalent linear programming problem, when possible. Many combinatorial optimization problems cannot be transformed in this manner but it is well known that this is the case for the shortest path problem. Consider the following *extended incidence matrix* A of the oriented degradation graph. Its rows are indexed by the nodes of the graph while its columns are indexed by its edges with an extra column of all ones. In each column indexed by edge (i, j), set the i^{th} component to -1, the j^{th} component to 1 and set all other entries to zero. For instance, the extended incidence matrix for the graph of figure 1 is given by

$$A = \begin{bmatrix} -1 & -1 & -1 & 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & -1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 & -1 & -1 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 0 & -1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \end{bmatrix}.$$

Now, the fact that we start at node 1 and end at node n is encoded in the vector $b = [-1, 0, 0, 0, 1]^t$. Then, the shortest path problem is equivalent to the linear program

$$\begin{aligned} z^\star = \quad & \min \quad c^T x \\ & \text{s.t.} \quad Ax = b \\ & \qquad\quad x \geq 0 \end{aligned} \tag{1}$$

where the random vector c contains the transition times for each edge of the graph.

2.2 The case of exponential transition times

We now apply the Dyer-Frieze-McDiarmid bound to our shortest path problem in the case where the transition times are independent and exponential. In this case, the mean residual times, i.e. the variables $E[c_i \mid c_i \geq h]$ satisfy the equality

$$E[c_i \mid c_i \geq h] = E[c_i] + h.$$

Then, an *upper bound* on the expected length of the shortest path is given by the following theorem.

Theorem 2.1. *(Dyer-Frieze-McDiarmid Inequality [2]) Assume that the random costs c_i are independent and satisfy*

$$E[c_i \mid c_i \geq h] \geq E[c_i] + \alpha h$$

for some $\alpha \in (0, 1]$. Then for any matrix $A \in \mathbb{R}^{n \times m}$ and any vector $b \in \mathbb{R}^n$, the optimal value z^* of the general linear program (1) satisfies

$$E[z^*] \leq \max_{S\,:\,\#S=n} \sum_{i \in S} E[c_i] x_i \tag{2}$$

for any feasible solution x, i.e. any x satisfying $Ax = b$.

A direct application of this theorem gives the following interesting corollary.

Corollary 2.1. *Consider problem (1) where the random costs are assumed to be independent and exponentially distributed and consider the associated deterministic linear program*

$$\begin{aligned} \zeta^\star = \quad & \min \quad E[c]^T x \\ & s.t. \quad Ax = b \\ & \qquad\quad x \geq 0 \end{aligned} \tag{3}$$

where the random costs are replaced by their expected values. Then the shortest path problem with optimal value denoted by z^* satisfies

$$E[z^*] \leq \zeta^*.$$

Proof. Take x equal to any binary vector minimizing (3). It is clear that the number of ones in this vector is less than the number of nodes in the graph. Then, the maximum value over all sets S of cardinality n in the right hand term in (2) is obtained when S is taken to be the set of indices i for which $x_i = 1$. Thus $\sum_{i \in S} E[c_i] x_i$ is exactly the cost of x , i.e. ζ^*. □

An important conclusion of this corollary is that, contrarily to the intuitive idea prescribed by common practice, replacing the random costs by their expected values cannot help for the problem of finding a lower bound to the inspection time of the system. A rigourous lower bound will be presented below.

3 A lower bound on the shortest path and inspection times

3.1 The mean residual time to failure for Weibull distributions

Analyzing the proof of the Dyer-Frieze-McDiarmid bound reveals the importance of studying the mean residual transition times. Here, we recall some results for mean residual times in the case where the variables have a Weibull distribution. Let X be a random variable with Weibull distribution

$$f_X(t) = \frac{\beta}{\eta}\left(\frac{t}{\eta}\right)^\beta e^{-(\frac{t}{\eta})^\beta}.$$

Then, the mean residual time to failure (MRTF) is given by

$$G_X(h) \triangleq E[X \mid X \geq h] = \eta e^{(\frac{h}{\eta})^\beta} \Gamma\left(1 + \frac{1}{\beta}, \left(\frac{h}{\eta}\right)^\beta\right),$$

where $\Gamma(a, h)$ is the incomplete gamma function defined by

$$\Gamma(a,h) = \int_h^{+\infty} t^{a-1} e^{-t} dt.$$

Lemma 3.1. *The first two derivatives of the MRTF for a Weibull distributed variable X are given by*

$$G'_X(h) = \frac{\beta}{\eta^\beta} h^{(\beta-1)} \left\{ \eta e^{\left(\frac{h}{\eta}\right)^\beta} \Gamma\left(1+\frac{1}{\beta}, \left(\frac{h}{\eta}\right)^\beta\right) - h \right\}$$

and

$$\begin{aligned} G''_X(h) &= -\frac{\beta^2}{\eta^\beta} h^{(\beta-1)} \left(1+\beta\left(\frac{h}{\eta}\right)^\beta\right) \\ &+ \frac{\beta}{\eta^{(\beta-1)}} h^{(\beta-2)} e^{\left(\frac{h}{\beta}\right)^\beta} \Gamma\left(1+\frac{1}{\beta}, \left(\frac{h}{\eta}\right)^\beta\right) \left(\beta\left(\frac{h}{\eta}\right)^\beta + \beta - 1\right). \end{aligned}$$

Moreover, when $\beta \geq 1$ we have

$$\lim_{h\to 0} G'_X(h) = 0 \text{ and } \lim_{h\to+\infty} G'_X(h) = 1$$

and if moreover $\beta < 2$ we have

$$G''_X(h) > 0, \quad \lim_{h\to 0} G''_X(h) = +\infty \text{ and } \lim_{h\to+\infty} G'_X(h) = 0.$$

Using this lemma, we can draw the following simple conclusion.

Proposition 3.1. *Assume that X is Weibull distributed with $\beta \in (1,2)$. Then, for all $h \geq 0$, we have*

$$E[X \mid X \geq h] \leq E[X] + h.$$

This result will be instrumental in the derivation of the bound.

3.2 A lower bound to the inspection time

In order to derive the lower bound, we need to clarify the behavior of the linear program (1) when subject to random costs. The presentation follows [2] and [3, Chapter 4]. For any family of n different columns of A indexed by B which are linearly independent and such that $A_B^{-1}b \geq 0$, we can find a feasible solution x satisfying $Ax = b$ and $x \geq 0$ in the following way:

$$\begin{cases} x_i = 0 \text{ forall } i \notin B \text{ and} \\ x_B = A_B^{-1} b \end{cases} \tag{4}$$

where x_B is the vector whose components are those of x with indices in B and A_B is the matrix whose columns are those of A whose indices are in B also. We will also sometimes use the notation $N = \{1, \ldots, n\} \setminus B$.

We then have the following standard result in linear programming theory.

Lemma 3.2. *([2, 3]) Let B be a subset of n indices such that $A_B^{-1}b \geq 0$. A vector x defined by (4) with respect to B will be a solution to program (1) if and only if $c_i \geq c_B^t A_B^{-1} a_i$ for all $i \notin B$ where a_i is the i^{th} column of A.*

A subset of indices B such that the columns of A_B are linearly independent and $A_B^{-1}b \geq 0$ is called a basis of the linear program. Solving the linear program thus consists of finding an optimal basis characterized by the property

$$c_i \geq c_B A_B^{-1} a_i \text{ for all } i \notin B. \tag{5}$$

The reason for appending the extra column of all ones to the incidence matrix is that the standard incidence matrix has rank equals to $n-1$ when the graph is connected. Thus, any basis for the shortest path problem must contain this extra column of ones which is easily seen to be orthogonal to any of the other columns.

Using these definitions, we now present the lower bound to the inspection time in the following theorem.

Theorem 3.1. *Consider the shortest path problem whose linear programming formulation is given by (1) where the components c_i of the cost vector c are independent and follow a Weibull distribution with parameters η_i and β_i, $i = 1, \ldots, n$. Let x be any feasible solution of (1), i.e. satisfying $Ax = b$ and $x \geq 0$. Then, the expectation of the random optimal value z^* admits the following lower bound*

$$\sum_r p_r \sum_{i \in B_r} E[c_i] x_i \leq E[z^*],$$

where (B_r) is the family of all bases for program (1) and for all r, p_r is the probability that B_r be optimal.

Sketch of the proof. The proof is adapted from the one of Dyer, Frieze and McDiarmid's inequality. For any feasible x, we can write

$$\begin{aligned} E[c^t x \mid B_r \text{ optimal }, c_{B_r}] \quad &= c_{B_r}^t x_{B_r} + \textstyle\sum_{i \notin B_r} E[c_i \mid \ B_r \text{ optimal }, c_{B_r}]^t x_i \\ &= c_{B_r}^t x_{B_r} + \textstyle\sum_{i \notin B_r} (E[c_i \mid c_i \geq c_{B_r} A_{B_r}^{-1} a_i \geq 0, c_{B_r}]^t x_i \\ &\geq c_{B_r}^t x_{B_r} + \textstyle\sum_{i \notin B_r} E[c_i]^t x_i + \textstyle\sum_{i \notin B_r} c_{B_r} A_{B_r}^{-1} a_i x_i \\ &= c_{B_r}^t x_{B_r} + E[c_{N_r}]^t x_{N_r} + c_{B_r} A_{B_r}^{-1} A_{N_r} x_{N_r}. \end{aligned}$$

The second equality is where both the underlying mechanism of linear programming and Proposition 3.1

play a crucial rôle. Now since

$$A_{B_r} x_{B_r} + A_{N_r} x_{N_r} = Ax = b$$

and $E[z^* \mid \ B_r \text{ optimal }, c_{B_r}] = c_{B_r} A_{B_r}^{-1} b$, we get

$$E[c^t x \mid \ B_r \text{ optimal }, c_{B_r}] \geq E[c_{N_r}]^t x_{N_r} + E[z^* \mid \ B_r \text{ optimal }, c_{B_r}].$$

Now, taking the expectation relative to c_{B_r} and using the formula of total probabilities with respect to the events "B_r is optimal" for all r, we easily get the announced result. □

This theorem cannot be used in crude manner. It explicitely requires that all probabilities p_r be estimated which amounts to a usually hudge number in complex cases. The main idea for using this result is to restrict to the bases which appear most often in the experiments. The following bound appears more tractable in practice.

Corollary 3.1. *Let x be the solution of the linear program (3) where the costs are replaced by their expected values, let B be the optimal basis associated with x and let $\hat{p}_B$ be a lower bound to the probability that B be optimal basis in (1) with confidence level $1-\alpha$. Then with probability $1-\alpha$ we have*

$$\hat{p}_B E[c]^t x \leq E[z^*].$$

Remark 3.1. *Of course, one can add to $\hat{p}_B E[c]^t x$ several more terms of the form $\hat{p}_r \sum_{i \in B_r} E[c_i] x_i$ for as many other bases occuring with nonneglectable probability as we want, using underestimations $\hat{p}_r$ of p_r for each new r. This results in sharper lower bounds to the mean inspection time.*

4 Simulations results

In this section we present our simulation results. We generate a hundred different shortest path problems on the graph of Figure 1. Each of these problems differs by the choice of the shape and scale parameters controlling the distribution of the cost on each edges. More precisely, for problem i, the cost c_j of edge j follows a Weibull distribution $W(\eta_j(i), \beta_j(i))$, where $\eta_j(i)$ was drawn at random from the normal distribution $\mathcal{N}(50, 100)$ and $\beta_j(i)$ was drawn from a uniform distribution over $[1, 2]$. For each problem, the expectation of the optimal cost is computed via Monte Carlo simulations over 1000 samples. Note that this is possible because of the simplicity of the chosen example. In order to compute our lower bound and following Remark 3.1, we use all the basis which occured to be optimal for at least one sample among the thousand samples. The bases are obtained as output of the simplex algorithm. Note that the only burden is to store these bases which is of course costless: we only take into account the small number of bases which frequently occur as optimal in the hundred tested samples of the shortest path problem. Finally, the underestimations $\hat{p}_r$ have been chosen as the lower bounds of the respective confidence intervals for the probabilities p_r with risk value $\alpha = 5\%$. The results are given in Figure 2 below.

In most cases, our lower bound is closer than the Dyer-Frieze-McDiarmid (DFM) upper bound to the expected cost in absolute value. Moreover, in general, the mean relative error between our bound and the expected value is less than 20% over the hundred generated problems (19.86 % in the displayed example).

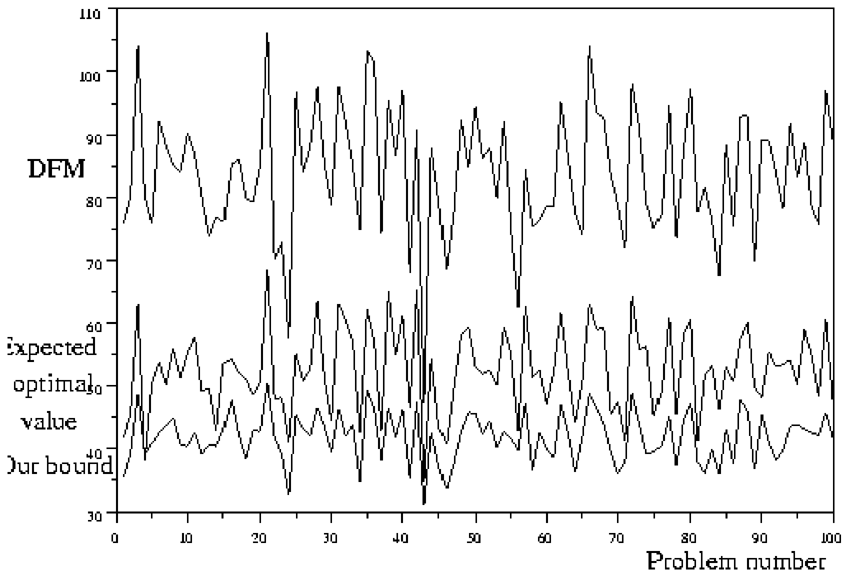

Figure 2: Comparison of the bounds for one hundred problems.

This very preliminary experimental results seem to be quite promising, and we plan to try our bound on real life problems in a short future.

AN INFERENCE CURVE-BASED RANKING TECHNIQUE FOR UNIVARIATE OBSERVATIONS WITH BIOMEDICAL APPLICATIONS

Christos Christodoulou, A. Karagrigoriou and F. Vonta

Key words: Correlation, influence curve, outliers.

COMPSTAT 2004 section: Model selection.

Abstract: In this paper we introduce a correlation ranking method which is established with the use of the influence curve. The method proposed has numerous applications among which one could mention outlier detection. For illustrative purposes, a number of real medical data sets are studied and the so called reference range is obtained.

1 Introduction

A way of "ranking" bivariate observations following a linear regression model in terms of their contribution to the fitting of the model has been introduced by Atkinson and Riani [1]. Their technique focuses exclusively on outlier detection for regression models. In this paper we propose a different technique for ranking univariate observations by means of the correlation between the sample data and their respective ranks. The proposed method is then used in various examples with both simulated and real data. In all the examples we concentrate on the topic of reference range which has been given considerable attention in various scientific areas among which is the medical research.

The paper is presented as follows: In Section 2, the main inference curve-based ranking technique is introduced while in Section 3 a number of examples and applications are fully discussed. A discussion section has been included at the end of the paper.

2 The proposed ranking technique

In this section we introduce the use of a technique for ranking univariate observations by means of the correlation between the sample data x_i and their respective ranks. The proposed method is based on a very clear and simple idea according to which the issue of ordering of the observations should not be based on their size but rather on their effect or contribution on the underlying model or process the observations suppose to satisfy. Such a ranking may be called "model-ranking". For example, for bivariate data that fit a p-dimensional regression model the observations could be ranked according to their contribution on the residuals or on their contribution on the coefficient of determination. A similar approach could be adopted for time series data.

It is of course understood that in many instances the underlying model is not available and therefore a model-ranking is not possible. In medical research and especially in laboratory research where biochemical characteristics behave independently no model may be appropriate or available. In such cases an artificial model may be implemented, like the one describing the (linear) relation between the observations and their corresponding traditional ranks. The alternative approach we propose here in such cases is based therefore on "(pseudo-)model-ranking".

For the pseudo-model-ranking we make use of the definition of the influence curve for bivariate data using as the quantity of interest the correlation coefficient and we rank the data according to their influence on the correlation coefficient. The influence value of the point (x, y) is

$$IC(x,y) = \frac{x-\mu_1}{\sigma_1} \cdot \frac{y-\mu_2}{\sigma_2} - \frac{\rho}{2}\left[(\frac{x-\mu_1}{\sigma_1})^2 + (\frac{y-\mu_2}{\sigma_2})^2 \right],$$

where μ_1, σ_1 are the sample mean and standard deviation of the x's, μ_2, σ_2 the corresponding values of the y's and ρ the sample correlation coeffitient between x and y. The three steps of the procedure are as follows:

Step 1: We construct a single regression model between the sample data and their respective ranks, $y_i = rank\,[x_i]\,,\ i = 1, 2, \ldots, n$. Note that here we refer to the traditional ranking (order statistics).
Step 2: Start with $j = n$ (the initial sample size).
Step 3: Calculate the influence curve of each pair of observations (x_i, y_i), $i = 1, 2, \ldots, j$. The observation with the smallest (worst) influence is assigned the higher ranking, namely $x^*_{(j)}$.
Step 4: Repeat Step 3, excluding all observations that have been assigned a rank such that $j = n - (\#$ of obs. already ranked). Let the ranked data be $x^*_{(1)}, \ldots, x^*_{(n)}$ with $x^*_{(1)}$ and $x^*_{(n)}$ the highest and lowest influence observations respectively.

The above ranking method could be used in various ways by the statistician. One way is by applying the method to identify possible outliers in a given set of data. Various outlier detection techniques can be found in the literature for both univariate and multivariate regression and time series models. Barnett and Lewis [2] provide an extensive literature review, while Davies and Gather [3] introduce the outlier region with the use of finite breakdown points [4]. Peña and Yohai [8] have introduced a procedure of high-breakdown robust point estimates for regression through which one succeeds in detecting groups of outliers. A large collection of graphical and other techniques for outlier diagnostics can be found in Atkinson and Riani [1] which have been applied to different types of regression models. In multivariate samples, a fast outlier detection procedure based on the analysis of the projections of the sample points onto a set of $2p$ directions was recently developed [7].

It is obvious that there are several statistical tools that could be used for outlier detection. For the purpose of this work, we have decided to select for this role, the correlation coefficient. As a result, the following step could be added to the above algorithm for the identification of possible outliers.

Step 5: Start with $x^*_{(1)}$ and $x^*_{(2)}$ and calculate R^2 repeatedly by adding each time the next ordered observation. If the inclusion of the kth ordered observation, $k = 3, 4, \dots, n$ results in $R^2 < \delta$ for some pre-assigned $0 < \delta < 1$ chosen by the statistician, then the observations $x^*_{(k)}, \dots, x^*_{(n)}$ are (possible) outliers.

Intuitively, if no outlying observations are present then the correlation coefficient between the observations and their ranks should be very close to 1 and their linear relation extremely strong. Naturally the value of δ is expected to be chosen very close to 1. Simulated data for various continuous and discrete distributions show that a threshold close to 0.95 is adequate for most applications.

For the sake of completeness we need to mention briefly here the traditional approach of Hoaglin, Mosteller, and Tukey [6] for identifying outliers. According to their approach which is based on the fourth spread, we lay off a multiple of $\frac{3}{2}$, upward from the upper fourth and downward from the lower fourth. The lower fourth, which is denoted by F_L is defined as the median of the observations lying between the minimum and the median of a given data set. The upper fourth, F_U is defined symmetrically with respect to the median. The resulting interval is

$$\Big(F_L - 1.5d_F, F_U + 1.5d_F\Big)$$

where $d_F = F_U - F_L$ is the fourth spread. Observations outside these cut-offs are regarded as outliers. A generalization of the above cut-offs is given by:

$$\Big(F_L - ad_F, F_U + ad_F\Big). \tag{2.1}$$

where a is a real number to be chosen by the statistician according to the definition of outliers she/he is willing to adopt.

3 Examples and applications

The issues raised and discussed in this article have numerous applications. Here we briefly cover the topic of reference range which is a main issue in medical research used for identifying abnormalities in clinical investigations. In most diagnostic tests, the reference range for the variables tested play the key role in determining the type and the extent of the therapeutic or pharmaceutical action to be taken. The reference range is defined as an interval inside which the normal (non abnormal) values of a certain characteristic lie.

Values outside the reference range are indicative of a malfunction and the patients should be properly treated. The most usual reference ranges are the inter-centile intervals based on the upper and lower 2.5th and 5th percentiles. It is natural that for the estimation of these percentiles caution is required in identifying any outliers. Note that the inclusion of outliers in the process of calculating the boundaries of the range may result in an unacceptable range that may be inadequate for preventive, diagnostic or therapeutic purposes.

(a) Simulated data

In order to test the effectiveness of the proposed ranking method in outlier detection, two short scale simulation studies were conducted. It should be pointed out that the objective of the simulation studies is the investigation of the effectiveness of the proposed method for cases with different degree of distinction between the two distributions involved. As a result the studies were decided to be based on the contamination of a basic distribution by distributions located very near as well as far enough from the basic distribution. In both studies, the standard Normal distribution was selected to play the role of the basic distribution. Furthermore, the Normal distribution N(3,1) has been selected as representative of the distributions located relatively close to the standard Normal so that the distinction between them is relatively difficult. Finally, the opposite role has been given to the Normal distribution N(6,1). In the first study, one hundred samples with 100 observations each were selected. Each sample consists of 95 observations randomly selected from the standard Normal distribution and 5 observations randomly selected from the Normal distribution with mean 6 and variance 1. In other words, each sample has been contaminated with a random sample of size 5 from the $N(6,1)$ distribution. The influence curve was calculated and the (pseudo)-model ranks were assigned (the higher the rank the lower the influence). The method has successfully identified all contaminated data as the least influential data in each sample. Indeed, for each sample, the method selects first as the most influential observations, the 95 observations from the $N(0,1)$ (ranks 1 through 95) and then selects the contaminated observations (ranks 96 through 100).

The correlation coefficient remains above the 0.95 threshold for all pure (non-contaminated) observations (a total of 9500 observations in all 100 samples). The 0.95 threshold is crossed for 476 out of 500 contaminated observations while for the remaining 24 contaminated cases the correlation coefficient remained incorrectly above the threshold. As a result, the first part of the method based on the influence curve has a 100% rate of success while the second part based on the correlation coefficient has only a 95.2% rate of success. Table 2 provides for all 100 samples combined the proportion of observations for which the correlation coefficient stays above or below the $\delta = 0.95$ threshold. The results are presented separately for the 9500 pure $N(0,1)$ observations and the 500 contaminated $N(6,1)$ observations.

	9500 $N(0,1)$ obs & 500 $N(6,1)$ obs.	
$\delta = 0.95$	**% of $N(0,1)$ obs.**	**% of $N(6,1)$ obs.**
ABOVE	100%	4.8%
BELOW	0%	95.2%

Table 1: First simulation study.

A second simulation study was contacted identical to the first one except that the $N(3,1)$ distribution is now responsible for the contamination. Note that due to the overlapping of the lower half of $N(3,1)$ with the upper half of the standard Normal, approximately 50% of the contaminated observations are expected never to be identified. The influence curve method though was successfully applied to the data with an overall (with all 100 samples combined) rate of success equal to 61.6%, which means that 61.6% of the contaminated observations where correctly identified as the least influential ones. Furthermore, in 65% of the samples the method correctly identified at least 3 (out of 5) contaminated observations as the least influential ones. Table 2 provides the proportion of samples where the proposed method recovered successfully 0, 1, 2, 3, 4, and 5 contaminated observations per sample.

95 $N(0,1)$ obs & 5 $N(3,1)$ obs per sample						
# of contaminated obs. identified	**0**	**1**	**2**	**3**	**4**	**5**
Proportion of samples (%)	2	10	23	22	29	14

Table 2: Second simulation study.

The above studies clearly indicate that the proposed ranking technique based on the influence curve combined with the correlation coefficient produce an extremely successful technique for identifying contaminated data.

(b) Real data

For illustrating the methodology proposed in this article, we make use of a set of real data on cholesterol and the transition mutation C677T of 5, 10-methylenetetrahydrofolate reductase (MTHFR) provided by the Molecular Genetics Department B and Laboratory of Forensic Genetics of the Cyprus Institute of Neurology and Genetics. A total of 515 individuals, 319 males and 196 females were examined and among other variables, the cholesterol level was measured in mMol/L (min=3.4, max=10.8, mean=6.28, std. dev.= 1.17, and median=6.2). Furthermore for 87 of these individuals the genotype frequencies for the MTHFR C677T polymorphism were established. 41 individuals (47%) were homozygous for the wild type allele (C/C), 34 (39%) were heterozygous (C/T), and 12 (14%) were homozygous for the mutant allele (T/T). The purpose of the study is the estimation of a 95% reference range for the cholesterol level as well as reference ranges for the cholesterol level for the C/C and C/T genotype for MTHFR C677T polymorphism. No range will be provided for the mutant homozygous genotype due to the small number of cases. Since the data do not follow the normal distribution, a series of transformations on the data to achieve normality is considered necessary. Making use of the Kolmogorov test, it is realized that the cholesterol level data do not come from a normal distribution (test statistic=0.119, p-value=0). After applying the log-transformation, we achieve normality (test statistic reduces to 0.0397, p-value=0.3921).

Applying now the 5-step-(pseudo) model-ranking method with $\delta = 0.95$ we observe that no outliers are present. Note that the Hoaglin, Mosteller, and Tukey (HMT) method arrives at the same results. Indeed, consider the generalized formula of HMT we introduced in equation (2.1) and assume that a is defined so that if the distribution is indeed normal then all observations of the sample that depart more than three standard deviations from the mean (or the median, since they coincide) are characterized as outliers and consequently they are discarded from the data set. Under this definition it is easily found that $a = 1.7$. Using this general formula for our example, we identify no outliers. Calculating the upper and lower 2.5th sample percentiles we arrive at the 95% reference range: $(4.25, 9.11)$.

Following the same procedure for the 41 cases for the wild type genotype for MTHFR C677T (MTHFR=1) and the 34 cases of the heterozygous genotype for MTHFR C677T (MTHFR=2) we identify one outlier in the former case and none in the latter. It should be pointed out that both the proposed method and the HMT method arrive at the same result. Figure 1 provides the corresponding correlation coefficients. The single outlier found is easily identified because of the significant drop in the value of the correlation coefficient (for MTHFR=1). The resulting 95% reference ranges are $(4.45, 8.37)$ for the wild type genotype and $(4.65, 8.82)$ for the heterozygous genotype.

Note that the above results indicate that the MTHFR C677T mutation has no effect on the cholesterol level. Such a conclusion is indeed expected since the MTHFR C677T mutation has not been shown in any study to affect cholesterol levels and further, MTHFR does not interact in anyway with cholesterol metabolism.

4 Discussion

In this work we introduce the notion of pseudo-model-ranking for which the observations are ranked according to their influence on an artificial regression model between the observations and their traditional ranks.

As it is well known the outlier detection plays a very important role not only in the analysis of biomedical data but in general in the analysis of any type of data. Indeed, the modelling, the statistical inference as well as the prediction inference may be heavily affected by the presence of outliers. The simulation studies undertaken as well as the biomedical applications considered in this work clearly indicate both the appropriateness and the effectiveness of the proposed method.

COMPSTAT'2004 Symposium

MODEL BASED VISUALIZATION OF PORTFOLIO STYLE ANALYSIS

Claudio Conversano and Domenico Vistocco

Key words: Constrained linear regression, mean integrated squared error, parallel coordinates, mutual funds benchmarking, active vs. passive management.

COMPSTAT 2004 section: Financial data analysis.

Abstract: The paper concerns multimanager management of Mutual Funds portfolios, a kind of investment allocating the financial resources to Mutual Funds instead of standard financial stocks. In particular, Mutual Funds portfolios investing on a single asset category (equity, bond, corporate, derivative) are considered. The goal is to provide a method to rank Mutual Funds investment style with respect to the returns of a target index named benchmark. To this aim, a rolling constrained multiple linear regression model is considered in order to estimate each Mutual Fund portfolio composition as well as the benchmark portfolio composition. Starting from such compositions, the Mean Integrated Squared Error (MISE) is computed to measure the proximity of each Mutual Fund portfolio returns to the benchmark portfolio returns. A visual inspection of this proximities is provided using parallel coordinates plot. The method allows to identify a specific management style for each Mutual Fund, discriminating active management Funds from passive management ones. To evaluate the effectiveness of the proposed method, an application on a set of Italian Mutual Funds operating in the European equity market is presented.

1 The framework

Nowadays, among the range of new financial products offered by investment banks, portfolios composed by Mutual Funds are an interesting opportunity for investors. Their aim is to offer the investor an "optimal" portfolio (in the Markovitz sense), i.e. a portfolio providing the maximum return with the minimum risk. Two main categories can be considered:

1) *Mutual Funds Individual Portfolios* (MFIP). For each client, the investment bank allocates resources in a basket of Mutual Funds instead of a set of different financial stocks.

2) *Mutual Funds Mixed Portfolios* (MFMP). The bank is able to offer the same product obtained by combining different quotas of Mutual Funds to a set of clients. Here, the product is not offered to a single investor but to many of them.

Hereinafter, we refer to MFMP investing on a single asset category (*mono-market management*). This choice allows to start from a set of quite homogeneous products to be evaluated on the basis of common criteria. In many countries (including Italy), investment banks are legally confined to provide general information to the official institutions governing the financial markets about their Mutual Fund asset allocation principles and the *benchmarks*. The latter are reference portfolios composed by one or more financial market indexes. The role of benchmark is threefold:

a) for the portfolio manager, it is a reference parameter in the asset allocation process;

b) for the investment bank internal auditing, it is a tool to evaluate the management style and the results of the management team;

c) for the client, it is a reference index to evaluate the portfolio management activity, since the returns of each Fund should not be too far from the benchmark ones, particularly if negatives.

Often, the official benchmark (also known as *strategic benchmark*) differs from the *operative benchmark*. The first is usually selected to minimize the risk of future negative deviations. In fact, to avoid the risk of losing clients, portfolio managers select benchmarks that can be easily replicated. Instead, operative benchmark is selected according to internal auditing indications, since it is commonly used to monitor the portfolio managing activity. As a consequence, a financial analyst wishing to evaluate the management style of a set of Mutual Funds managed by various investment banks should refer to a benchmark that it is meant to be representative of the Mutual Funds specific sector, since information about each specific portfolio composition can not be retrieved easily.

2 Data, method and notation

We consider Italian Mutual Funds operating to the European equities sector. We collect daily time series from January 4, 1999 to September 30, 2002 (976 observations) concerning:

- a set of 39 Italian Mutual Funds;
- the Morgan Stanley Europe Equity Index (benchmark);
- the benchmark constituents indexes concerning 10 activity sectors, namely: *Energy (ENR), Materials (MAT), Industrials (IND), Consumer Discretionary (CDIS), Consumer Staples (CSTA), Health Care (HC),Financial (FNCL), Information Technology (IT), Telecommunication Services (TEL), Utilities (UTI))*[1].

Each series is quoted in Euro and is rescaled on weekly basis (the Wednesday observation is considered as representative of the whole week, as common practice in financial data analysis). As a result, the final weekly time series are composed of 195 observations.

The proposed method, to be described formally in the following section, is in three steps. The first step is the estimation of the benchmark port-

[1] A more analytical decomposition resulting in more sectors can be used depending on the accuracy level of the analysis. Of course, when increasing the number of sectors the interpretability of final results become more difficult.

folio composition. It takes into account the benchmark constituents using a constrained rolling regression model ([1],[2]), aimed to evaluate the impact of each constituent in the generation of the benchmark portfolio returns (step 1A). The same approach is used for each Mutual Fund portfolio to identify the main differences in the portfolio management style, through the estimation of the portfolio weights of each activity class (step 1B). Once the portfolio compositions of both Mutual Fund portfolios and benchmark portfolio have been estimated, a ranking of the Mutual Fund investment styles is made with respect to both the whole benchmark portfolio composition (global ranking) and each benchmark constituent (partial ranking). The Mean Integrated Squared Error (MISE) allows to obtain these rankings (Step 2). Finally, using interactive parallel coordinates plots, a visual inspection of the results of previous steps is provided (Step 3).

Since we apply a rolling regression model, we denote with h the number of weeks composing the temporal window. Furthermore:

- $t = 1, \ldots, T$ indicates time occasions,
- $f = 1, \ldots, F$ indicates the different Mutual Funds,
- $s = 1, \ldots, S$ indicates the activity sectors of the benchmark constituents.

In our application we use $h = 52$ (corresponding to the number of weeks in a year), $T = 195$, $F = 39$, $S = 10$ (since the sectorial composition of the benchmark portfolio refers to the 10 above-mentioned activity sectors). We apply a constrained rolling regression model $T - h$ times. The model is applied separately for the benchmark and the Mutual Funds, namely:

1.) using as covariates the benchmark constituents indexes returns and as response the benchmark index returns (*step 1A*);

2.) using as covariates the benchmark constituents indexes returns and as response the Mutual Funds returns (*step 1B*).

3 Formal description of the method

STEP 1: Style Analysis (Sharpe-like)[3]. We consider $T - h = 143$ occasions and define:

- $\mathbf{r}^{(j)}_{BMK}$: the $h \times 1$ vector of benchmark returns ($j = 1, \ldots, T - h$)
- $\mathbf{R}^{(j)}_{CONST}$: the $h \times S$ matrix of the benchmark constituents returns ($j = 1, \ldots, T - h$ and $s = 1, \ldots, S$).
- $\mathbf{r}^{(f,j)}_{FUND}$: the $h \times 1$ vector of the returns of the Mutual Fund f ($f = 1, \ldots, F$, and $j = 1, \ldots, T - h$).

STEP 1A: *Estimation of the benchmark sector composition.* To estimate the benchmark sector composition we define the following multiple regression model [2]:

$$\mathbf{r}^{(j)}_{BMK} = \mathbf{R}^{(j)}_{CONST}\beta^{(j)}_{BMK} + \epsilon \qquad (j = 1, \ldots, T - h)$$

with the constraints:

$$\begin{cases} \sum_{s=1}^{S} \beta_{BMK}^{(j)} = 1 \\ \\ 0 \leq \beta_{BMK}^{(j)} \leq 1 \qquad (s = 1, \ldots, S) \end{cases}$$

The model coefficients indicate the benchmark composition with respect to the S different constituents. Since the rolling estimation process is repeated $j = 1, \ldots, T-h$ times, we obtain $T-h$ model coefficient vectors. They form the following matrix:

$$\hat{\mathbf{B}}_{BMK} = \begin{bmatrix} \hat{\beta}_{BMK_1}^{(1)} & \cdots & \hat{\beta}_{BMK_1}^{(j)} & \cdots & \hat{\beta}_{BMK_1}^{(T-h)} \\ \vdots & & \vdots & \vdots & \\ \hat{\beta}_{BMK_S}^{(1)} & \cdots & \hat{\beta}_{BMK_S}^{(j)} & \cdots & \hat{\beta}_{BMK_S}^{(T-h)} \end{bmatrix}$$

$\hat{\mathbf{B}}_{BMK}$ is a $S \times (T-h)$ matrix such that, for each j, $0 \leq \hat{\beta}_{BMK}^{(j)} \leq 1$ and $\sum_{s=1}^{S} \hat{\beta}_{BMK}^{(j)} = 1$.

STEP 1B: *Estimation of Mutual Funds portfolio sector composition.* Likewise step 1, to estimate each Mutual Fund sector composition we define the following multiple regression model [2]:

$$\mathbf{r}_{FUND}^{(f,j)} = \mathbf{R}_{CONST}^{(f,j)} \beta_{FUND}^{(f,j)} + \epsilon \qquad (f = 1, \ldots, F) \quad (j = 1, \ldots, T-h)$$

with the constraints:

$$\begin{cases} \sum_{s=1}^{S} \beta_{FUND}^{(f,j)} = 1 \\ \\ 0 \leq \beta_{FUND}^{(f,j)} \leq 1 \qquad (s = 1, \ldots, S) \end{cases}$$

In this case, for the Mutual Fund f the model coefficients express its portfolio composition with respect to the sector s. Since the rolling estimation process is repeated $j = 1, \ldots, T-h$ times, we obtain $T-h$ vectors, that form the matrix:

$$\hat{\mathbf{B}}_{FUND} = \begin{bmatrix} \hat{\beta}_{FUND_1}^{(f,1)} & \cdots & \hat{\beta}_{FUND_1}^{(f,j)} & \cdots & \hat{\beta}_{FUND_1}^{(f,T-h)} \\ \vdots & & \vdots & \vdots & \\ \hat{\beta}_{FUND_S}^{(f,1)} & \cdots & \hat{\beta}_{FUND_S}^{(f,j)} & \cdots & \hat{\beta}_{FUND_S}^{(f,T-h)} \end{bmatrix}$$

$\hat{\mathbf{B}}_{FUND}$ is a $S \times (T-h)$ matrix such that, for each j, $0 \leq \hat{\beta}_{FUND}^{(f,j)} \leq 1$ and $\sum_{s=1}^{S} \hat{\beta}_{FUND}^{(f,j)} = 1$. A matrix $\hat{\mathbf{B}}_{FUND}$ is obtained for each Mutual Fund f $(f = 1, \ldots, F)$.

Information obtained in Step 1 are the starting point to rank the asset allocation process of each Fund in steps 2 and 3.

STEP 2: Mutual Funds Management Style Ranking. The estimation of the benchmark portfolio composition (step 1A) and that of each Mutual Fund portfolio composition (step 1B) allow to rebuild the F Mutual Funds portfolios and to compare them with the benchmark portfolio composition.

To this purpose, the *Mean Integrated Squared Error* (MISE) is cnsidered. It measures the proximity between an estimated curve $\hat{m}$ and the true function m and it is used in the framework of regression smoothing through kernel functions[4]. Here, f is a marginal density and w is a weight function. The MISE, denoted with d_M, can be meant as the expectation of the *Asymptotic Squared Error* (ASE), denoted with d_I, namely:

$$d_M(\hat{m}, m) = E\{d_I(\hat{m}, m)\}$$

with $d_I(\hat{m}, m) = \int(\hat{m} - m(x))^2 f(x)w(x)dx$.

Hereinafter, we assume the benchmark portfolio time series returns is the true function m to be estimated using the returns of the Mutual Fund recomputed according to the portfolio weights estimated in step 1B. This assumption allows to discriminate between two different portfolio management styles:

a)*passive management*: the asset manager investment style is driven by the benchmark portfolio composition and the corresponding MISE is small;

b)*active management*: the asset manager investment style is not necessarily driven by the benchmark portfolio composition. In this case, the corresponding MISE is high.

STEP 3: *Visualisation of the Management Style*. The whole information obtained in the previous steps can be represented using interactively parallel coordinates plots [5].

These can be considered as a generalisation of a two-dimensional Cartesian Plot, since they maps the k-dimensional space onto two display dimensions using k equidistant axes, which are parallel to one of the display axes. The axes correspond to the dimensions and are linearly scaled from the minimum to the maximum value of the corresponding dimension. Each data item is presented as a polygonal line, intersecting each axes at the point corresponding to the value of the considered dimension. Although the basic idea of parallel coordinates is quite simple, this tool is powerful in revealing a wide range of data characteristics, including the ability to diagnose one-dimensional features (such as marginal densities), two-dimensional features (such as correlations) and nonlinear structures, as well as multidimensional features (such as clustering, hyperplanes and the modes).

In our method, parallel coordinates plots are used to visualize together different portfolio management styles. For each observation, we plot the global MISE (calculated w.r.t. the benchmark portfolio returns) and the sectorial MISE (calculated w.r.t. the returns of sector indexes). The information deriving from this kind of visualization can be combined with return and risk measures in order to evaluate the way the management style affect the Mutual Fund performance.

Mutual Fund	**Global MISE**	**Average Rank**	**Average Return**	**Perfor- mance**	**Historical Volatility**
1. Gestnord	**0.117**	**10.45**	-0.038	-10.391	2.270
2. Arca	0.119	14.73	-0.017	-7.043	2.256
3. Ras	0.148	10.64	**-0.003**	-5.654	2.476
4. Investire	0.157	17.36	-0.044	-11.303	2.242

Table 1: The 5 most passive vs. the 5 most active Mutual Funds according to the global MISE (first column) and other risk/return measures.

4 Main results

The proposed method has been applied for the 39 Italian Mutual Funds described in section 2. For sake of brevity we summarize just the main results. Table 1 reports the most 5 *passive Funds* (i.e. those reporting the lowest value of the global MISE) compared to the most 5 *active Funds* (i.e. those reporting the highest value of the global MISE). For comparison purposes, also the most common risk/return measures are reported, namely: a) the average rank (second column), i.e. the average rank of the Mutual Fund, obtained when ordering observations increasingly with respect to the value of the sectorial MISE; b) the avarage return (third column), i.e. the average of the weekly returns each Fund reported in the whole period; c) the performance (fouth column), i.e. the total return of the Fund in the whole period; d) the historical volatility (last column), i.e. the standard deviation of the weekly returns in the whole period. The table shows that the global MISE reflects the overall management style, because the average rank of the most passive Funds is lower than the global MISE of the most active Funds. Furthermore, considering together the performance, the average return and the volatility of the two groups of Mutual Funds, it is evident that an active management style usually improves the Mutual Fund performance and does not increase the risk (volatility).
Finally, the investment style of the two groups of Funds is compared though parallel coordinates plots using the *Mondrian*[6] software.

Figure 1 shows the global and sectiorial MISE for the 39 Funds. In the top panel the polygons corresponding to the 5 most passive Mutual Funds have been highlighted and similar visualization is available for the 5 most active

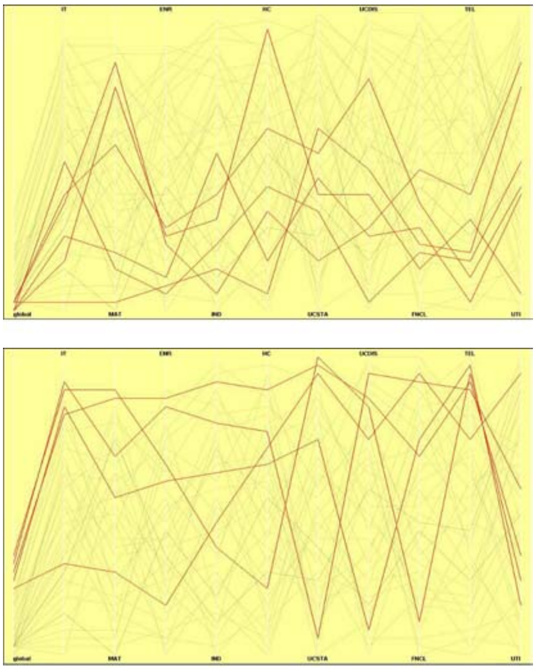

Figure 1: Parallel coordinates plot of the Global and sectorial MISE. Highlited are the polygons of both the 5 most passive Mutual Funds (top panel) and the 5 most active Mutual Funds (bottom panel).

Mutual Funds (bottom panel). Comparing the two panels of the figure, it is possible to note that passive Funds tend to show a relatively similar investment style, since the poligons of the corresponding parallel coordinates are quite homogeneous. Instead, investment style of active Funds is quite heterogeneous, showing that the asset allocation strategy for sectors like Consumer Staples (CSTA) and Financial (FNCL) tends to diverge from the relative benchmark constituents indexes, since the partial ranking (MISE) is high.

5 Final remarks

The analysis presented in the previous section revealed the effectiveness of the proposed method. First, Mutual Funds presenting a small MISE refers to an investment style which is coherent with the benchmark composition (and then with the financial market variations), and they should at least provide the same risk and return of the benchmark. Second, information about portfolio compositions can be considered in a perspective way, since the sector composition of both the benchmark and the Mutual Fund portfolios can be

used to compose a portfolio of Mutual Funds (MFMP) on the basis of a prespecified risk/return target.
The proposed method can be also applied for more analytical sectorial decompositions of the benchmark portfolio in order to rank in different ways Mutual Funds investment styles. With some minor changes the method can be extended to mixed Mutual Funds, in the case two or more benchmarks are used as representatives of the target market. Other results to be drawn are: a) the comparison of our rankings with other commonly used ranking criteria (like those provided by the rating agency Morningstar); b) the interactive visual analysis of the results of the method combined with risk/return measures; c) the different consideration of positive and negative deviations among the returns of the Mutual Funds and those of the benchmark in the computation of MISE; d) the investigation of the relations between the sectorial ranks and the global ranks.

VISUALIZATION IN CLASSIFICATION PROBLEMS

D. Cook, D. Caragea and V. Honavar

Key words: Tour methods, classification problems, support vector machines.

COMPSTAT 2004 section: Data visualization.

Abstract: In the simplest form support vector machines (SVM) define a separating hyperplane between classes generated from a subset of cases, called support vectors. The support vectors "mark" the boundary between two classes. The result is an interpretable classifier, where the importance of the variables to the classification, is identified by the coefficients of the variables defining the hyperplane. This paper describes visual methods that can be used with classifiers to understand cluster structure in relation to known classes in data.

1 Introduction

The classification community has been overly focused on predictive accuracy. For many data mining tasks understanding a classification rule is as important as the accuracy of the rule itself. Going beyond the predictive accuracy to gain an understanding of the role different variables play in building the classifier provides an analyst with a deeper understanding of the processes leading to cluster structure. Ultimately this is our scientific goal, to solve a problem and understand the solution. With a deeper level of understanding researchers can more effectively pursue screening, preventive treatments and solutions to problems.

In the machine learning community, which is driving much of the current research into classification, the goal is that the computer operates independently to obtain the best solution. In data analysis, we're still a long way off this goal. Most algorithms will require a human user to twiddle with many parameters in order to arrive at a satisfactory solution. The human analyst is invaluable at the training phase of building a classifier.

This paper describes the use of graphics to build a better classifier based on support vector machines (SVM). We will plot classification boundaries in high-dimensional space and other key aspects of the SVM solution. The visual tools are based on manipulating projections of the data, and are generally described as tour methods. Our analysis is conducted on a particular data problem, the Italian olive oils data where the task is to classify oils into their geographic area of production based on the fatty acid composition. We focus on SVM because they operate by finding a hyperplane which maximizes the margin of separation between the two classes. This is similar to how we believe the eye perceives class boundaries. As a result of visualizing class structure in relation to SVM we have suggestions about how to find simpler but accurate classifiers.

2 Support vector machines

SVM is a binary classification method that takes as input labeled data from two classes and outputs a model for classifying new unlabeled data into one of those two classes. SVM can generate linear and non-linear models. In the linear case, the algorithm finds a separating hyperplane that maximizes the margin of separation between the two classes. The algorithm assigns a weight to each input point, but most of these weights are equal to zero. The points having non-zero weight are called *support vectors*. The separating hyperplane is defined as a weighted sum of support vectors. It can be written as, $\{\mathbf{x} : \ \mathbf{x}'\mathbf{w} + b = 0\}$, where $\mathbf{x}$ is the p-dimensional data vector, and $\mathbf{w} = \sum_{i=1}^{s} (\alpha_i \cdot y_i)\mathbf{x_i}$, where s is the number of support vectors, y_i is the known class for case $\mathbf{x}_i$, and α_i are the support vector coefficients that maximize the margin of separation between the two classes. SVM selects among the hyperplanes that correctly classify the training set, the one that minimizes $\|\mathbf{w}\|^2$, which is the same as the hyperplane for which the *margin* of separation between the two classes, measured along a line perpendicular to the hyperplane, is maximized. The classification for a new unlabeled point can be obtained from $f_{\mathbf{w},b}(\mathbf{x}) = \text{sign}(\mathbf{w} \cdot \mathbf{x} + b)$.

We will be using the software SVM Light 3.50 [5] for the analysis. It is currently one of the most widely used implementations of SVM algorithm.

3 Tours methods for visualization

The classifier resulting from SVM, using linear kernels, is the normal to the separating hyperplane which is itself a 1-dimensional projection of the data space. Thus the natural way to examine the result is to look at the data projected into this direction. It may also be interesting to explore the neighborhood of this projection by changing the coefficients to the projection. This is available in a visualization technique called a manually-controlled tour.

Generally, tours display linear combinations (projections) of variables, $\mathbf{x}'\mathbf{A}$ where $\mathbf{A}$ is a $p \times d(< p)$-dimensional projection matrix. The columns of A are orthonormal. Often $d = 2$ because the display space on a computer screen is 2, but it can be 1 or 3, or any value between 1 and p. The earliest form of the tour presented the data in a continuous movie-like manner [1], but recent developments have provided guided tours [3] and manually controlled tours [2]. Here we are going to use a $d = 2$-dimensional manually-controlled tour to recreate the separating boundary between two groups in the data space.

We will be using the tour methods available in the data visualization package GGobi (`www.ggobi.org`).

4 The analysis of the Italian olive oils

To explain the visualization techniques we will use a data set on Italian olive oils. The olive oil data [4] contains 572 instances (cases) that have been chemically assayed for their fatty acid composition. There are 8 attributes (variables), corresponding to the percentage composition of 8 different fatty acids (palmitic, palmitoleic, stearic, oleic, linoleic, linolenic, arachidic, eicosenoic), 3 major classes corresponding to 3 major growing regions (North, South, Sardinia), and 9 sub-classes corresponding to areas in the major regions.

The data was collected for studying quality control of olive oil production. It is claimed that olive oils from different geographic regions can be distinguished by their fatty acid signature, so that forgeries can be recognized. The multiple classes create a challenge for classification, and the class structure is interesting: the classes have dramatically different variance structure, there are both linear and nonlinear boundaries between classes and some classes are difficult to separate. There are some surprises in the data.

4.1 Approach

Because there are 9 classes and SVM works only with 2 classes, we need to define an approach to building a classifier working in pairwise fashion. The most obvious start is to develop a classifier for separating the 3 regions, and then hierarchically work within region to build classifiers for separating areas.

In each classification we will run SVM. In the visualization we will highlight the cases that are chosen as support vectors and use the weights of the support vectors to construct the best separating projection. We will also examine the correlations between predicted values and variables to determine the importance of the variables for the classification.

4.2 Analysis

South vs Sardinia/North: This separation is too easy so it warrants only a short treatment. If the analyst blindly runs SVM with the oils from southern Italy in one class and the remaining oils in another class, then the result is a perfect classification, as shown in the plot of the predicted values on the horizontal axis of Figure 1. However if the analyst plots eicosenoic acid alone (vertical axis in Figure 1) she would notice that this also gives a good separation between the two classes. Eicosenoic acid alone is sufficient to separate these regions. When we examine the correlations between the predicted values and the variables we can see that although eicosenoic acid is the variable that is most correlated with predicted values that several other variables, palmitic, palmitoleic and oleic also contribute strongly to the prediction. Clearly, this classifier is too complicated. The simplest, most accurate rule would be to use only eicosenoic acid, and split the two classes by:

```
Assign to south if eicosenoic acid composition is more than 5%.
```

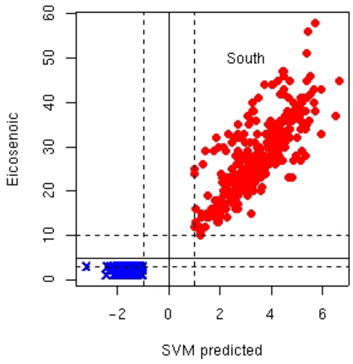

Figure 1: Examining the relationship between the results of the SVM classifier and one variable, eicosenoic acid. The horizontal axis displays the predicted values from the SVM classifier. The vertical axis displays the values of eicosenoic acid.

The minimum eicosenoic acid value for southern oils is 10%, and the maximum eicosenoic acid value for Sardinian and northern oils is 3%. Thus given the variance difference between the two groups a boundary at 5% makes sense. To obtain a solution numerically, the analyst could use eicosenoic acid alone in the SVM, quadratic discriminant analysis or logistic regression. Linear discriminant analysis does not give a good boundary because the two groups have very different variance.

Sardinia vs North: This is an interesting classification problem, so it warrants an in-depth discussion. Plotting the data (Figure 2) two variables at a time reveals both a fuzzy linear classification (left) and a clear non-linear separation (middle) which would be difficult to model. A clean linear separation can be found by a linear combination of linoleic and arachidic acids (right). The circle at lower left in the plot is an axis that represents the combination of variables that are shown, and the numbers at right are the numerical values of the projection. Variable 7, linoleic, has a projection coefficient equal to 0.969, and variable 9, arachidic, has a projection coefficient equal to 0.247. This class boundary warrants some investigation. Very often explanations of SVM are accompanied by an idealized cartoon of two well-separated classes, with support vectors highlighted, and the separating hyperplane drawn as a line. We would like to reconstruct this picture in high-dimensional data space using tours to examine the classification results. To do this we need to turn the SVM output into visual elements. First, we generate a grid of points over the data space, select the grid points within a tolerance of the separating hyperplane. Then we will use the manually

Figure 3: Sequence of rotations that reveals the bounding hyperplane between oils from Sardinia and northern Italy: (Left) Starting from oleic vs linoleic, (Middle) Arachidic acid is rotated into the plot vertically, giving a combination of linoleic and arachidic acid, (Right) The separating hyperplane in the direction of the nonlinear separation.

correlations between predicted values and variables. According the the correlations linoleic is the most important variable followed by oleic, arachidic, palmitoleic, but stearic acid has a large weight value so we are curious about the contribution of this variable. We begin with the projection of the data into linoleic vs oleic acids because these two variables provided a simple linear boundary. Then other variables will be rotated into the plot in combination with linoleic to match the order of importance as provided by the weights. Since oleic acid has a low weight value we believed that its contribution to the separating hyperplane is mostly due to its strong correlation with linoleic acid. We were wrong. The separating hyperplane runs orthogonally to the linear relationship between oleic and linoleic, lower left to upper right rather than horizontally. Thus, it is clear that oleic acid is used even though its weight is small relative to linoleic acid. Next, arachidic acid is rotated into the plot, in combination with linoleic acid. Here the clear linear separation between the two classes can be seen, but it is not the projection corresponding to the SVM separating hyperplane. So, stearic acid is rotated into the plot in combination with linoleic and arachidic acid. Finally, the separating hyperplane is clearly visible, and the support vectors defining the hyperplane lie on opposing edges of the groups. Its clear that stearic acid is used in building the classifier. The boundary is too close to the northern oils. This surprised us, and we re-checked our planar computations several times, but this is the boundary. A quick fix could be obtained by adjusting the shift parameter value to shift the plane to closer to the middle of the separation between the two classes.

In general, the simplest but as accurate solution would be obtained by entering only two variables, linoleic and arachidic acids, into a classifier which should roughly give a rule as follows:

```
Assign to Sardinia if 0.97 x linoleic+2.5 x arachidic > 11%
```

This was obtained by using the projection coefficients provided by the tour, but it could just have easily been obtained by fitting the SVM model or some other classification model using only linoleic and arachidic acids.

North: The oils from the 3 areas in the north (Umbria, East/West Liguria) are difficult to separate. Working purely from graphical displays we might conclude the areas are not separable. But SVM tells us otherwise. The results are that the 3 areas can be perfectly separated using a linear kernel. So we attempt to find the projection of the data which separates the 3 areas. Working from the correlations between the variables and the predicted values, and from the weights for each variable in the separating hyperplane we rotate variables into view. Figure 4 displays the results. Sure enough, with a combination of most of the variables, a projection of the data where the 3 classes are separated can be found. The combination uses stearic, linoleic, linolenic and arachidic horizontally, and palmitoleic, stearic, linoleic and linolenic vertically. What we learn is that the SVM solution is about as

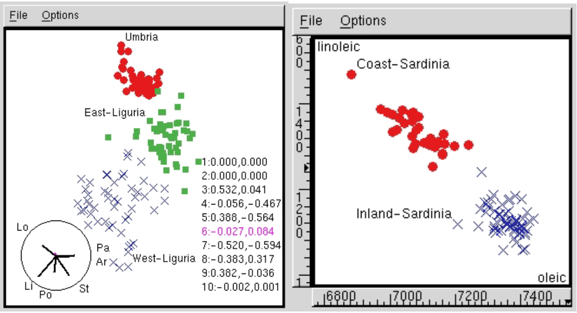

Figure 4: (Left) Projection of northern Italy oils. (Right) Projection of Sardinian oils.

good as possible, and although not easy to simplify using 5 of the 8 variables may provide an adequate classification.

Sardinia: The oils from coastal Sardinia are easily distinguishable from the inland oils using oleic and linoleic acids (Figure 4). A simple rule would be provided by: Assign to Inland Sardinia if $0.5 oleic - 0.75 linoleic > 27$.

South: Now this is the interesting region! There are 4 areas. There is no natural way to break down the 4 areas into a hierarchical pairwise grouping to build a classification scheme using SVM. The best but still poor results are obtained if the analyst first classifies Sicily against the rest. The remaining 3 areas can be almost perfectly separated using linear kernels. Why is this?

Looking at the data, using tours, with the oils from Sicily excluded, it is clear that the oils from the 3 other areas are readily separable (Figure 5, left). But when Sicily (orange open squares) is included it can be seen that the variation on the Sicilian oils is quite large (Figure 5, right). These points almost always overlap with the other oils in the tour projections. These pictures raised suspicions about Sicilian oils. It looks like they are a mix of the oils from the other 3 areas. Indeed, from informal enquiries, it seems that this is the case, that Sicilian olive oils are made from olives that are imported from neighboring areas. The solution is to exclude Sicilian oils from any analysis.

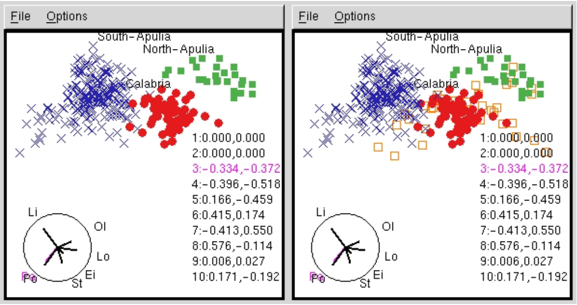

Figure 5: Projection of southern Italy oils.

Summary of analysis: In summary the concluding remarks about this data set are to beware of the oils designated from Sicily, as they do not appear to be pure oils. The remaining geographic production areas do seem to produce distinct fatty acid signatures, and its possible to quantify the differences with linear classifiers.

5 Summary and conclusion

SVMs provide a good complement to visual methods. The results from SVM are visually intuitive, unlike results from methods such as linear discriminant analysis where variance differences can produce a boundary that is too close to the group with the larger variance. Methods such as trees provide boundaries that are restricted to separations in individual variables. Logistic discriminant analysis, though, should compete with SVM and provide similarly accurate and interpretable linear boundaries.

As we raised in the introduction it is reasonable to be laborious in a training phase of building a classifier. Human input to the machine learning process can provide valuable insight into the scientific problem. With the visual tools described in this paper it is possible to visualize class structure in high-dimensional space and use this information to tailor better classifiers for a particular problem. We used just one example data set and one classification technique, but the approach works generally on other real-valued multivariate data, and for understanding other classification techniques.

ANALYSIS OF THE MIB30 BASKET IN THE PERIOD 2000-2002 BY FUNCTIONAL PC'S

Damiana G. Costanzo and Salvatore Ingrassia

Key words: Functional data, principal components, financial data.

COMPSTAT 2004 section: Functional data analysis.

Abstract: The MIB30 basket refers to the 30 most capitalised and traded companies on the Italian Stock Exchange. Related share prices and related quantities are updated during the phase of continuous trading at a frequency of one a minute on the basis of the prices of the latest contracts concluded on each share. The daily traded volumes of these 30 shares in the period from January 3rd, 2000 to December 30th, 2002 are here investigated from an explorative point of view using functional principal component techniques.

1 Introduction

Functional data are essentially curves and trajectories, the basic rationale is that we should think of observed data functions as single entities rather than merely a sequence of individual observations. Even though functional data analysis often deals with temporal data, its scope and objectives are quite different from time series analysis: while time series analysis mainly focuses on modeling data, or in predicting future observations, the techniques developed in FDA are essentially exploratory in nature: the emphasis is on trajectories and shapes; moreover unequally-spaced and/or different number of observations can be taken into account as well as series of observations with missing values, see Ramsay & Silverman [5], [6].

In this paper statistical properties of the daily series of the traded volumes of the shares composing the MIB30 basket in the period from January 3rd, 2000 to December 30th, 2002 are investigated from a functional data analysis perspective. We remark that the MIB30 basket synthesizes the performance of the Italian Stock Exchange within the Telematic Share Market; at the beginning, in 1975, the term MIB was the acronym of "Milano Indice Borsa"; subsequently it took on the new meaning of "Mercato Italiano di Borsa" since the market had become effectively national.

The rest of the paper is organised as follows: in the next section we outline functional data modeling and give some details about functional principal component analysis; in Section 3 we introduce the MIB30 basket dataset and present the results of our analysis; finally in Section 4 we compare the dynamics of the first functional PC with the dynamics of the MIB30 index in order to explore the possibility of the construction of stock market indices based on functional indicators.

2 Functional PCA

Let $\{\omega_1, \ldots, \omega_n\}$ be a set of n units and let $\mathbf{y}_i = (y_i(t_1), \ldots, y_i(t_p))$ be a sample of measurements of a variable Y taken at p times $t_1, \ldots, t_p \in \mathcal{T} = [a, b]$ in the i-th unit ω_i, $(i = 1, \ldots, n)$. Such data $\mathbf{y}_i$ $(i = 1, \ldots, n)$ are regarded as *functional* because they are considered as single entities rather than merely sequences of individual observations, so they are called *raw functional data*; indeed the term functional refers to the intrinsic structure of the data rather than their explicit form. In order to convert raw functional data into a suitable functional form, a smooth function $x_i(t)$ is assumed to lie behind $\mathbf{y}_i$ which is referred to as the *true functional form*; this implies, in principle, that we can evaluate x at any point $t \in \mathcal{T}$. The set $\mathcal{X}_\mathcal{T} = \{x_1(t), \ldots, x_n(t)\}_{t\in\mathcal{T}}$ is the *functional dataset.*

In functional data analysis the statistical techniques posit a vector space of real-valued functions defined on a closed interval for which the integral of their squares is finite. If attention is confined to functions having finite norms, then the resulting space is a Hilbert space; however we often require a stronger assumption so we assume $\mathcal{H}$ be a *reproducing kernel Hilbert space* (r.k.h.s.), which is a Hilbert space of real-valued functions on $\mathcal{T}$ with the property that, for each $t \in \mathcal{T}$, the evaluation functional L_t, which associates f with $f(t)$, $L_t f \to f(t)$, is a bounded linear functional.

In such spaces the objective in principal component analysis of functional data is the orthogonal decomposition of the empirical variance function:

$$v(t,u) := \frac{1}{n-1}\sum_{i=1}^{n}\{x_i(t) - \overline{x}(t)\}\{x_i(u) - \overline{x}(u)\} \tag{1}$$

(which is the counterpart of the covariance matrix of a multidimensional dataset) in order to isolate the dominant components of functional variation.

In analogy with the multivariate case, the functional PCA problem is characterized by the decomposition of the variance function:

$$v(t,u) = \sum_j \lambda_j \xi_j(t)\xi_j(u) \tag{2}$$

where $\lambda_j, \xi_j(t)$ satisfy the eigenequation: $\langle v(s,), \xi_j\rangle_h = \lambda_j \xi_j(u)$, where the eigenvalues:

$$\lambda_j := \int_\mathcal{T} \xi_j(t)v(t,u)\xi_j(u)dt\,du$$

are positive and non decreasing while the eigenfunctions must satisfy the constraints:

$$\int_\mathcal{T} \xi_j^2(t)dt = 1 \qquad \text{and} \qquad \int_\mathcal{T} \xi_j\xi_i(t)dt = 0 \qquad (i < j).$$

The ξ_j*'s* are usually called *principal component weight functions.* Finally the principal component scores (of $\xi(t)$) of the units in the dataset are the values w_i given by:

$$w_i^{(j)} := \langle x_i, \xi_j \rangle = \int_{\mathcal{T}} \xi(t) x_i(t) dt \, . \tag{3}$$

The decomposition (2) defined by the eigenequation (2) permits a reduced rank least squares approximation to the empirical covariance function v. Thus, the leading eigenfunctions ξ define the principal components of variation among the sample functions x_i.

3 A functional PC analysis of the MIB30 basket dataset

Raw data considered here consist of the total value of the traded volumes of the shares composing the MIB30 basket in the period January 3rd, 2000 - December 30th, 2002. They have been collected in a 30 × 758 matrix. We remark that an important characteristic of this basket is that it is "open" in that the composition of the index is normally updated twice a year, in the months of March and September (ordinary revisions). Moreover, in response to extraordinary events, or for technical reasons ordinary revisions may be brought forward or postponed with respect to the scheduled date.

In particular in our data set there are 21 companies which have remained in the basket for the three years while the other 9 places in the basket have been shared by a set of other companies which have been remaining in the basket for shorter periods. Due to the connection among the international financial markets, data concerning the closing days (as week-ends and holidays) are regarded here as missing data.

In literature functional PCA is usually performed from original data (x_{ij}); here we prefer to work on the daily standardized raw functional data:

$$z_{ij} := \frac{x_{ij} - \bar{x_j}}{s_j} \qquad (i = 1, \ldots, 30, \quad j = 1, \ldots, 758) \, , \tag{4}$$

where $\bar{x_j}$ and s_j are respectively the daily mean and standard deviation of the e.e.v of the shares in the basket. We shall exhibit later how such transformation can gain an insight into the PC trajectories understanding.

The first PC alone accounts for the 89.4% and the second PC accounts for the 6.9% of the whole variability. In Figure 1 we give the trajectories of the first two functional principal components which show the way in which such set of functional data varies from its mean, and, in terms of these modes of variability, quantifies the discrepancy from the mean of each individual functional datum.

The meaning of functional principal component analysis is a more complicated task than the usual multidimensional analysis, however here it emerges the following interpretation:

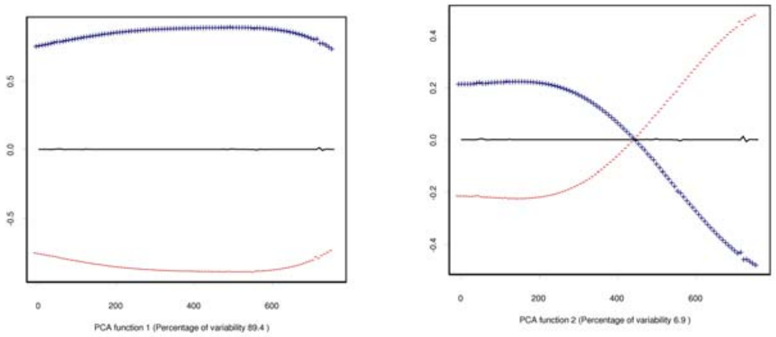

Figure 1: Plot of the first 2 functional principal components.

i. The first functional PC is always positive, then shares with large scores of this component during the considered period have a large traded volume as compared to the mean value on the basket; it can be interpreted as a *long term trend component.*

ii. The second functional PC changes sign at $t = 431$ which corresponds to September 11th, 2001 and the final values, in absolute value, are greater than the initial values: this means that shares having good (bad) performances before September 11th, 2001 have been going down(rising) after this date; it can be interpreted as a *shock component.*

This interpretation is confirmed by the following analysis of the raw data. As it concerns the first PC, for each company we considered its minimum standardized value over the three years $z_i^{(\min)} = \min_{j=1,\dots,758} z_{ij}$ $(i = 1, \dots, 30)$. In particular $z_i^{(\min)}$ is positive (negative) when the traded volumes of the i-th share are always greater (less) than the mean value of the MIB30 basket during the three years.

As for the second PC, let $\bar{x}_{Bi}$ be the average of the traded volumes of the ith company over the days: 1,...,431 (i.e. before September 11th, 2001) and $\bar{x}_{Ai}$ the corresponding mean value after September 11th, 2001. Let us consider the variation per cent:

$$\delta_i := \frac{\bar{x}_{Ai} - \bar{x}_{Bi}}{\bar{x}_{Bi}} 100\% \qquad i = 1, \dots, 30 .$$

If δ_i is positive (negative) then the ith company increased (decreased) its mean e.e.v. after the September 11, 2001.

Consider the scores on the two first PCs given in (3), respectively $\mathbf{w}_i^{(1)}$ and $\mathbf{w}_i^{(2)}$. We observed that the correlation coefficient between the $z_i^{(\min)}$ and $\mathbf{w}_i^{(1)}$ is equal to 0.96 and the correlation coefficient between the δ_i and $\mathbf{w}_i^{(2)}$ is equal to -0.84, see Ingrassia and Costanzo [3] for details.

4 A comparison between the dynamics of the first FPC and the MIB30 index

In our opinion, the obtained results open methodological perspectives for the construction of new financial indices having some suitable statistical properties. As a matter of fact, the construction of some existing stock market indices has been criticized by several authors, see e.g. Elton and Gruber [2].

In Costanzo [1] the dynamics of the MIB30 index in the three years 2000, 2001 and 2002 have been investigated using the *phase-plane plot*; here we compare such dynamics with the ones coming from the first functional. This technique may provide information about pure dynamics of the event and compare it within time, since it focuses as on the rate of change of the index rather than its actual size. The functional index is regarded as a harmonic process in which energy is exchanged between the potential and the kinetic states; thus, as mentioned above, the phase-plane plot draws the acceleration against the velocity. As a matter of fact, the kinetic energy is proportional to the square of the velocity (i.e. the first derivative of the function) and the potential energy is proportional to the acceleration (i.e. the second derivative). In economics, potential energy corresponds to available capital, human resources, raw material and other resources that are at hand to be used in economic activity; kinetic energy corresponds to the manufacturing process in full swing, when these resources are moving along the assembly line (see [6]). For a general dynamic process, velocity represents its rate of change, while acceleration indicates the input or whatever resources or forces produce this change. Thus, in financial markets, the potential energy may correspond to "strength" of the economic situation, both the realistic one and the one perceived by financial operators. The kinetic energy corresponds to the confidence of the financial operators in economy in such "strength". In fact, a financial index reflects the confidence of the financial operators in the economic situation: when the markets are confident, the value of the index tends to increase and exhibits stable patterns over time; shocks, as wars or dramatic events, produce both short transitory effects and longer-lasting readjustments in market behaviour. In the phase-plane we plot acceleration on the vertical axis, versus the velocity on the horizontal axis. The interpretation of this graphical representation follows Ramsay and Silverman [6], Ramsay and Ramsey [4].

In Figure 2 (left column) we give the phase plane plots of the MIB30 index in the three years 2000, 2001 and 2002. Concerning the year 2000, we note three large cycles surrounding zero, plus two small cycles that are much closer to the origin. The largest one starts in the beginning of February (Feb), with positive velocity but near zero acceleration. In this period the velocity of the index reaches its absolute maximum value in the year; the other maximum value of the velocity is roughly at the beginning of December. As remarked before, the size of the radius of the cycles is an important aspect of the plot. When the markets consider the economic situation good, they react with high level of confidence: the level of trading increases and the rate of change of the index is high. This large cycle ends to the middle of April (Apr). The cusp corresponding to the smallest cycle starts at the middle of May and lasts for about two months, until the middle of July (Jul). During this period both velocity and acceleration are very low, near zero. Note that the location of the center of this smallest cycle indicates a positive and decreasing velocity. The second largest cycle starts at the middle of October (Oct) and it continues until the end of the year.

As for the year 2001 there is just one evident large cycle. It is represented by the intermediate cycle starting in January till about the end of April. Note that its horizontal center is located to the left of the plot. The subsequent smaller cycle moves from the middle of May till the end of July. The largest cycle starts at the beginning of August with negative velocity and acceleration. The cycle moves clockwise through August and passes the horizontal zero acceleration line around the end of the month. We see now in the plot a bulge to the left starting from the middle of September, roughly when the catastrophic event took place: acceleration reached its maximum value but it was not followed by a positive velocity. Velocity stays negative until the beginning of October. This cycle closes at the end of October with very low velocity of the index. Note that in this plot the cusp now corresponds to the cycle spanning the last two months of the year and it is very small in size, with very low velocity and acceleration.

To summarize, the year 2001 started with a not very good performance of the index in terms of its rate of change, this is shown by the first two cycles corresponding to the first six/seven months of the year in the plot. After that it started to perform better; note, in fact, how the largest cycle is characterized by net negative velocity for its evident horizontal location of the center to the left, but at the same time net velocity increases for its vertical location of the center is above zero. The shock event in September interrupted some way this better performance: the year closed with a very small cycle.

Finally for the year 2002, we remark the rate of change of the index lasts in the following year. Note indeed the impressive change in the cycles in the year 2002 from the year 2000. Almost all cycles shift to the left; that is, they have now their horizontal centers on the left, which denotes a net negative velocity almost during the whole year. Further, the size of their radius with respect to the horizontal axes of the plot, denotes lower velocity of the index compared to the year 2000. Note that the cusp occurs again in the same period mid May - mid July, as in year 2000, but it has dramatically shifted to the left. Strictly speaking in year 2002, as a consequence of September 11th in the previous year, the overall slope of the index becomes more negative and the amplitude of the short term cycles shrinks.

The phase plane plot of the first PC concerning the years 2000, 2001 and 2002 is given in Figure 2 (right column). The interpretation of the plot is analogous as in the MIB30 case. However, the first PC "index" summarizes in a clearer way than the MIB30 index the dynamics of the events in the three years here considered. In fact, concerning the year 2000 the plot shows a very large cycle with a positive velocity during all the year but with an acceleration which is positive until the end of February only. Following the economic interpretation previously outlined, this kind of circle denotes a positive trend which is characterized however by a kinetic energy (the confidence of the financial operators in the strength of the economic situation) which starts to decrease already in the first part of the year. Concerning the year 2001, it is strongly evident in the plot the shock event of September 11th, since velocity even though positive during all the year, it is strongly increasing before that date then it is rapidly decreasing. For the year 2002 we remark the consequence of the last event in the rate of change of the first PC index. In fact the phase plane plot shows negative and decreasing both velocity and acceleration.

The results here presented suggest that the shares scores on this harmonic could be a good ingredient for a new family of financial indices trying to capture as most as possible of the variability of the prices in the share basket. This provides ideas for further developments of functional principal component techniques in the financial field.

BAGGING A STACKED CLASSIFIER

**Christophe Croux, Kristel Joossens
and Aurelie Lemmens**

Key words: Classification, cross-validation, machine learning, resampling.

COMPSTAT 2004 section: Classification.

Abstract: Combining several classifiers to achieve a better predictive performance can be done by stacking. In this paper, we propose an algorithm to find an optimal weighted average of the different classifiers, yielding a systematically better cross-validated error rate on the training data. This combined classifier is then compared to other stacking methods. Furthermore, we study the potential of bagging as a way to improve the performance of stacked classifiers.

1 Introduction

Suppose that one needs to classify an incoming email as being spam or not. For doing so, several supervised two-class classification methods (e.g. logistic regression, k-nearest neighbors, neural networks, decision trees, discriminant analysis) can be used. However, it can be time consuming and quite difficult to select the most appropriate classifier. Each classifier has indeed its own advantages and disadvantages and could well be adapted to one specific task, but not recommended for another. This issue can be solved by combining, in a fully-automated way, different classifiers. The combined classifier should perform better than each single classifier.

In the classification literature, several classifier combination methods have already been proposed and can be categorized in two groups. Some algorithms combine classifiers of the same type. For example, the boosted tree is a linear combination of several decision trees (e.g. Hastie et al. [2]). A second category of combination methods handles classifiers of different types. Within this second class, we focus on a method introduced by Wolpert [5] in the neural network literature and called stacked generalization. In the statistical literature this method was considered by LeBlanc and Tibshirani [3], who called it stacked classification. A brief review of the stacking principle will be given in Section 2.

In this paper, we propose a new, easy-to-implement and flexible algorithm to combine different classifiers. It is constructed in such a way that the final error rate, as estimated by ten-fold cross-validation, will be minimized. Furthermore, in Section 3, we will apply the bagging technique to reduce the variability of the stacked classifier, hereby further improving its performance.

2 Stacked classification

Consider a training dataset $Z = \{(x_i, y_i) | 1 \leq i \leq n\}$, containing n observations. For the training data, we observe the values of the binary variable Y, indicating to which source population an observation belongs to. This variable Y needs to be predicted using X, a vector of p explicative variables. The realizations of X on the training set are $x_1, \ldots, x_n$. The aim is to predict the value of Y for a new instance x. A classifier $C(x; Z)$ is constructed on the basis of the training set. It takes values on the interval $[0, 1]$: the higher the value of $C(x; Z)$, the higher the likelihood that an observation with features x belongs to the source population with label "Y=1". The value of $C(x; Z)$ is called the "score" attached to x. Classifiers taking only the values 0 and 1 can be thought of as a special case were only the most extreme values are given as score.

Several supervised classification rules exist. In this paper, four well-known methods are considered: classification trees, discriminant analysis, logistic regression and k-nearest neighbors. Classification trees yield a non-parametric classification procedure, and are widely used in applied fields such as medicine and botany. Linear discriminant analysis is the most traditional supervised classification method, optimal if both source populations are normal with the same covariance matrix. It is a parametric method, where the scores are given by linear combinations of the explicative variables. Logistic regression is another parametric classification technique where the conditional probabilities $P(Y = 1|x)$ are modeled by means of the logit transformation. Finally, the k-nearest neighbors method consists of finding the k-closest neighbors to an observation x (according to a certain distance). The value $C(x; Z)$ is then given by the frequency of observations for which $y_i = 1$, among the k-nearest neighbors (we select $k = \sqrt{n}$). The different classifiers have been computed using the standard S-plus implementation. Of course, other methods such as Support Vector Machines or Random Forests, could also have been taken as level-zero classifiers.

It is well recognized that there does not exist a unique best classifier. Suppose that K different initial classifiers $C_1, \ldots, C_K$ are available. These initial classifiers can be combined in one single stacked classifier. Wolpert [5] called the initial classifiers the "level-zero" components. The idea is to use the outcomes of the "level-zero" classifiers as inputs of the "level-one" classifier. In other words, the training dataset for this "level-one" classifier is given by $\{(C^*(x_i; Z), y_i) | 1 \leq i \leq n\}$, where $C^*(x_i; Z) = (C_1(x_i; Z), \ldots, C_K(x_i; Z))^t$ is obtained by stacking the different level-zero classifiers. As level-one classifiers, one could again consider logistic regression, a decision tree etc.

Wolpert [5] and Leblanc and Tibshirani [3] advise to use predicted scores obtained by cross-validation instead of the $C_j(x_i, X)$, for $j = 1, \ldots, K$ and $i = 1, \ldots, n$. As such, less overfitting should occur, leading to a better performance on future data to classify. Moreover, the cross-validation reduces the risk of having high correlation between the level-zero classifiers. Hence, throughout this paper, the level-one classifiers will be constructed from the stacked vector $C^*(x_i; Z) = (C_1^-(x_i; Z), \ldots, C_K^-(x_i; Z))^t$, where $C_j^-(x_i; X)$ is obtained via cross-validation for $j = 1, \ldots, K$. To reduce the computation time, the $C_j^-(x_i; Z)$ were computed via 10-fold cross-validation. Formally, the training dataset Z is split into ten subsets, Z_1, …, Z_{10}. Predictions for the observations belonging to a subset Z_l are then based on a classifier constructed with $Z \setminus Z_l$ as training set, for $l = 1, \ldots, 10$.

The algorithm for obtaining an "optimal" level-one classifier will be outlined in the next subsection.

2.1 A new algorithm for combining classifiers

We restrict attention to stacked classifiers obtained as linear combinations of the component classifiers:

$$C_W(x; Z) = \beta_1 C_1(x; Z) + \cdots + \beta_K C_K(x; Z). \tag{1}$$

The coefficients $\beta_1, \ldots, \beta_K$ need to be chosen in such a way that the stacked classifier $C_W(x; Z)$ performs "better" than the initial classifiers. We require these coefficients to sum up to one and to be non-negative, such that they can be interpreted as the weights attached to each classifier. If a component classifier performs particularly bad, it receives a low or even zero weight, and has no impact on the final classification. The combined classifier C_W is therefore an "optimal" *weighted* average of the component classifiers. The weights $\beta_1, \ldots, \beta_K$ are now selected in such a way that they optimize a given criterion, such as the *error rate*, i.e. the percentage of misclassified observations. Other criteria do exist, such as the area under the receiver operating curve (ROC). The algorithm proposed in this paper works for any criterion of choice, and can be used for any set of component classifiers, making it very flexible. In this short paper, we restrict attention to the error rate as performance criterion. Note that Leblanc and Tibshirani [3] worked with the mean squared error as criterion, a natural choice in the regression setting but less comon in the classification literature. Since the population error rate is unknown, we work with the (10-fold) cross-validated error rate as an estimate of it. This latter is known to be an unbiased estimator of the error rate, in contrast to the apparent error rate. Finding the optimal values for $\beta_1, \ldots, \beta_K$ is not easy, certainly not for high values of K. Hence, we propose the following greedy algorithm:

- Compute, via 10-fold cross validation, the scores for every component classifier $C_j^-(x_1; Z), \ldots, C_j^-(x_n; Z)$ for $j = 1, \ldots, K$.
- Using the previously computed scores, compute the cross-validated error rate associated with the classifiers (without prior information, classify an observation in the first source population if the value of the score exceeds the threshold 0.5). These are used to sort the classifiers from

the smallest to the highest error rate. We denote the ordered classifiers as $C_{(1)}, \ldots, C_{(K)}$.

- Maximizing the criterion over the space of all possible values of $\beta_1, \ldots, \beta_K$ is difficult, since the objective function to minimize might be non differentiable. We propose an iterative procedure. First find α_1 such that the error rate of the combined classifier

$$C^1(x;Z) = \alpha_1 C_{(1)}(x;Z) + (1-\alpha_1)\, C_{(2)}(x;Z)$$

is minimized, where α_1 ranges over the interval $[0,1]$. A simple univariate optimization routine, like grid search, can be used. For $k = 2$ to $K-1$, find α_k such that the error rate of

$$C^k(x;Z) = \alpha_k C^{k-1}(x;Z) + (1-\alpha_k)\, C_{(k+1)}(x;Z)$$

is minimized. After a first cycle is completed, one could rearrange the terms and express C^{K-1} as a convex combination of all level-zero classifiers

$$\beta_1 C_1(x;Z) + \cdots + \beta_K C_K(x;Z).$$

A new cycle might then be computed, finding successively the best convex combination of $C_{(j)}$ and C^b, for $j = 1, \ldots, K$, where C^b is the currently "best" combination of level-zero classifiers. In the present version of the program, we perform three full cycles after which no significant further improvement was observed.

The coefficient $\beta_1, \ldots, \beta_K$ obtained in this way are used as weights for the final classifier C_W in (1). By construction, the classifier C_W always has a lower (10-fold cross-validated) error rate than each single level-zero classifier. Note that there is no guarantee, however, that the global optimum is reached.

To illustrate this procedure, we applied the greedy algorithm for finding C_W to 12 datasets available on the UCI repository [4]. The size n and the number of explicative variables p of these datasets are reported in Table 1. The datasets are previously cleaned from missing values. Each dataset is split into a training set Z (80% of the observations) and a test set T (20% of the observations). The training set Z is used to obtain both the level-zero classifiers and the stacked classifiers. The test sets will be used in the sequel.

Table 1 reports the cross-validated error rates for every level-zero classifier (classification tree, discriminant analysis, logistic regression, k-nearest neighbors (NN)) and for the optimal weighted average C_W of these four classifiers. No level-zero classifier clearly outperforms the others, justifying the choice for combining classifiers. As already mentioned 2, the error rates obtained by the C_W on the training sample are by construction always lower than those associated with the initial classifiers. The improvement is quite

				Level-Zero Classifiers				Stacked

Table 1: Cross-validated error rates (in %) of the level-zero classifiers and the optimal weighted average C_W. The first two columns contain the number of observations n and number of variables p of each dataset.

substantial, amounting until 31.44 % (Iono data) or even 60.00 % (Mushroom data) of relative improvement in error rate with respect to the best level-zero classifier. In one case (the Breast data), the k-nearest neighbors classifier performs equally as C_W. In this case, the weight associated with the k-nearest neighbors classifier turns out to be one.

At first sight, the results are very encouraging. However, one should not forget that the weights of the combined classifier are determined to minimize the cross-validated error rate computed on the training data. There is a risk that the reported error rates, albeit obtained by cross-validation, are still over-optimistic. Therefore, in the following subsection, we compute the error rates on the *test set*, and compare different level-one classifiers.

2.2 Empirical comparison of different stacking methods

Table 2 reports the error rates computed on the test set for the level-zero classifiers and the optimal weighted average C_W. One may observe from Table 2 that the weighted method does not systematically provide the lowest test error rates, even if it is still the case for 8 out of 12 datasets. When a single component performs better, the weighted combination has an error rate very close to it. Moreover, for each level-zero classifier, it is possible to find at least one dataset on which the level-zero classifier performs drastically worse than the stacked classifier C_W.

Table 2 also reports the results of other stacking methods. The level-one combination methods under consideration include a decision tree, linear discriminant analysis, logistic regression and k-nearest neighbors. One may

	Level-Zero Classifiers				Stacked Classfiers

Table 2: Test error rates in % for the 4 different level-zero classifiers, for the optimal weighted average C_W, and for stacking by 4 different level-1 classifiers.

observe that the different ways of combining the level-zero estimators yield different error rates, even if this heterogeneity is less pronounced than among the level-zero classifiers. The stacked logistic regression seems to be the best stacking method on the datasets under investigation, giving on the whole the smallest test error rates. Note that the weighted average does not outperform the other stacking methods anymore on the test set. In the next section, we will apply bagging on the stacked classifiers.

3 Bagging the stacked classifiers

Error rates esimated by cross-validation are known to be very volatile. The bagging technique, originating from machine learning, helps to reduce the variance and improves the performance of unstable classifiers [1]. Therefore, we propose to apply the bagging algorithm to the weighted classifier C_W, described in section 2.1. Practically, the bagging procedure consists of computing classifiers on B different bootstrap samples of size n drawn from the initial training set Z. These bootstrap samples are obtained by drawing with replacement observations from Z, yielding $Z^{*1},\ldots,Z^{*b}$. The bagged classifier is then obtained by averaging over all predicted scores:

$$C_{bag,B}(x;Z)=\frac{1}{B}\sum_{b=1}^{B}C_W(x;Z^{*b}).$$

Bagging is an easy-to-implement procedure and can be applied to any given classification method.

In Figure 1, the test error of $C_{bag,B}$ is plotted with respect to B, for

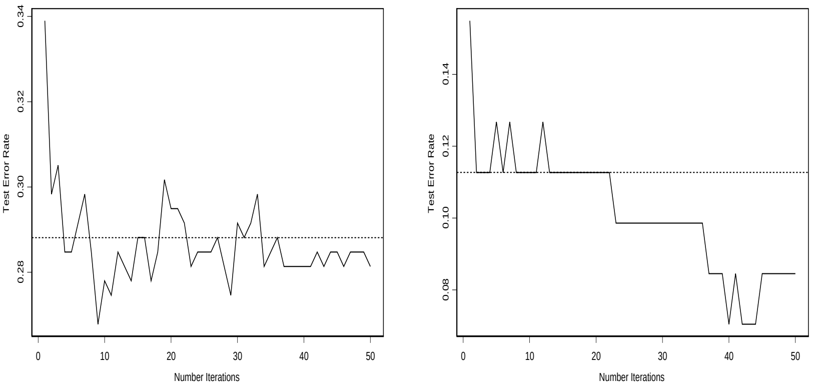

Figure 1: Test error rates w.r.t. the number of bootstrap steps B for stacked classification using as level one classifier (left panel) the weighted average C_W for the Cmc dataset (right panel) discriminant analysis for the Iono dataset. The dotted line corresponds to the error rate for the classification method without bagging.

	Bagged Stacked Classifiers

7	0.00	0.12	0.12	0.00	0.12
8	21.4	22.0	20.7	20.1	23.3
9	5.10	4.89	5.32	5.21	5.10
10	7.81	3.13	3.13	4.69	5.21
11	1.75	0.88	0.88	0.88	0.88
12	12.5	15.0	15.0	15.0	15.0

Table 3: Test error rates of several bagged stacked classifiers (with $B = 50$): the weighted average C_W together with stacking by 4 different level-1 classifiers.

$B = 1, \ldots, 50$. In the left panel, bagging is applied on the weighted average classifier C_W for the Cmc dataset. One may observe that the test error of the bagged classifier improves the starting stacked classifier for large values of B. In the right panel of Figure 1, the performance gain obtained by bagging is illustrated even more clearly: here we bagged the stacked classifier using discriminant analysis in level-one. The initial stacked classifier has a test error rate of 12.6%, decreasing until 8.14% after $B = 50$ bagging steps.

Table 3 reports the test error rates of the combination methods after 50 bagging steps. The results indicate that, for most datasets and classifiers, bagging indeed reduces the test error rate of the stacked classifiers (45 times out of 60). The bagging also reduces the differences in performance across the different stacking methods. Moreover, it turns out that the bagged weighted combination method outperforms the others on 6 out of 12 datasets, and is comparable to the bagged stacked classifiers using decision tree or logistic regression as level-one classifier.

As a conclusion, this paper introduced a new combination method of classifiers which was compared to existing stacking methods. It was shown that this optimal weighted combination performed fairly well. Moreover, we also studied the possible advantage of applying bagging on stacked classifiers. It came out that the bagged weighted combination classifier outperformed (or, at least, performed comparatively as) the other combination methods (bagged or not) for most of the datasets under consideration.

DEVELOPING A MICROSIMULATION SERVICE SYSTEM

Joszef Csicsman and Cecilia Fenyes

Key words: Microsimulation, simulation.

COMPSTAT 2004 section: Simulations.

Abstract: The microsimulation procedure examines social and economic changes by assessing the effect of each provision with small units and the description of the overall effects is derived from these assessments. Relevance of the results relating to the society as a whole is ensured by the database which is a national representative sample of the units or households of such size that guarantees the required statistical reliability. Naturally, the range of social and economic changes that can be modelled in this way is defined by the information available on the microsimulation units in the database.

1 Introduction

In the past few years the Hungarian Central Statistical Office (KSH), the Ministry of Economic Affairs (GM), the Ministry of Finance (PM) and other departments of the government have had no opportunity to analyse large data sets to establish policy proposals.

The available analytical systems - usually based on EXCEL - are, in methodological respect, questionable, because it is hard to accept the reports based on small data sets both in mathematical and in economical sense.

A research group was founded for the project jointly by the Research Centre for Financial Economics of the Budapest University of Technology and Economics and Új Calculus Bt. The aim of the project is to develop and maintain a model system which allows analysing data collections and databases available in the administration for economists. Naturally, this methodology can also be used for processing other types of data too.

In accordance with the international applications the research group creates technical and methodological conditions for analysing large data sets and developing a SAS Software based microsimulation modelling system.

Till now a methodology to assess the impact of government programs has not been available.

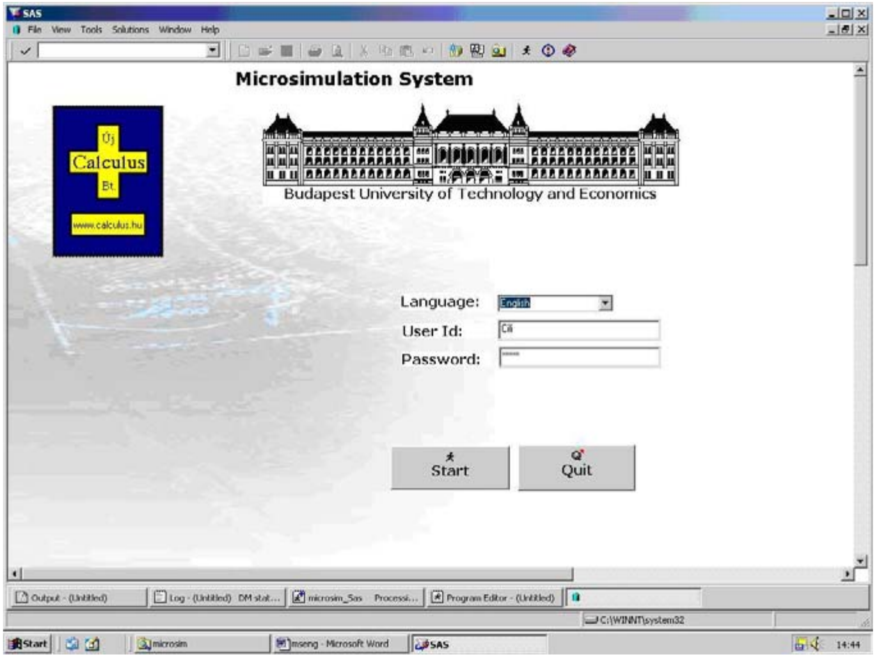
By utilizing research experience of the university more exact analyses could be prepared to qualify and quantify policy options.

As an outcome of this project a Microsimulation Modelling System will be developed which will be suitable for modelling the decisions of economic and social policy, and - complying with the national and international requirements - well-founded analyses can support the policy proposals of the government.

The following description will present the recent results of the project in a framework in which great number of university theses have been developed.

2 The Microsimulation Service System

As it can be seen in the Main menu, the language of the program is adjustable. At the moment English and Hungarian versions are available, but because the system works from a dictionary and the compilation does not need any special knowledge (only the command of the language), it is very easy to translate it into any other language.



Language: English

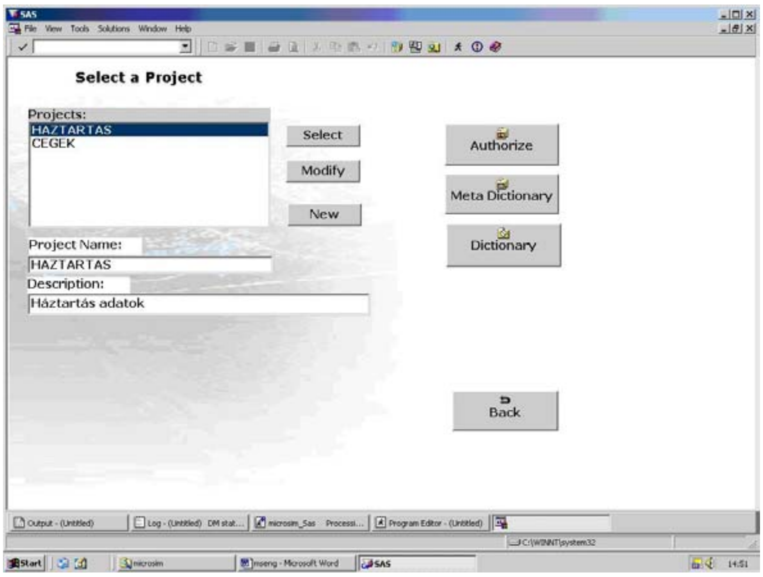
Password: *****

2.1 Project selection

Prior to running a particular simulation a Project is to be selected (or created, if it does not exist), because the next steps are related to the data we want to use.

Without selecting a project 3 tasks can be chosen. By selecting ‘Authorize’ rights of the users can be set. By pushing the button ‘Meta dictionary’ the data’s of meta can be read or set, which are independent in any project (nomenclatures and numeric values). By pressing Dictionary the dataset of languages can be found. After selecting or creating the Project or selecting a task, the Project Handling frame will appear:

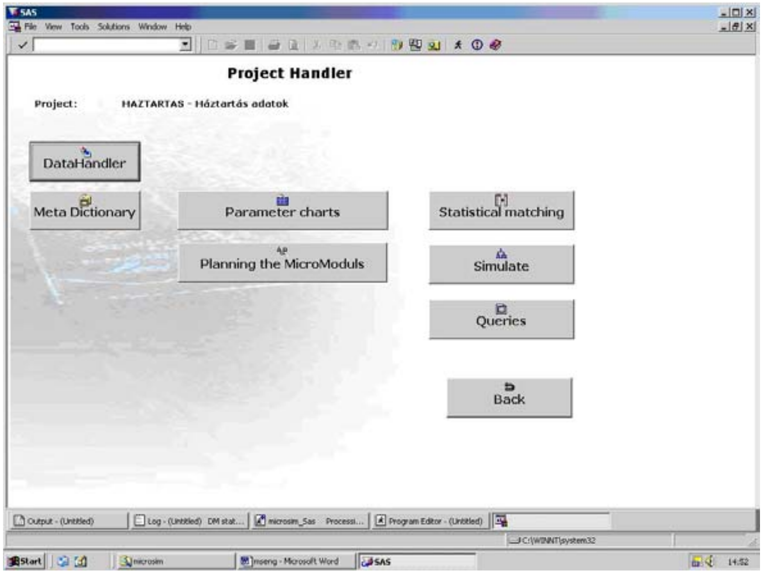


Select a Project

Projects:
HAZTARTAS
CEGEK

Project Name:
HAZTARTAS

Description:
Háztartás adatok



Project Handler

Project: HAZTARTAS - Háztartás adatok

2.2 Datahandling

a) Manipulating the input data

The system can handle text form and SAS files. Expanding the types of importable external files is one of the tasks of the next developing period.

b) Data protection

Due to the public environment use of a password entry and different levels of users is unavoidable.

2.3 Meta Dictionary

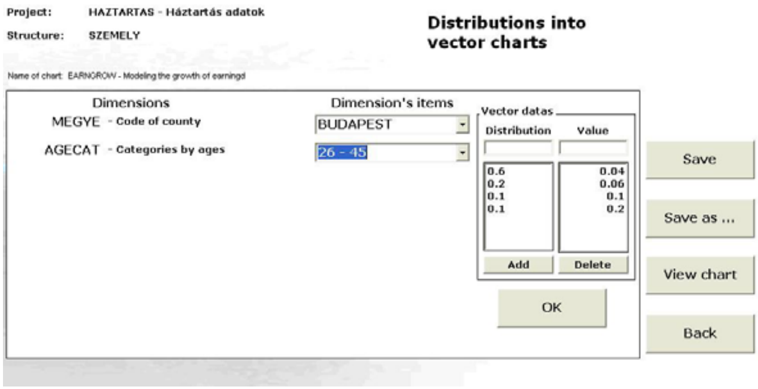
The Meta Dictionary contains all the information about the data and datasets: identifier, type, length and name of nomenclatures and pointers, structures of input datasets. Also the file catalog is the part of the meta. On the following screenshot the list of nomenclatures can be seen with a user friendly screen to view or modify it. Numeric values, structures of datasets, and the file catalog will be shown in similar frames.

2.4 Estimation algorithms

The parameter charts of estimation algorithms can be filled with the help of a graphical user interface, so economists can determine the internal algorithms without any SAS programming knowledge.

One of our most important goals is to complete these mathematical algorithms to provide opportunity for making appropriate analysis.

One of the frames, which helps to fill in the 'Value assignment upon distribution' parameter chart can be seen below:



Project: HAZTARTAS - Háztartás adatok

2.5 Micromodules

Micromodules are Base Sas codes. During the simulation the selected micromodules will run on every record of the input dataset. This means that micromodules set the changes, which will occur. Here we prepared the platform for making micromodules without the knowledge of Base Sas. The code will be generated from the rows of modul steps (down, left) made by the user using almost only the mouse.

2.6 Running the simulation

This frame is to set all the parameters of the simulation. Input file(s) can be chosen, name of the output file must be set, and here the micromodules can be selected to run from the list of the premade micromodules.

2.7 Analysing

After running the simulation it is very important to have opportunity to analyse the input and output data. The Analyse function of the system can help analysts, who are not experienced in SAS programming. For Analysis the procedures of SAS can be used very well.

2.8 Statistical matching

Statistical Matching is to pair the records of two data sets without having any key variable. The records of the secondary data sets are separated into groups

by their selected attributes (they can be defined in the section of parameter charts, by selecting ‘statistical matching - parameter chart of teams’ from the list of type of table). The statistical matching goes through on every records of the primary data set. By the attributes of the record the member of the appropriate group (which is a record of the secondary data set) will be paired with this record.

If there is only one data set and the records of the same dataset are intended to be paired (like the simulation of marriage), it is also solved in the microsimulation system.

EFFECTIVENESS IN ENSEMBLE OF CLASSIFIERS AND THEIR DIVERSITY ON BIG MEDICAL DATA SET

Malgorzata Maria Cwiklinska-Jurkowska and P. Jurkowski

Key words: Fixed and trained combining classifiers, diversity, accuracy.

COMPSTAT 2004 section: Classification.

Abstract: The dependence of stacked combining accuracy on diversity was studied for real-life medical classification problem of thyroid disease recognition. The simple fixed (minimum, maximum, product, average, mean and majority vote) and also trained methods (with second step-the Bayesian discrimination) were examined. Base classifiers were both of type: crisp (classification trees, neural network) and fuzzy (parametric and nonparametric Bayesian discrimination).

We studied nine measures of diversity for oracle outputs of correct/ incorrect classification decisions. For trained ensemble methods we obtained smaller Spearman correlations between classification errors and diversity than for fixed combining.

1 Introduction

In order to avoid the possible loss of information, classifiers can be pooled. The recognition rate of a combination is usually better than that of each individual classifier [17]. Multiple classifier systems have been attempted in a variety of pattern recognition fields e.g. [4], [17]. Diversity among individual classifiers of the team is expected to be important for effectiveness in classifier combination [16]. The relationship between different combining accuracy and diversity of classifiers' ensemble was studied on generated data by Kucheva et al. [7], [8], [9] and Shipp et al. [14].

The purpose of the paper was the experimental examining dependence on diversity of accuracy of stacked fixed and also of stacked trained combining methods [4] on the basis of the real medical data set for thyroid disease recognition. The big data set with three groups was used [11]. The learning set consists of 3772 examples and testing set of 3428 examples. We employed all of 21 mixed variables, 15 binary and 6 continuous.

2 Constituent and combined classifiers

Let us denote as c- the number of classes $\pi_1, \ldots, \pi_c$, L-the number of classifiers $D_1, ..., D_L$. The L classifiers' outputs for classification to c groups of an observation $\boldsymbol{x}$ can be organized in a decision profile ***DP(x)*** matrix:

j-th (*j=1,. . . , c*) matrix column of ***DP(x)*** contains posterior probabilities (alternatively 0 or 1 for two applied crisp classifiers) that an observation $\boldsymbol{x}$ belongs to *j-th* population. For simple combining from the matrix ***DP(x)*** of the decision profile we obtain only one raw vector- of possibilities of belonging to c classes. For example, it contains averages (or minimum, maximum, median, product, majority vote) of column elements of matrix ***DP(x)***. For trained combination rule- all elements of the profile matrix ***DP(x)*** coming from first-step discrimination are features for second-step discrimination.

We used such constituent Bayesian discriminant classifiers as linear, quadratic, kernel and nearest neighbour. These base nonparametric classifiers were chosen with the best parameters, so are optimal in their classes: the kernel radius and the number of neighbours are optimized using a leave -one-out error estimation. Binary decision trees were also applied. To choose the most efficient one we tried CART [1] and QUEST tress [10] with different parameters. The artificial dipolar neural network, used in the research, consists of one layer of formal neurons with binary activation function [1].

The stacked combining- of different classifiers on the same feature set (all 21 mixed variables) - is examined. The error of classification was estimated by resubstitution, cross-validation method or by using the testing sample.

3 Diversity of classifiers

We applied 9 diversity measures [8], among them 4 averaged pairwise ones and 5 working on the whole group of classifiers. Let us consider oracle outputs of classification decisions (binary vectors: with values equal to 1 if correct decision of a classifier D_j for an observation $\boldsymbol{x}$ or zeros for incorrect classifications).

	$D_j$correct	$D_j$fail
$D_i$correct	a	b
D_i fail	c	d

Table 1: Summary table for relationship between two classifiers D_i and D_j with probabilities ($a+b+c+d$=1).

Pairwise measures

Q	Yule's Q statistic $Q=(ad\text{-}bc)/(ad+bc)$
D	disagreement measure $D = b + c$
DF	double-fault measure $DF=d$

Non-pairwise measures (comparing accuracies of several classifiers)

$E(ENTROPY\ )$	The entopy measure
HS	Hansen and Salamon measure of difficulty θ [5]
KW	Kohavi-Wolpert variance [6]
κ $(KAPPA\ )$	Measurement of interrater agreement
GD	Generalized diversity [13]
CFD	Coincident failure diversity [after: 8]

DF, *GD* and *CDF* are non symmetric measures (if we swap all values 1 by 0 and vice versa). Measures of similarity (the smaller the value the more diverse) are: Q, D, κ and *HS.*

For any L (number of all considered classifiers) it is fulfilled:

KW=(L-1) $D_{AVG}/2L$ (average of D is taken from all possible pairs of classifiers)

and for L=3 it holds: $D = 2/3E$ [8].

4 Results and discussion

Wang et al. [16] showed that when a high diversity between two or more different data mining techniques exists, combining them produce better classifications. They concluded that a multiple classifier system can only improve the performance when the members in the system are diverse from each other. Thus we added to combining some methodologically different techniques than Bayesian discrimination- the most efficient classification tree (CART with 18 nodes; test error =0.006) and the neural network. Accuracies of constituent classifiers are presented in Tab. 2. Duin et al. [4] showed that although the individual classification performances on the difficult datasets are poor, they still contain valuable information for the combination rules. When we rejected, from the set of all Bayesian constituent classifiers {1-5}, the worst basic quadratic discrimination, we obtained decrease of the correct classification rate- for the average and median rule. Most of considered combining teams however do not contain the worst quadratic method or the normal kernel with the pooled covariance matrices (Tab. 2).

Number	Method	Test-sample error
1.	Linear discrimination Pp	0.0619
2.	Quadratic discrimination Pe	0.5984
3.	Normal kernel r=0.5 ; Pp pooled covariance matrix	0.0614
4.	Normal kernel r=0.5 ; Pe; not pool.covariance matrices	0.4739
5.	6 Nearest Neighbour	0.0596
6.	Classification tree	**0.006**
7.	Neural Network	0.039

Table 2: Test-sample classification errors of individual classifiers.Pp: probabilities a priori proportional to sizes of groups. Pe: probabilities a priori equal in groups.

Standard statistical software SAS 8.2 was applied for building Bayesian classifiers, Statistica 5.0 for classification trees and we used also the program for the dipolar neural network [1]. We assessed fixed and trained ensemble errors and computed nine diversity measures [8] for different teams - subsets of above individual classifiers.

Combining classifiers is particularly useful for difficult problems – a large amount of noise, limited number of training data or unusually high dimensional patterns [15]. In used data the sizes of groups were much bigger than the number of variables, so the improvement, reached by some of examined combining *fixed* methods, was not apparent. On the other hand, *trained* combining gave much smaller classification errors - the smallest one for the kernel method (error=0.0005).

4.1 Relationships between measures of diversity

Teams 1-6 are the following: for Team 1- individual classifiers from Tab.2 are {1-6}; 2: {1-5}; 3: {1,2,3,5,6}; 4: {1,3,5,6}, 5:{1,3,5}; 6: {1,3,4,5,6}. Teams 7-12 are as above six ones, but with additionally 7th individual classifier from Tab. 1 (neural network). For these 12 teams of classifiers from learning sample and 12 teams from the testing one (polled into set of 24 teams) we examined the different relationships.

Q is the only measure that varies between -1 and 1 and attains zero for independent classifiers, like Pearson correlation coefficient, and additionally does not depend on accuracy of individual classifiers - taken with the same accuracy p [8]. Classifiers that tend to recognize the same objects correctly have positive values of Q and those which give errors for different objects deliver negative Q: thus negative dependence is preferable [7]. We obtained 6 values of Q near to 0 and the rest - positive.

For *HS* diversity measure we prefer teams of classifiers of the following property: the points that are difficult for some classifiers are easy for other classifiers (that means - we want *HS* to be small). This property, analogously to sets with negative Q, is called: "negative dependence": [8], though *HS* is always nonnegative as the variance. We examined *HS* measure for 12 subsets of classifiers for learning sample and 12 for testing one (Fig.1). Best by the criterion of *HS* have proved team 7 and 8 (with smallest *HS* equal to 0.063 and 0.071 for testing sample- Fig. 1 and with 0.07 and 0.08 for the learning sample).

Examined features- errors and diversities- are not symmetrically distributed - the Spearman rank order correlations were calculated. The cluster analysis was also performed on the basis of 24 combining teams (Fig. 2). For diversity measures the bigger cluster consists of all symmetric measures: *Q, KAPPA, HS, KW, D* and *ENTROPY*. Similarity measures: *Q, KAPPA* and *HS* are placed right in this cluster. Q is highly correlated with all measures from this cluster- negatively (with *D, KW* and *ENTROPY*) or positively (with *KAPPA* and HS). The asymmetric *DF* (double fault) measure can be regarded as one-element cluster. It can be explained by the fact that for *DF* we treat as similar the classifiers, only rejecting the same observations, without any knowledge of other classifying combinations. Very similar in constructing *GD* and *CDF* are close in the dendrogram. Strongly related measures: *D, KW* and *ENTROPY* are very highly positively correlated and

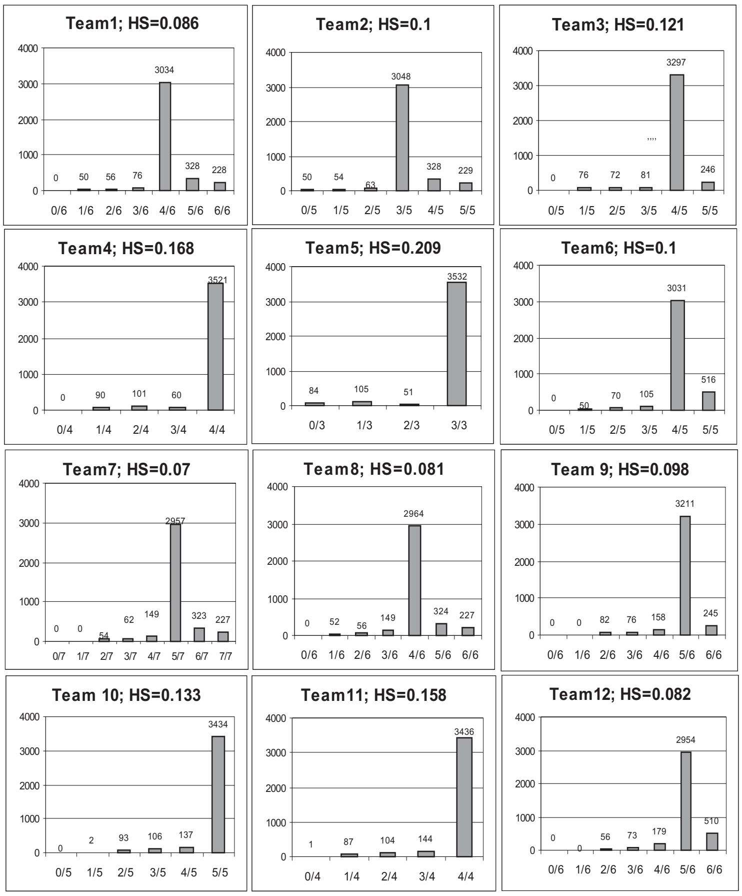

Figure 1: Hansen and Salamon measure of difficulty *HS* for 12 different teams of 7 individual classifiers. Histogram of the number of patients from testing sample that are correctly classified by i/L of L classifiers (horizontal axis). Classifiers performed on the testing sample.

lay near in the dendrogram. Some of the above effects for examined by us real medical data are consistent with results obtained by Shipp and Kuncheva [14] for big generated data set.

4.2 Simple fixed fusion

For most of classifiers teams - median and average fusion methods reached smallest errors and only for teams 4, 5 and 11- the most accurate was the maximum fusion method. Effectiveness of the product combining method is significantly positively correlated with minimum and maximum rule. Accu-

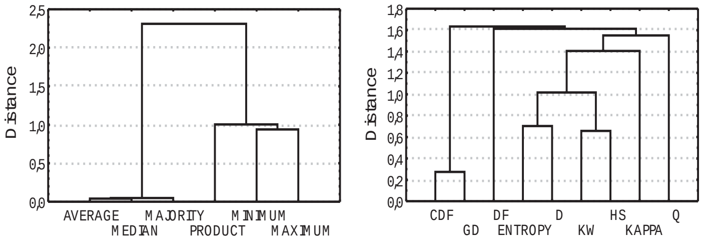

Figure 2: Cluster analysis. Left: classification errors of fixed combining methods. Right: measures of diversity

racy of average for considered medical data is highly positively correlated with median and majority vote. We obtain two clusters (Fig. 2): average with median and majority vote and the second one: product, minimum and maximum. Chen & Cheng [3] showed (in the two-class classification problem): median and majority vote produce the same result, but- for non symmetric distributions- average may yield a completely different decision (much more or much less correct), when a number of constituent classifiers becomes large.

The negative (positive) sign of highest correlations from Tab. 3 confirms the fact that a measure belongs to the similarity group (or respectively to the strict diversity measure group) with only the exception of *DF* measure- single cluster among diversity measures. The stronger relationship with accuracy we can observe for measures from the cluster $\{Q$, *KAPPA, HS, D, KW* and *ENTROPY*$\}$, i.e. for symmetric measures.

	Q	DF	κ	HS	D	KW	ENT	GD	CFG
Minimum	**-0.75**	**0.41**	**-0.55**	**-0.69**	**0.77**	**0.74**	**0.78**	0.36	0.36
Maximum	**-0.73**	0.37	**-0.55**	**-0.63**	**0.75**	**0.72**	**0.75**	**0.40**	**0.42**
Majority	0.36	**0.42**	0.49	0.10	-0.09	-0.06	-0.16	-0.22	-0.23
Product	**-0.78**	**0.42**	**-0.57**	**-0.64**	**0.78**	**0.76**	**0.78**	0.37	0.39
Median	0.41	0.40	0.51	0.21	-0.18	-0.14	-0.22	-0.21	-0.22
Average	**0.37**	**0.42**	0.48	0.17	-0.11	-0.07	-0.17	-0.21	-0.22

Table 3: Spearman correlations between measures of diversity and errors of fixed fusion methods (bolded- significant p=0.05).

4.3 Trained fusion

Similar to above analysis was also done for 14 trained fusion methods, with second-step discrimination. For probabilities a priori equal and proportional to sizes of groups we executed 7 discriminant Bayesian methods: parametric -linear and quadratic- and nonparametric ones-normal kernel with pooled and not pooled covariance matrices (radii $r = 1$ and $r = 0.5$) and nearest neighbour ($k = 6$ neighbours). For each individual fuzzy classifier- the vectors of posterior probabilities are linearly dependent. Similarly, the vectors coming from crisp classifiers (containing 1 or 0) are redundant: one vector can be removed. Thus, to remove the problem of pooled covariance matrix's singularity, one column (out of 3) of posterior probabilities for each classifier in trained fusion or one binary column of crisp classifier was not taken to calculations for second-step discrimination.

Spearman correlations between diversities and errors of trained fusion methods were significant only for *DF* diversity measure with linear, quadratic and nearest neighbour discrimination and also for *HS* measure with quadratic trained method (all methods with prior probabilities proportional to sizes of groups). Correlations between accuracies of trained combining separately were much higher than between simple fixed combined classifiers and we obtained two clusters of 14 second-step methods.

5 Concluding remarks

The correlation between diversity measures separately and also between accuracy of fixed combining was higher than between diversity measures and effectiveness of classification. For trained ensemble methods we obtained even smaller relationships between accuracy and diversity than for fixed combination while we achieved the highest correlations-of all considered kinds-between accuracy of trained methods separately. Considered diversity measures of combining classifiers are not very good indicators of effectiveness, especially for trained fusion methods.

It would be interesting to find measures that are higher correlated with accuracy of combining classification, because they might be used for constructing the efficient ensemble of classifiers.

TEST OF CONTINUITY OF A REGRESSION FUNCTION

Václav Čapek

Key words: Nonparametric regression, change-point, M-smoothers, resampling.

COMPSTAT 2004 section: Nonparametrical statistics.

Abstract: A test of continuity of a regression function based on M-smoothers is proposed. Its limit behavior both under the null hypothesis (no jump) and the alternative (there is a jump) are presented. Critical values are obtained using bootstrap. The theoretical results are accompanied by a real data example.

1 Introduction

Consider the nonparametric regression model

$$Y_i = m(x_i) + \varepsilon_i, \quad i = 1, \dots, n, \tag{1}$$

where m is an unknown function defined on $[0, 1]$ and $\varepsilon_1, \dots, \varepsilon_n$ are independent, identically distributed random variables having a symmetric distribution function F. Random variables $Y_1, \dots, Y_n$ are observed at design points $0 \le x_1 \le \cdots \le x_n \le 1$.

Suppose that the model is of the form

$$m(x) = m_0(x) + \Delta \mathbf{I}_{\{x > \tilde{x}\}}, \quad x \in (0, 1), \tag{2}$$

where m_0 is a smooth function and Δ and $\tilde{x}$ are unknown real parameters. The case $\Delta \neq 0$ and $\tilde{x} \in (0, 1)$ corresponds to a jump in the regression function m. We want to test whether m has a jump or not. Denote the null and the alternative hypotheses by

$$\begin{aligned} H_0 : \quad & \Delta = 0 && (3) \\ H_A : \quad & \Delta \neq 0 \text{ and } \tilde{x} \in (0, 1). && (4) \end{aligned}$$

There are not many papers concerning the problem of testing H_0 against H_A. Müller and Stadtmüller [7] developed a test for the case of a fixed design with regular grid on the basis of a quadratic statistic. Horváth and Kokoszka [5] considered a test procedure based on local polynomial smoothers for the same setup.

Our test is based on M-smoothers. We recall now the needed notion on M-smoothing techniques for a continuous regression (assume $\Delta = 0$). For the above model denote $F(y - m(x))$ by $F_x(y)$. For ψ nondecreasing and left-continuous and some function G put

$$\lambda_G(t) = -\int \psi(y-t)\, dG(y), \quad t \in \mathbf{R}$$

and

$$\lambda_G^{-1}(u) = \inf\{t :\, \lambda_G(t) \ge u\}.$$

It is easy to see that for ψ nondecreasing, left-continuous and antisymmetric with $\lambda'_G(0) > 0$, where $\lambda'_G(t)$ denotes the derivative, one gets

$$m(x) = \lambda_{F_x}^{-1}(0) \tag{5}$$

and that $\lambda_{F_x}^{-1}(0)$ is unique.

The M-smoother $m_n(x)$ is defined as an empirical analogue to (5)

$$m_n^h(x) = \lambda_{\hat{F}_x^h}^{-1}(0), \tag{6}$$

where $\hat{F}_x^h$ is a kernel estimator of F_x defined by

$$\begin{aligned} \hat{F}_x^h(y) &= \mathbf{I}_{\{Y_1 \le y\}} \int_{-\infty}^{x_1} h_n^{-1} K((x-z)/h_n)\, dz \qquad (7) \\ &\quad + \sum_{i=2}^{n-1} \alpha_{ni}^h(x) \mathbf{I}_{\{Y_i \le y\}} + \mathbf{I}_{\{Y_n \le y\}} \int_{x_{n-1}}^{\infty} h_n^{-1} K((x-z)/h_n)\, dz, \end{aligned}$$

with weights

$$\alpha_{ni}^h(x) = \int_{x_{i-1}}^{x_i} h_n^{-1} K((x-z)/h_n)\, dz, \quad i = 2, \dots, n-1.$$

Here $\mathbf{I}_{\{A\}}$ denotes an indicator of an event A, K is a kernel and $h = \{h_n\}_{n=1}^{\infty}$ is a sequence of bandwidths. The subscript n indicates a possible dependence of h_n on the number of observations.

In other words, the estimator $m_n^h(x)$ of the unknown regression function m at the point x is a solution of minimization problem (with respect to t)

$$\sum_{i=1}^{n} \rho\big(Y_i - t\big) \int_{x_{i-1}}^{x_i} K\Big(\frac{x-z}{h}\Big)\, dz,$$

where the function ρ is a loss function, assumed to be convex and differentiable.

When choosing $\rho(x) = x^2$ one gets here the classical kernel estimator of $m(x)$. In case $\rho(x) = |x|$ the problem leads to LAD procedures. The M-smoother $m_n^h(x)$ is a generalization of the M-estimator as well as of the kernel one.

Such setup was considered in Härdle and Gasser [4]. They derived results on the limit distribution of $m_n^h(x)$. Antoch and Janssen [1] established its limit probability inequalities. The random design case was considered for example in Härdle [3].

2 Procedure

The idea of detecting of a jump in the data is to use one-sided M-smoothers. We construct two different estimates, say m^h_{n+} and m^h_{n-} based on kernels

$$K_+(z) = 2K(z)\mathbf{I}_{\{z>0\}} \text{ and } K_-(z) = 2K(z)\mathbf{I}_{\{z<0\}}, \tag{8}$$

where K is a symmetric kernel. In this setup, $m^h_{n+}(x)$ is an estimate of the unknown function m at point x based only on observations (Y_i, x_i) having $x_i > x$, while $m^h_{n-}(x)$ is an estimate based only on observations (Y_i, x_i) having $x_i < x$.

We expect that $m^h_{n+}(x_i) - m^h_{n-}(x_i)$ will be sensitive to a possible jump in m. Therefore we propose to use the test statistic

$$T^h_n = \sqrt{nh_n} \max_{i=1,\dots,n} |m^h_{n+}(x_i) - m^h_{n-}(x_i)|. \tag{9}$$

Large values of T^h_n indicate possible discontinuity and so the critical region of the test will be of the form

$$T^h_n \geq \gamma_n(\alpha)\sqrt{\log n}, \tag{10}$$

where α is a level of the test.

An approximation for the critical value $\gamma_n(\alpha)$ is needed. It can be obtained using bootstrap or a limit distribution. In this paper we choose the bootstrap method. Let $m^h_n(x)$ be the estimator of the unknown regression function $m(x)$ defined in (6). Denote residuals by

$$\hat{\varepsilon}_i = Y_i - m^h_n(x_i), \quad i = 1, \dots, n. \tag{11}$$

Let $\varepsilon^*_1, \dots, \varepsilon^*_n$ be a bootstrap sample from $\hat{\varepsilon}_1, \dots, \hat{\varepsilon}_n$ and denote

$$Y^*_i = m^h_n(x_i) + \varepsilon^*_i, \quad i = 1, \dots, n. \tag{12}$$

A bootstrap analogue to (5) is defined by

$$m^{*g}_n(x) = \lambda^{-1}_{\hat{F}^{*g}_x}(0), \tag{13}$$

where $\hat{F}^{*g}_x$ is computed similarly as $\hat{F}^h_x$ in (7), but for the observations $Y^*_1, \dots, Y^*_n$ and the sequence of bandwidths $g = \{g_n\}$.

The bootstrap version of the test statistic T^h_n is then

$$T^{g*}_n = \sqrt{ng_n} \max_{i=1,\dots,n} |m^{g^*}_{n+}(x_i) - m^{g^*}_{n-}(x_i)|, \tag{14}$$

where $m^{g^*}_{n+}$ and $m^{g^*}_{n-}$ are bootstrap estimators based on kernels K_+ and K_- defined in (8).

We expect that the behavior of T^{g*}_n is similar to the behavior of T^h_n and that the critical value $\gamma_n(\alpha)$ can be approximated by the appropriate quantile of the distribution of T^{g*}_n.

3 Theoretical results

Introduce now the set of conditions under which the results are given:

(C1) F is symmetric.
(C2) $\lambda_F \in \mathrm{Lip}(1)$ and $\lambda'_F(0) > 0$.
(C3) K is a symmetric density with support $[-L, L]$, $L > 0$ and $\|K\| = \sup_z K(z) = \mathbf{K} < \infty$.
(C4) ψ is nondecreasing, left continuous, antisymmetric and $\|\psi\| < \infty$.
(C5) $m_0 \in \mathrm{Lip}(1)$.
(C6) The design points $0 = x_0 \le x_1 \le \cdots \le x_n \to 1$, $n \to \infty$, satisfy $\delta_n = \max_{1 \le i \le n}(x_i - x_{i-1}) = O(n^{-1})$.
(C7) The sequence of bandwidths $h = \{h_n\}$ satisfies $\log n/(nh_n) \to 0$ and $nh_n^3 \to 0$ for $n \to \infty$.
(C8) The sequence of bandwidths $g = \{g_n\}$ satisfies $ng_n \to \infty$ and $ng_n^3 \to 0$ as $n \to \infty$.
(C9) The bandwidth sequences h and g satisfy $g_n = o(h_n/\log n)$ for $n \to \infty$.

Conditions (C8) and (C9) describe the necessary behavior of the bandwidth sequence g. Its proper choice is crucial for a good performance of the bootstrap.

The first Theorem describes the behavior of the test statistic T_n^h under the null hypothesis. It is a consequence of Theorem 2.1 in Antoch and Janssen [1].

Theorem 3.1. *Assume (C1)–(C7) and H_0. Then*

$$(\log n)^{-1/2}\, T_n^h \xrightarrow{a.s.} 0 \ \text{ as } n \to \infty.$$

The next theorem asserts that the statistic T_n^h can be taken as a diagnostic tool for the detection of a possible discontinuity of the regression function m. Moreover, since the maximum in the definition of T_n^h is, with probability tending to 1, reached near the point of the jump $\tilde{x}$, it can be used as a preliminary estimate of the location of the jump.

Theorem 3.2. *Assume (C1)–(C7) and H_A. Then*

$$\liminf_{n\to\infty} (\log n)^{-1/2}\, T_n^h = +\infty \quad a.s.$$

and moreover

$$(\log n)^{-1/2} \left[\sqrt{nh_n} \max_{i:|x_i - \tilde{x}| > Lh_n} |m_{n+}^h(x_i) - m_{n-}^h(x_i)| \right] \xrightarrow{a.s.} 0 \ \text{ as } n \to \infty.$$

Finally we present a result on the behavior of the bootstrap version of T_n^h. Note that the result does not depend on whether H_0 or H_A is true.

Theorem 3.3. *Assume (C1)–(C9). Then*

$$(\log n)^{-1/2} T_n^{g*} \xrightarrow{P^*} 0 \quad [\mathrm{P}] \ a.s.$$

From Theorems 3.2 and 3.3 it directly follows that whenever we use a quantile $\gamma_n^*(\alpha)$ of the distribution of T_n^{g*} as an approximation for the critical value $\gamma_n(\alpha)$ we get a consistent test.

Proofs of all the above theorems will be published elsewhere.

4 The Klementinum data

The data comprise 218 average annual temperatures measured in Prague since 1775 till 1992, see Figures 1 and 2. These data were analysed by many authors in order to detect climatic changes, see Jarušková [6], Horváth and Kokoszka [5] and Goderniaux [2].

We analyse the data using methods introduced above. For computations we chose combinations of the Epanechnikov kernel $K_e(z) = \frac{3}{4}(1 - z^2)\mathbf{I}_{\{|z| \le 1\}}$ and the uniform one $K_u(z) = \frac{1}{2}\mathbf{I}_{\{|z| \le 1\}}$ and the loss functions $\rho_1(x) = |x|$ and $\rho_2(x) = x^2$.

The most important step is the proper choice of the bandwidth. We have chosen the cross-validation method. We denote the cross-validation statistic as

$$CV(h) = \sum_{i=1}^{n} [Y_i - m_{n_{-i}}^h(x_i)]^2, \tag{15}$$

where $m_{n_{-i}}^h(x_i)$ is the leave-one-out M-smoother estimator (with the observation (Y_i, x_i) omitted). Values of $CV(h)$ over a grid of several h's are computed and the minimizer is used for evaluating the final estimate. Actually this procedure has been repeated a couple of times and in each step the grid has been softened around the actual optimum.

We started with a grid $(10, 11, 12, \ldots, 30)$. In the second step we used a grid $(15.0, 15.1, 15.2, \ldots, 20.0)$. The final grids were different for different choices of kernels and loss functions, see Table 1.

kernel	ρ_1	ρ_2
Epanechnikov	$(18.80, 18.81, \ldots, 19.00)$	$(19.00, 19.01, \ldots, 19.20)$
uniform	$(15.90, 15.91, \ldots, 16.10)$	$(17.30, 17.31, \ldots, 17.50)$

Table 1: Cross-validation grids for bandwidth selection.

The results are shown in Figures 1 and 2. The final bandwidth used is in the title of each figure. The dashed-and-dotted and dotted lines are the estimates m_{n+}^h (”right”) and m_{n-}^h (”left”). The values of $\sqrt{nh}\,|m_{n+}^h(x_i) - m_{n-}^h(x_i)|$ are suitably scaled, possitioned to the bottom of each figure and plotted with a solid line.

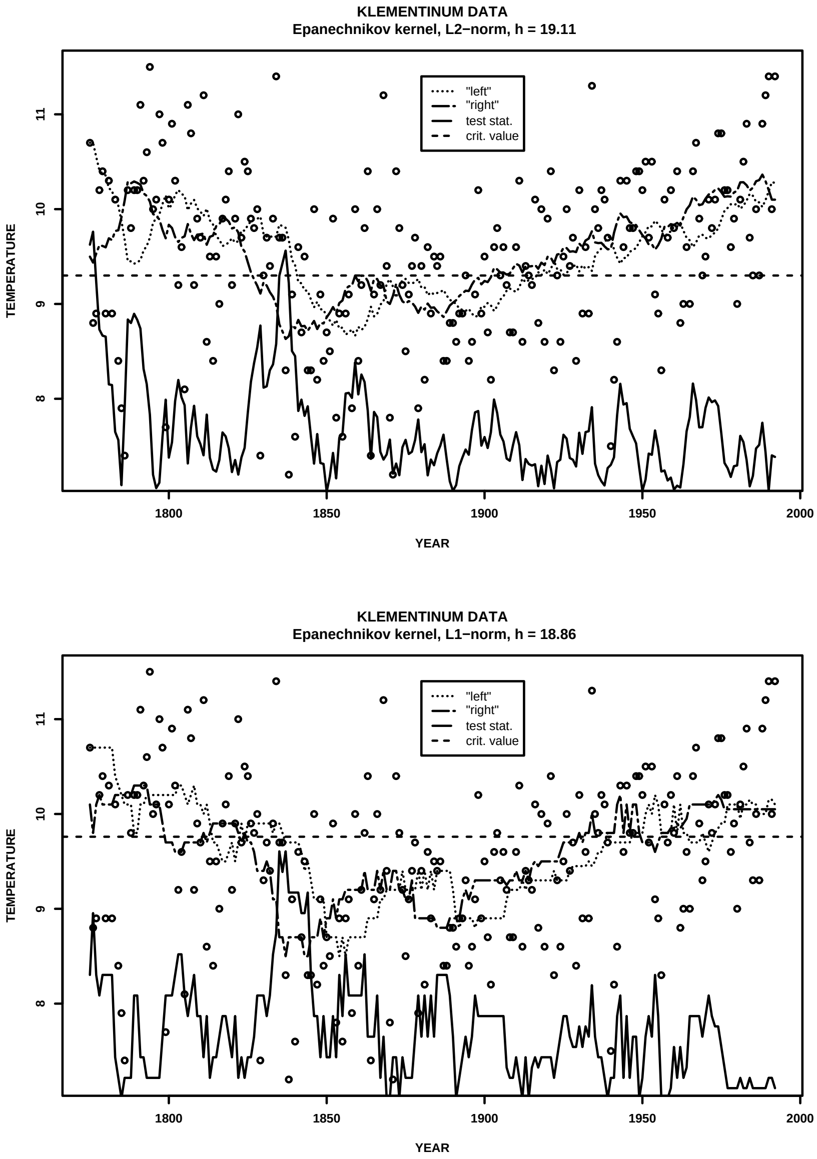

Figure 1: Klementinum data – Epanechnikov kernel.

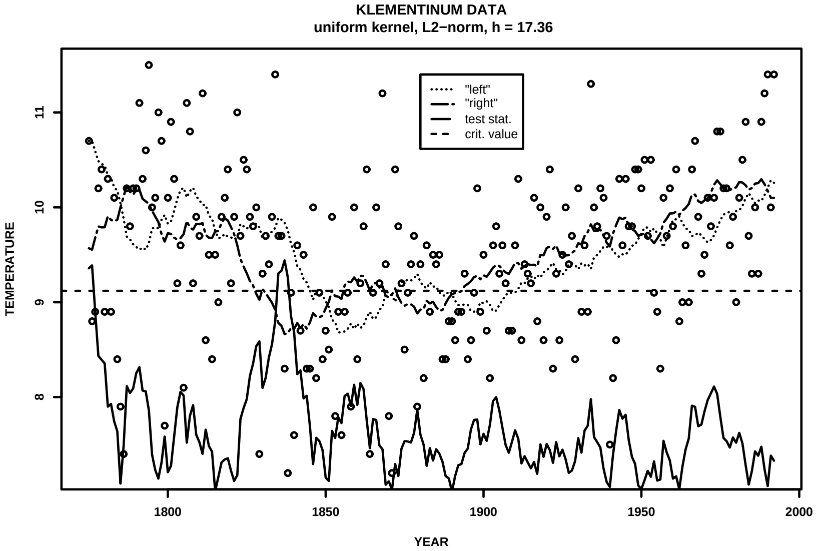

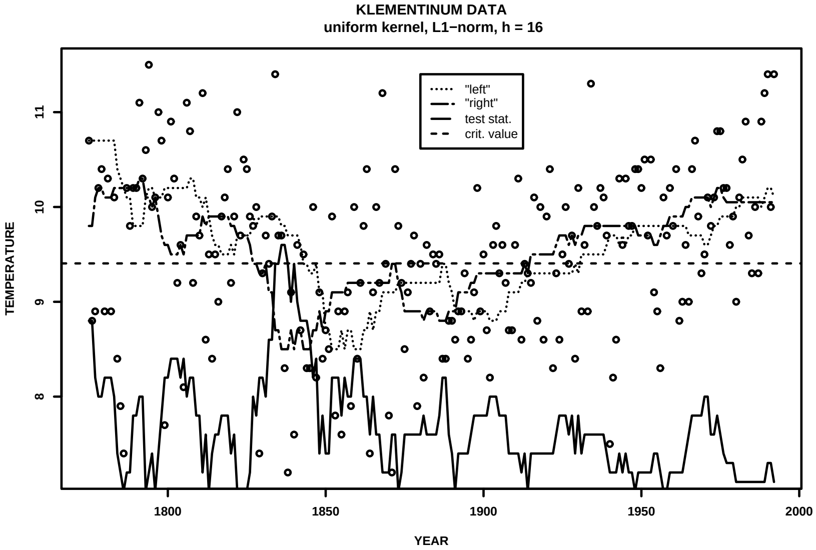

Figure 2: Klementinum data – uniform kernel.

The dashed line is the critical value for the test – the 95% quantile of the distribution of T_n^{g*}. It was estimated by resampling from $\hat{\varepsilon}_1, \ldots, \hat{\varepsilon}_n$. The resampling was repeated 200 times for each combination of kernels and loss functions. The value of the bandwidth g was calculated as $h/\log n$, see (C9).

Whenever the maximum of $\sqrt{nh}\,|m^h_{n+}(x_i) - m^h_{n-}(x_i)|$ exceeds the critical value we reject H_0. The null hypothesis was rejected in three of four cases, see Figures 1 and 2.

Peeks around the year 1836 clearly indicate a jump in the data. This result is in accord with results of other authors, see Jarušková [6] and Goderniaux [2].

Cases where ρ_1 is used do not indicate the jump as clearly as the cases using ρ_2. This may be due to the fact that LAD procedures are not so sensitive to outliers and there is probably an outlier around the year 1836. The critical value is in some figures exceeded also in the early measurements, before 1800. We are not sure about the jump in the regression at that point since it is to close to the beginning and some boundary effects of kernel estimators can play their role there.

Such result encourages the author to continue developing the method in detail and further studying the Klementinum data. The method could, for example, answer the question, whether the variance of the measurements in Klementinum is smooth along the years or not.

COMPSTAT'2004 Symposium

ROBUST ESTIMATION OF DIMENSION REDUCTION SPACE

Pavel Čížek

Key words: Dimension reduction, robust estimation, local M-estimation.

COMPSTAT 2004 section: Robustness, Dimensional reduction.

Abstract: Most dimension reduction methods based on nonparametric smoothing are highly sensitive to outliers and to data coming from heavy tailed distributions. We show that the recently proposed MAVE and OPG methods by Xia et al. [13] allow us to make them robust in such a way that preserves all advantages of the original approach. The proposed combination of MAVE and OPG with local one-step M-estimators is sufficiently robust to outliers and data from heavy tailed distributions, it is relatively easy to implement, and surprisingly, it performs as well as the original methods when applied to normally distributed data.

1 Introduction

In regression, we aim to estimate the regression function, which describes the relationship between a dependent variable $y \in \mathbb{R}$ and explanatory variables $X \in \mathbb{R}^p$. This relationship can be, without prior knowledge, modelled nonparametrically, but an increasing number of explanatory variables makes nonparametric estimation suffer from the curse of dimensionality. There are two main approaches to deal with high dimensional X variables: we can either assume a simpler form of the regression function or we can try to reduce the dimension of the space of explanatory variables. The latter, more general approach received a lot of attention recently, see Li [9] and Xia et al. [13], for instance, and it is also in the focus of our interest here.

A dimension-reduction (DR) regression model can be written as

$$y = g(B_0^\top X) + \varepsilon, \tag{1}$$

where g is an unknown smooth link function, B_0 represents a $p \times D$ orthogonal matrix, $D \leq p$, and $E(\varepsilon|X) = 0$ almost surely. Hence, to explain the dependent variable y, the space of p explanatory variables X can be reduced to a DR space given by $B_0^\top X$ with a smaller dimension D (the columns of B_0 are called directions in this context). The dimension reduction methods aim to find the dimension D and matrix B_0 defining the DR space.

Recently, Xia et al. [13] proposed a new method, the minimum average variance estimation (MAVE), that improves in several aspects over other existing estimators. First, MAVE does not need undersmoothing when estimating the link function g to achieve a faster rate of convergence. Second, MAVE can be applied to many models including time series data. Further, the MAVE approach renders generalizations of some other existing methods; for example, the outer product of gradients (OPG) estimator extends the average derivative estimator (ADE) of Härdle and Stoker [6].

Despite many features, MAVE does not seem to be robust to outliers in the dependent variable y as discussed in Čížek and Härdle [3] since it is based on local least-squares estimation. Similar sensitivity to outliers in the space of explanatory variables X (so-called leverage points), was observed and remedied in the case of the sliced inverse regression (SIR) by Gather et al. [5]. Because of many advantages that MAVE and OPG have, we address their low robustness to outlying observations and propose ways to improve them without affecting main strengths of MAVE and OPG.

The rest of the paper is organised as follows. First, we describe both the MAVE and OPG methods (Section 2). Then we propose their robust enhancements that overcome inherent computational difficulties (Section 3). Finally, we compare all estimators by means of simulations (Section 4).

2 Estimation of dimension reduction space

In this section, we present the MAVE and OPG methods (Sections 2.1 and 2.2) as well as a procedure for determining the effective DR by means of cross validation (Section 2.3).

2.1 The MAVE method

Let d represent the working dimension, $1 \leq d \leq p$. For an assumed number d of directions B in model (1), Xia et al. [13] proposed to minimize the unexplained variance $E\{y - g(B^\top X)\}^2$, where the unknown function g is locally replaced by a linear approximation; that is, $g(B^\top X) \approx a_{X_0} + b_{X_0}^\top B^\top (X - X_0)$ around some X_0. The novel feature of MAVE is that one minimizes simultaneously with respect to directions B and coefficients a_{X_0} and b_{X_0} of the local linear approximation. Hence, given a sample $(X_i, y_i)_{i=1}^n$, one minimizes

$$\min_{\substack{B:B^\top B = I_p \\ a_j, b_j, j=1,\ldots,n}} \sum_{i=1}^n \sum_{j=1}^n [y_i - \{a_j + b_j^\top B^\top (X_i - X_j)\}]^2 w_{ij}, \tag{2}$$

where w_{ij} are weights describing the local character of linear approximation. Initially, weights at any point X_0 are given by a multidimensional kernel function K_h, where h refers to a bandwidth: $w_{i0} = K_h(X_i - X_0)\{\sum_{i=1}^n K_h(X_i - X_0)\}^{-1}$; $i = 1, \ldots, n$. Additionally, once we have an estimate $\hat{B}$ of the DR space, it is possible to iterate using weights based on distances in the reduced space: $w_{i0} = K_h\{\hat{B}^\top (X_i - X_0)\}[\sum_{i=1}^n K_h\{\hat{B}^\top (X_i - X_0)\}]^{-1}$.

Xia et al. [13] also proposed a non-trivial iterative estimation procedure based on repeating two simpler optimizations of (2): one with respect to a_j, b_j given an estimate $\hat{B}$ and another with respect to B given estimates $\hat{a}_j, \hat{b}_j$. This computational approach greatly simplifies and speeds up estimation.

2.2 The OPG method

Based on the MAVE approach, Xia et al. [13] also generalised ADE of Härdle and Stoker [6] to more dimensions. Instead of using a moment condition for the gradient of the regression function g in model (1), $E\{\nabla g(X)\} = 0$, they start from the average outer product of gradients (OPG), $\Sigma = E\{\nabla g(X)\nabla^\top g(X)\}$. It can be shown that the DR matrix B consists of the d eigenvectors corresponding to the d largest eigenvalues of Σ. Recalling that local linear fitting solves for a given sample $(X_i, y_i)_{i=1}^n$

$$\min_{a_j, b_j} \sum_{i=1}^n [y_i - \{a_j + b_j^\top (X_i - X_j)\}]^2 w_{ij}, \tag{3}$$

we can estimate Σ by $\hat{\Sigma} = \frac{1}{n}\sum_{i=1}^n \hat{b}_j^\top \hat{b}_j$, where $\hat{b}_j$ are estimates of b_j from 3). Hence, the OPG method consists in estimating $\hat{\Sigma}$ and determining its d eigenvectors corresponding to the d largest eigenvalues. The choice of weights w_{ij} follows the same rules as for MAVE.

OPG does not exhibit the convergence rate of MAVE. On the other hand, it is easy to implement, fast to compute, and can be flexibly combined with robust estimation methods. Moreover, our simulations show that it can perform as well as MAVE if just one or two directions, $d \leq 2$, are of interest.

2.3 Dimension of effective reduction space

The described methods can estimate the DR space for a given dimension d. To determine d, Xia et al. [13] extend the cross-validation (CV) approach of Yao and Tong [14] and estimate d by $\hat{d} = \operatorname{argmin}_{0 \leq d \leq p} CV(d)$, where

$$CV(d) = \sum_{j=1}^n \left[y_j - \sum_{i=1, i\neq j}^n \frac{y_i K_h\{\hat{B}^\top (X_i - X_j)\}}{\sum_{i=1, i\neq j}^n K_h\{\hat{B}^\top (X_i - X_j)\}} \right]^2 \tag{4}$$

for $d > 0$ and $CV(0) = \frac{1}{n}\sum_{i=1}^n (y_i - \bar{y})^2$ to incorporate the possibility of y and X being independent. Note that this CV criterion can be also used to select bandwidth h, which results in two-dimensional CV over d and h. Although we use this time-demanding strategy in our simulations, in practice it is possible to consistently select bandwidth h^* in the DR space for the largest dimension $d = p$ and employ this bandwidth for all other dimensions.

3 Robust enhancements

As Čížek and Härdle [3] argued, both MAVE and OPG seem to be highly sensitive to outliers in data. Our aim is to propose robust enhancements of MAVE and OPG that should keep their present qualities, increase their robustness, and be computationally feasible. We discuss first general ways of making MAVE and OPG more robust (Section 3.1). Next, we address computational issues and try to propose robust MAVE and OPG that would be computationally feasible (Section 3.2). Finally, we adapt the CV procedure mentioned in Section 2.3 for robust estimation (Section 3.3).

3.1 Robust MAVE and OPG

There are many robust estimation methods alternative to least squares in linear regression. Using these methods in nonparametric regression adds a requirement on easy and fast implementation, and on the other hand, eliminates need for robustness against leverage points to some extent. During last decades, local L- and M-estimators have become particularly popular and well studied, see Boente and Fraiman [1], Čížek [2], and Härdle and Tsybakov [7], Fan and Jiang [4], respectively.

Theoretically, the application of local L- or M-estimation to MAVE and OPG reduces to replacing the squared residuals in (2) and (3) by a general convex function $\rho_{\hat{\sigma}}$ of residuals, where $\hat{\sigma}$ is an estimate of the variance of residuals. Many robust choices of $\rho_{\hat{\sigma}}$ depend on an estimate of residual variance, which is typically treated as a nuisance parameter or is set proportional to the median absolute deviation (MAD). To reflect local estimation window given by w_{ij} in (2) and minimize computational cost, we propose to estimate the variance of residuals in (2) and (3) by weighted MAD with weights w_{ij}.

In the case of OPG, this means that one applies a local polynomial M-estimator with a given function $\rho_{\hat{\sigma}}$ and a variance estimate $\hat{\sigma}$ and then searches the directions $\hat{B}$ as described in Section 2.2.

In the case of MAVE, having a general objective function $\rho_{\hat{\sigma}}$ leads to

$$\min_{\substack{B:B^\top B=I_p \\ a_j,b_j,j=1,\ldots,n}} \sum_{i=1}^{n}\sum_{j=1}^{n} \rho_{\hat{\sigma}}\left[y_i - \{a_j + b_j^\top B^\top (X_i - X_j)\}\right] w_{ij}. \tag{5}$$

Although (5) cannot be minimized using the algorithm proposed by Xia et al. [13], the optimization can be still carried out by repeated estimation of (5) with respect to a_j, b_j given an estimate $\hat{B}$ and with respect to B having estimates $\hat{a}_j, \hat{b}_j$. The first step is just the already mentioned local M-estimation. The second step, estimating of B, requires a reformulation of (5). For $B = (\beta_1, \ldots, \beta_d)$ given $(a_j, b_j) = (a_j, b_{j1}, \ldots, b_{jd})$, (5) is equivalent to

$$\min_{B:B^\top B=I_p} \sum_{i=1}^{n}\sum_{j=1}^{n} \rho\left[y_i - \left\{a_j + \sum_{k=1}^{d} \beta_k^\top b_{jk}(X_i - X_j)\right\}\right] w_{ij}. \tag{6}$$

This represents a standard regression problem with n^2 observations and pd variables. Thus, it can be estimated by a regression M-estimator, and our simulations show that estimating MAVE this way leads to slightly better estimates than the original algorithm. Unfortunately, the size of regression (6) will be enormous as the sample size increases, which will hinder computation. For example, there are very fast algorithms available for computing least squares and L$_1$ regression in large data sets, see Koenker and Portnoy [8], and even in these two cases, computation becomes 10 to 20 times slower than the original algorithm for samples of 100 observations! Thus, this algorithm seems to be disqualified from practical use.

3.2 One-step estimation

To be able to employ the fast original MAVE algorithm, robustness has to be achieved only by modifying the weights w_{ij} in (2). To achieve this, we propose to use one-step M-estimators as discussed in Fan and Jiang [4] and Welsh and Ronchetti [12]. More precisely, we employ the (iteratively) reweighted least squares approach: using an initial highly robust estimate $\hat{\beta}^0 = \{\hat{B}^0, \hat{a}_j^0, \hat{b}_j^0\}$, we construct weights w_{ij} such that the objective function (2) is equivalent to (5) at $\hat{\beta}^0$ and then perform the original algorithm using the constructed weights. As the initial robust estimator, we use L$_1$ regression, which guarantees robustness against outliers and fast computation.[1]

3.3 Robust cross-validation

The robust estimation of the DR matrix B_0 is not sufficient if dimension d is not known. Using the CV criterion described in Section 2.3 can lead to a bias in dimension estimation (and bandwidth selection) even if a robust estimator of B_0 is used, see Ronchetti et al. [10]. Now, due to the local nature of nonparametric regression, we have to “protect” primarily against outliers in the y-direction. In this context, the L$_1$ estimator is highly robust and the same should apply to CV based on L$_1$ rather than L$_2$ norm, which was already studied by Wang and Scott [11]. Thus, we propose to use instead of (4)

$$CV(d) = \sum_{j=1}^{n} \left| y_j - \sum_{i=1, i \neq j}^{n} \frac{y_i K_h\{\hat{B}^\top (X_i - X_j)\}}{\sum_{i=1, i \neq j}^{n} K_h\{\hat{B}^\top (X_i - X_j)\}} \right|. \tag{7}$$

4 Simulations

In this section, we study finite sample properties of discussed methods by means of simulations. First, we introduce models used for simulations (Section 4.1). Next, we compare original OPG and MAVE and their modifications proposed in Section 3 (Section 4.2). Finally, we examine the performance of the L$_1$ and L$_2$ CV dimension selection (Section 4.3).

[1] Assuming a robust choice of bandwidth, one does not have to protect against leverage points: estimation is done in a local window given by the bandwidth and a kernel function.

4.1 Simulation models

Throughout this section, we consider the following nonlinear model

$$y_i = (X_i^\top \beta_1)^2 - (0.5 + X_i^\top \beta_2)^2 + 15\cos(X_i^\top \beta_3) + 0.5\varepsilon_i, \tag{8}$$

where all explanatory variables have the standard normal distribution in $\mathbb{R}^{10}$ and $\beta_1 = (1,2,3,0,0,0,0,0,0,0)/\sqrt{14}$, $\beta_2 = (-2,1,0,1,0,0,0,0,0,0)/\sqrt{6}$, and $\beta_3 = (0,0,0,0,0,0,0,1,1,1)/\sqrt{3}$. Thus, the true dimension of the reduced space is $D = 3$. To compare the robust properties of all estimators, we use three error distributions: $\varepsilon_i \sim N(0,1)$, $\varepsilon_i \sim t_1$, and $\varepsilon_i \sim 0.95N(0,1) + 0.05U(-600,600)$, where $N(\mu,\sigma), t_f$, and $U(a,b)$ refer to the normal, Student, and uniform distributions. For the sake of brevity, we refer further to these three cases as NORMAL, STUDENT, and OUTLIERS, respectively. Presented simulation results are done for sample size $n = 100$, 100 repetitions, the Gaussian kernel and bandwidth chosen by CV (7).

Let us note that we compare the performance of all methods by the distance of the estimated space $\hat{B}$ and the true space $B_0 = (\beta_1, \beta_2, \beta_3)$. It can be measured by $m_0(\hat{B}) = m(\hat{B}, B_0) = \|(I - B_0 B_0^T)\hat{B}\|$ for $d \leq D = 3$ and by $m_0(\hat{B}) = m(\hat{B}, B_0) = \|(I - \hat{B}\hat{B}^T)B_0\|$ for $d \geq D = 3$, see Xia et al. [13].

4.2 Estimation of dimension reduction space

Using simulations described in Section 4.1, we compare MAVE and its modifications (given the limited space, we omit results on OPG). The compared methods include MAVE defined by (5) using the following functions $\rho_{\hat{\sigma}}$: (i) $\rho_{\hat{\sigma}}(x) = x^2$ (LS, the original MAVE); (ii) $\rho_{\hat{\sigma}}(x) = |x|$ (L1), (iii) $\rho_{\hat{\sigma}}(x) = \int \operatorname{sgn}(x)\min(|x|, \hat{\sigma}))dx$ (HUBER), (iv) $\rho_{\hat{\sigma}}(x) = \int \operatorname{sgn}(x)\max\{0, \min(|x|, \hat{\sigma}) - \max(0, |x| - 2\hat{\sigma})\}dx$ (HAMPEL).[2] The function L1 was implemented by algorithm described in Section 3.1 and HUBER and HAMPEL as local one-step M-estimators discussed in Section 3.2.

The simulation results are summarized in Table 1 and clearly document the need for and advantages of robust modifications of MAVE. For data NORMAL, all estimates except for MAVE HAMPEL perform almost equally well. MAVE HAMPEL provides worse estimates since it fully rejects data points with residuals larger than $3\hat{\sigma}$. For data STUDENT, all robust versions of MAVE provide similar results, whereas the estimates by original MAVE LS exhibit rather large errors, especially in the first direction β_1. For data OUTLIERS, there is a large difference between non-robust MAVE LS and robust modifications of MAVE, which documents sensitivity of the original MAVE estimator to outliers. Although all robust estimators perform similarly, MAVE HAMPEL is best due to its full-rejection feature. Let us note that results can be further improved by adjusting function $\rho_{\hat{\sigma}}$.

[2] The functions named HUBER and HAMPEL correspond to the standard Huber and Hampel ψ-functions with parameters 1 and 1, 2, 3, respectively.

Data	**Method**	**Parameter**			
		$m_0(\hat{\beta}_1)$	$m_0(\hat{\beta}_2)$	$m_0(\hat{\beta}_3)$	$m_0(\hat{B})$
NORMAL	MAVE LS	0.004	0.089	0.094	0.147
	MAVE L1	0.005	0.061	0.097	0.149
	MAVE HUBER	0.005	0.100	0.095	0.164

OUTLIERS	LS	2, 14	1, 5	10, 8	12, 8	75, 65
OUTLIERS	HAMPEL	0, 9	0, 43	1, 24	13, 9	86, 15

Table 2: Estimates of the DR dimension by OPG LS and OPG HAMPEL using L_2 (CV, first number) and L_1 (CVA, second number) cross validation. Entries represent numbers of samples out of 100 with estimated dimension d.

4.3 Cross-validation simulations

Simulating again from model (8), we estimated the DR dimension $\hat{d}$ ($D = 3$) using OPG with $\rho_{\hat{\sigma}}$-functions LS and HAMPEL and the L_2- and L_1-based CV criteria (4) and (7). Results for data NORMAL and OUTLIERS are summarized in Table 2. Clearly, one can be almost indifferent between the CV criteria for data NORMAL. For data OUTLIERS, only the combination of a robust estimator with L_1-CV leads to results resembling the true model. When judging results in Table 2, one should take into account that this nonlinear inference is based on only 100 observations in $\mathbb{R}^{10}$. Nevertheless, results can be improved, for example, by using more time-demanding MAVE.

5 Conclusion

We proposed robust enhacements of MAVE and OPG that are as good as the original methods under 'normal' data, are robust to outliers and heavy-tailed distributions, and are easy to implement. Should we pick up one method for a general use, MAVE HUBER seems to be the most suitable candidate as (i) MAVE LS is not robust, (ii) MAVE L1 is slow to compute, see Section 3.1, and (iii) MAVE HAMPEL does not perform so well for normal data.

COMPSTAT'2004 Symposium

NONPARAMETRIC UNSUPERVISED CLASSIFICATION OF SATELLITE WAVE ALTIMETER FORMS

Sophie Dabo-Niang, Frédéric Ferraty and Philippe Vieu

Key words: Curves data, curves classification, functional statistics, modal curve, altimetric curves, satellite data.

COMPSTAT 2004 section: Functional data analysis.

Abstract: We present a new unsupervised classification method for curves. The main feature of our approach is to take fully into account the continuous nature of these data. The presentation will be centered around a real data problem coming from geophysical sciences, and which consists in classifying a set of altimetric curves registered by the satellite Topex/Poseidon upon the Amazonian basin.

1 Introduction

Let us look at the following data, corresponding to altimetric measurements registered by the satellite Topex/Poseidon around an area of 25 kilometers upon the Amazon River. Each altimetric data, is represented by its wave on the range $(0, 70)$, and the satellite is registering 10 curves each second. Indeed we just kept a sample of 500 waves, randomly selected among all the numerous curves that we had at hand. It is known that each wave is linked with the kind of ground treated by the satellite, and the idea for the Amazonian basin is to use these altimetric data for hydrological purpose.

To fix the idea, we present in Figure 1 a set of 20 randomly selected among these curves. A deeper presentation of these data can be found in Frappart [2]. We can see clearly from Figure 1 that there are several different forms of waves, that could be interpreted by different kinds of grounds. With other words, in the Amazonian basin, these different forms are corresponding to different levels of water (lake, small river, large river, ...). Some of these curves are very flat (for instance curves numbers 13 and 42). They are known to be noise spanned by the satellite and they should be ignored in the remaining of the study. Other wave curves are of several different forms: there are curves with one peak and small tails (for instance curves numbers 23 and 24); there are other curves with one peak and high tails (for instance curves numbers 3 and 138); there are curves that look to have more than one peak (for instance curves numbers 1 and 7); there are also curves that looks without peak (for instance curves numbers 5 and 26); ... The reader can find in Frappart [2] some comments about the possible links between these different forms and different kind of waters.

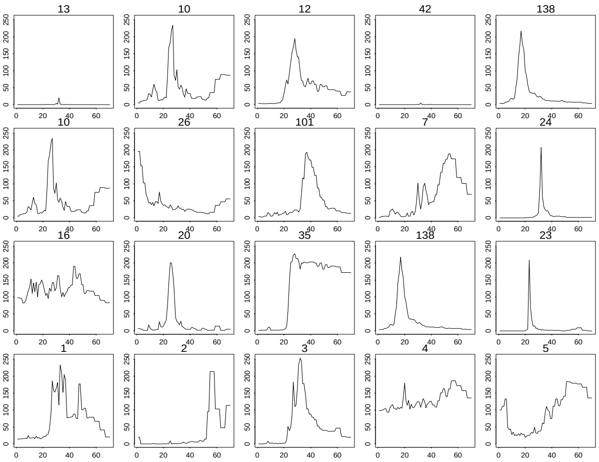

Figure 1: Some wave altimetric curves.

So, the questions are simple: Are these curves separable in different groups? And, if it is the case, how could we assign some given curve to one among these groups? With statistical words this problem can be summarized by the following question: How can we classify these altimetric curves data? This question is known as an unsupervised curves classification problem. It is an unsupervised problem because we do not have at hand any categorical response variable, and it is a curve classification problem because the data sets are clearly of functional nature. Advances on *Functional Statistics* (see Ramsay and Silverman [6] and Ferraty and Vieu [3] and [4], for references) allow to have at hand several different statistical procedures for dealing with such kind of data, including supervised curves classification problem. The unsupervised classification problem is much more difficult because the groups are unknown before the study.

2 The nonparametric functional methodology

The statistical modelling for treating curves data consist in looking at them as a sample of independent realizations $X_1, \ldots, X_n$ of some functional variable X taking values in some abstract infinite dimensional space (E, d), d being some measure of proximity between curves (for instance a metric or a semi-metric). For instance, in the altimetric data set discussed before, each X_i is a whole wave curve, $X_i = \{X_i(t), t \in (0, 70)\}$.

Let $S \subset E$ be some subset of curves. Keeping in mind what happens in the unfunctional case (that is for finite dimensional data), the most natural centrality index for classification purpose would be the notion of modal curve rather than the notion of mean curve or median curve. A first work in this direction has been done by Gasser et al. [5] and the recent paper by Dabo-

Niang et al. [1] gives asymptotic support to these ideas when d is a metric. According to these authors, the modal curve, denoted $X_{modal,S}$, is defined as the curve of the sample S which maximizes the quantity

$$Q_{mod}(x) = \sum_{\{i, X_i \in S\}} K\left(\frac{d(X_i, x)}{h}\right).$$

Let us just tell that in the altimetric application presented below we will use the classical quadratic weight function (called too *kernel*):

$$K(u) = \frac{3}{2}(1 - u^2)1_{u \in (0,1)}.$$

On the other hand, it is possible to extend to the functional case the notion of median curve, denoted $X_{median,S}$, by considering the one of the sample S which minimizes the quantity:

$$Q_{med}(x) = \sum_{\{i, X_i \in S\}} d(X_i, x).$$

Clearly, as in the unfunctional case, both the mean and the median curves are interesting only in the situation of homogeneous data, while the modal curve would be more useful for detecting any structural differences between data. This is exactly the idea that we are going to use for our classification purpose, and we will look for some difference (in the sense of the measure d) between the modal curve $X_{modal,S}$ and one among $X_{mean,S}$ or $X_{median,S}$. Because of the horizontal shift in the curves it is much more reasonable for these altimetric data to use $X_{median,S}$ rather than $X_{mean,S}$ (but the same methodology could be used with $X_{mean,S}$ and could be efficient for other functional data sets). We would like to consider the quantities:

$$\frac{d(X_{modal,S}, X_{median,S})}{d(X_{median,S}, 0) + d(X_{modal,S}, 0)},$$

but, in order to get a more stable criterion, we use L (randomly generated) subsamples $S^{(l)} \subset S$ ($l = 1, \ldots, L$, each subsample being of the same size M_S), and we introduce the following heterogeneity charateristic for the set of curves S:

$$HIR(S) = \frac{1}{L}\sum_{l=1}^{L} \frac{d(X_{modal,S^{(l)}}, X_{median,S^{(l)}})}{d(X_{median,S^{(l)}}, 0) + d(X_{modal,S^{(l)}}, 0)}.$$

Concerning our altimetric example, these parameters were taken to be $L = 50$ and $M_S = Card(S)/2$.

This quantity will be used to reply to the important question: Does a set of curves S need to be splitted into the K subgroups $S_1, \ldots S_K$ or does not? This can be done by heuristic considerations according to the experience of the user, but in other cases there is necessity for some automatic stop criterion. This automatic procedure is based on a comparison between $HIR(S)$ and its splitted version:

$$HIR(S; S_1, \dots S_K) = \frac{1}{Card(S)} \sum_{k=1}^{K} Card(S_k) HIR(S_k),$$

and we will use as a statistics to decide for splitting or not

$$GAIN = GAIN(S; S_1, \dots S_K) = \frac{HIR(S) - HIR(S; S_1, \dots S_K)}{HIR(S)}.$$

We will do (*respectively* undo) the splitting of S into $S_1, \dots S_K$ if $GAIN$ is (*respectively* is not) less that some fixed threshold γ. To fix the ideas, note that for our altimetric example below this threshold was taken to be $\gamma = 0$, but for other data sets this threshold can be taken larger.
